WILEY

HANDBOOK OF Measuring System DESIGN

EDITORS PETER H. SYDENHAM RICHARD THORN

Volume 3

Valve Exhibit 1077
Valve v. Immersion

VOLUME 1

Contributors.

Preface.

Abbreviations and Acronyms.

Introduction.

PART 1. FOUNDATIONS OF MEASURING.

SECTION 1. THE PROCESS OF MEASURING.

1. Sophistication of Measurement and its Body of Knowledge (Peter H. Sydenham).

2. Organization of Instrument Science (Joseph McGhee).

3. Measures and Metrics; Their Application (Peter H. Sydenham)

4. Economic Consideration of Measurement (Peter H. Sydenham).

5. Humans in the Real World (Joseph McGhee).

6. Substructure of Human-Machine Systems (Joseph McGhee).

SECTION 2. MEASURING THEORY AND PHILOSOPHY.

7. Introduction to Measurement Theory and Philosophy (Ludwik Finkelstein).

8. Formal Theory of Measurement (Ludwik Finkelstein).

9. Nature and Properties of Measurement (Ludwik Finkelstein).

10. Extensions of the Representational Theory of Measurement (Ludwik Finkelstein).

11. Measurement Theory in Physical, Social, and Psychological Science (Ludwik Finkelstein).

12. Fuzzy Approaches for Measurement (Eric Benoit, Laurent Foulloy and Gilles Mauris).

13. Signals, Information and Knowledge, and Meaning (Qing Ping Yang).

14. Hierarchical Aspects of Measurement Systems (Joseph McGhee).

15. Typical Measurement Systems Architecture (Joseph McGhee).

SECTION 3. ENVIRONMENTAL FACTORS.

16. Reduction of Influence Factors (Paul P.L. Regtien)

17. EMC and EMI (Kim R. Fowler).

SECTION 4. FEEDBACK IN MEASURING SYSTEMS.

18. Nature and Scope of Closed-loop Systems (Peter H. Sydenham).

19. Dynamic Behavior of Closed-loop Systems (Peter H. Sydenham).

20. Closed-loop Sampled Data Systems (Peter H. Sydenham).

21. Nonlinear Closed-loop Systems (Peter H. Sydenham).

SECTION 5. MESSAGING THEORY.

22. Characteristics and Theory of Knowledge (Luca P. Mari).

23. Principles of Semiotics as Related to Measurement (Luca P. Mari).

24. Principles of Epistemology as Related to Measurement (Timothy Lindsay John Ferris).

SECTION 6. SIGNAL THEORY.

25. Introduction to Signals in Physical Systems (Eugen Georg Woschni).

26. Signal Classification (Eugen Georg Woschni).

27. Signals in the Frequency Domain (Eugen Georg Woschni)).

28. Signals in the Time Domain (Eugen Georg Woschni).

29. Relationship Between Signals in the Time and Frequency Domain (Eugen Georg Woschni).

30. Statistical Signal Representations (Eugen Georg Woschni).

31. Discrete Signal Theory (Eugen Georg Woschni).

32. Geometrical Signal Representation (Eugen Georg Woschni).

33. Coding Theory and its Application to Measurement (Eugen Georg Woschni).

34. Modulation Theory (Eugen Georg Woschni).

SECTION 7. SYSTEMS THEORY.

35. Systems in the Time-Domain (Eugen Georg Woschni).

36. Systems in the Frequency Domain (Eugen Georg Woschni)

37. Relationship Between Systems in the Time and Frequency Domain (Eugen Georg Woschni).

38. Stability Issues (Eugen Georg Woschni).

SECTION 8. SOURCES OF INFORMATION ON MEASUREMENT.

39. Characteristics of Data, Information, Knowledge, and Wisdom (Timothy Lindsay John Ferris).

40. Sources of Information (Peter H. Sydenham).

41. Terminology and Classification of Measurement Systems (Peter H. Sydenham).

42. Information Databases of Relevance to Measurement (Peter H. Sydenham).

PART 2. UNITS, STANDARDS AND CALIBRATION.

SECTION 1. STANDARDS SUPPORTING MEASUREMENT.

43. Units (Brian W. Petley).

44. Types of Paper Standards and their Purpose (Halit Eren).

SECTION 2. CALIBRATION.

45. Calibration Process (Halit Eren).

46. Calibration Interval (Peter H. Sydenham).

47. Internet Calibration (Richard A. Dudley).

PART 3. ERROR AND UNCERTAINTY.

SECTION 1. ERROR AND UNCERTAINTY.

48. Common Sources of Errors in Measurement Systems (Dietrich Hofmann).

49. General Characterization of Systematic and Stochastic Errors (Martin Halaj).

50. Errors in Signal Systems (Eugen Georg Woschni).

51. Errors in Digital Signal Systems (Luca P. Mari).

52. Error Models, Error Budgets and their Calculation (Rudolf Palencár).

53. Calculation and Treatment of Errors (Joseph McGhee).

54. Explanation of Key Error and Uncertainty Concepts and Terms (Luca P. Mari).

55. Uncertainty Determination (Joseph McGhee).

PART 4. MEASURING SYSTEM BEHAVIOR.

SECTION 1. MEASURING SYSTEM SPECIFICATION.

56. Transfer Characteristics of Instrument Stages (Peter H. Sydenham).

57. Static Considerations of General Instrumentation (Peter H. Sydenham).

58. Description of Accuracy: Linearity, and Drift (Peter H. Sydenham).

59. Introduction to the Dynamic Regime of Measurement Systems (Peter H. Sydenham).

60. Zero-order System Dynamics (Peter H. Sydenham).

61. First-order System Dynamics (Peter H. Sydenham).

62. Second-order System Dynamics (Peter H. Sydenham).

VOLUME 2

PART 5. MEASURING SYSTEM DESIGN.

SECTION 1. ENGINEERING A MEASURING SYSTEM.

63. Outline of Systems Thinking (Peter H. Sydenham).

64. Executing A Measuring System Design (Peter H. Sydenham).

65. Life Cycle Concept (Floyd Guyton Patterson Jr.).

66. Phases of System Life Cycle (Kim R. Fowler).

67. Principle of Concept of Operations (ConOps) (Jack Ring).

68. Setting the System Boundaries (Joseph McGhee).

69. Requirements Allocation (Andrew Kusiak and Fang Qin).

SECTION 2. DESIGN METHODOLOGIES.

70. Measuring System Design Methodologies (Ludwik Finkelstein).

71. Modeling Methodology (Peter H. Sydenham).

72. Mathematical Methods of Optimization (Halit Eren).

SECTION 3. ELECTRONIC AND ELECTRICAL REGIME.

73. Overview of Electrical and Electronic Technique (Peter H. Sydenham).

74. Basic Electronic Components (Peter H. Sydenham).

75. Electronic System Building Blocks (Peter H. Sydenham).

76. Electronic Systems Design (Peter H. Sydenham).

77. Limits of Detection in Electronic Systems (Peter H. Sydenham).

78. Embedded Systems (Timothy Wilmshurst).

79. Testing Electronic Systems (Patrick D.T. O'Connor).

SECTION 4. FINE MECHANICAL REGIME.

80. Principles of Fine Mechanics – Kinematic and Elastic Designs (Peter H. Sydenham).

81. Principles of Fine Mechanics – Systems Considerations (Peter H. Sydenham).

82. Kinematical Regime – Members and Linkages (Peter H. Sydenham).

83. Kinematical Regime - Fasteners, Bearings (Peter H. Sydenham

84. 83. Kinematical Regime – Rotary Motion (Peter H. Sydenham

85. Elastic Regime of Design – Design Principles (Peter H. Sydenham).

86. Elastic Regime of Design – Spring Systems (Peter H. Sydenham).

87. Elastic Regime of Design – Plates and Bimorphs (Peter H. Sydenham).

88. Error Sources in Fine Mechanics (Peter H. Sydenham).

SECTION 5. VISIBLE RADIATION REGIME.

89. Optical Materials (Pak L. Chu).

90. Optical Elements (Pak L. Chu).

91. Light Sources and Detectors (Miroslaw Jonasz).

92. Optical Measuring Instruments (Peter H. Sydenham).

93. Testing Optical and Other Radiation Systems (Alan J. Cormier).

SECTION 6. HUMAN FACTORS ENGINEERIN.

94. Human Factors Engineering (Nicholas I. Beagley).

95. Human-Machine Interface (Nicholas I. Beagley).

96. The Domains of Human Factors Integration (Nicholas I. Beagley).

97. Design Methodology (Nicholas I. Beagley).

SECTION 7. QUALITY IN MEASURING SYSTEMS.

98. Reliability and Maintainability (Patrick D.T. O'Connor).

99. Safety Organization (Peter H. Sydenham).

100. Safety Analysis Methods (Peter H. Sydenham).

101. Assessing and Demonstrating Safety (Peter H. Sydenham).

102. Introduction to the Legal Process (Christopher Sweet).

103. Legal Liability Issues for Designers – A Case Study (Christopher Sweet).

PART 6. MODELING MEASURING SYSTEMS.

SECTION 1. MODELING MEASURING SYSTEMS.

104. Models of the Measurement Process (Luca P. Mari).

105. Modeling with LabVIEW™ (Wieslaw Ttaczala).

106. Virtual Instrumentation in Physics (Wieslaw Ttaczala).

PART 7. ELEMENTS: A – SENSORS.

SECTION 1. SENSOR FUNDAMENTALS.

107. Principles of Sensor Science (Joseph McGhee).

108. Transducer Fundamentals (Paul P.L. Regtien).

109. Structure and Energy in Sensor Systems (Joseph McGhee).

110. Signal/Energy Matrix Modeling (Joseph McGhee).

111. Classification of Sensors (Joseph McGhee).

112. Systematic Description of Sensors (Paul P.L. Regtien).

113. Force-feedback Sensors (Barry E. Jones).

SECTION 2. THE SENSING INTERFACE.

114. Models of the Sensor Interface (Qing Ping Yang).

115. Designing the Sensor Interface (Qing Ping Yang).

116. Selection of Sensors (Paul P.L. Regtien).

117. Materials in Measuring Systems (Peter H. Sydenham).

118. Ultrasonic Sensors (Peter J. Lesniewski).

119. Ultrasonic Instrumentation Principles (Lawrence C. Lynnworth).

120. Ultrasonic Instrumentation Design (Lawrence C. Lynnworth).

PART 8. ELEMENTS: B – SIGNAL CONDITIONING.

SECTION 1. ANALOG SIGNAL CONDITIONING.

121. Signals in the Presence of Noise (Richard Burdett).

122. Operational Amplifiers (Joseph McGhee).

123. Instrumentation Amplifiers (Joseph McGhee).

124. Specialized Amplifiers for Measurement Systems (Joseph McGhee).

125. Outline of Purpose of Analog Data Filters (Joseph McGhee).

SECTION 2. ELECTRICAL BRIDGES.

126. Electrical Bridge Circuits – Basic Information (Zygmunt L. Warsza).

127. Unbalanced DC Bridges (Zygmunt L. Warsza).

SECTION 3. AI SIGNAL PROCESSING TECHNIQUES>

128. Name and Scope of AI Techniques (Ajith Abraham).

129. Artificial Neural Networks (Ajith Abraham).

130. Rule-based Expert Systems (Ajith Abraham).

131. Evolution Computation (Ajith Abraham).

VOLUME 3

PART 9. ELEMENTS: C – DATA ACQUISITION AND PROCESSING SYSTEMS.

SECTION 1. DAS COMPONENTS.

132. Data Acquisition Systems (DAS) in General (Gerd Wöstenkühler).

133. Amplifiers and Filters for DAS (Gerd Wöstenkühler).

134. Analog Multiplexers (Gerd Wöstenkühler).

135. Sample-hold Circuits (Gerd Wöstenkühler).

136. Quantizing Theory Relevant to DAS (Gerd Wöstenkühler).

137. Coding for Data Converters (Gerd Wöstenkühler).

138. Sampling Theory Relevant to DAS (Gerd Wöstenkühler).

139. Analog-to-Digital (A/D) Converters (Gerd Wöstenkühler).

140. Integrating Type (A/D) Converters (Gerd Wöstenkühler).

141. Digital-to-Analog (D/A) Converters (Gerd Wöstenkühler).

SECTION 2. DIGITAL SIGNAL PROCESSING (DSP).

142. Z-transforms (Armar Bousbaine).

143. DFT and FFTs (Gerd Wöstenkühler).

144. DSP Chip Sets (Iain Paterson-Stephens).

145. DSP Tools (Iain Paterson-Stephens).

146. Principles of DSP Hardware Design (Iain Paterson-Stephens).

147. Ideal Digital Filters Approximation (Joseph McGhee).

148. General Performance of the Digital Filter (Joseph McGhee).

149. Low-, High-, and Band-pass Digital Filters (Joseph McGhee).

150. Finite Impulse Response (IIR) Digital Filters (Joseph McGhee).

151. Finite Impulse Response (FIR) Digital Filters (Joseph McGhee).

SECTION 3. COMPUTERS IN MEASURING SYSTEMS.

152. Fundamentals of the Stored Program Digital Computer (Joseph McGhee).

153. Single Address Instruction Microcomputer (Joseph McGhee).

154. Internal Operation of the Microprocessor (Joseph McGhee).

155. External Operation of the Microprocessor (Joseph McGhee).

156. Memory Management in the Microprocessor (Joseph McGhee).

157. Data Acceleration in Computers (Joseph McGhee).

158. Microcontroller Systems (Joseph McGhee).

159. Designing and Building Software for Measuring Systems (Joseph E. Kasser).

SECTION 4. INTELLIGENT MEASURING SYSTEMS.

160. Smart Sensor System Features (Peter H. Sydenham).

161. Knowledge-based Systems (Dietrich Hofmann).

PART 10. ELEMENTS: D – MEMS.

SECTION 1. MICRO ELECTRO MECHANICAL SYSTEMS (MEMS).

162. Principles of MEMS (Janusz Bryzek).

163. Uses and Benefits of MEMS (Janusz Bryzek).

164. Principles of MEMS Actuators (Janusz Bryzek).

PART 11. ELEMENTS: E – COMMUNICATION IN MEASURING SYSTEMS.

SECTION 1. DISTRIBUTED AND NETWORKED MEASURING SYSTEMS.

165. Introduction to Networked Instrumentation (Joseph McGhee).

166. Instrument Interconnection (Joseph McGhee).

167. Asynchronous and Synchronous Interface Protocols (Joseph McGhee).

168. RS 232 and EIA/TIA 232 Serial Interface (Joseph McGhee).

169. Voltage and Current Loop Transmission (Joseph McGhee).

170. IEEE-488 Instrumentation Bus (Joseph McGhee).

171. Local Area (LANs) and Wide Area Networks (WANs) (Joseph McGhee).

172. Fieldbus Systems (Halit Eren).

173. Scheduling Systems (Emil Michta).

PART 12. ELEMENTS: F – SIGNALS AND NOISE.

SECTION 1. NOISE AND INTERFERENCE.

174. Typical Signals Arising in Measurement (Eugen Georg Woschni).

175. Comparison of Analog and Digital Signal Handling (Joseph McGhee).

176. Signals and Signal-t0-noise Ratio (Richard Burdett).

177. Grounding and Shielding (Kim R. Fowler).

178. Noise Matching and Preamplifier Selection (Richard Burdett).

179. Input Connections; Grounding and Shielding (Richard Burdett).

SECTION 2. SIGNAL RECOVERY IN THE PRESENCE OF NOISE.

180. Bandwidth Reduction of Baseband DC Signals (Richard Burdett).

181. Amplitude Modulated Signals: The Lock-in Amplifier (Richard Burdett).

182. Boxcar and Signal Averages (Richard Burdett).

183. Correlators in Signal Extraction (Richard Burdett).

184. Photon Counting (Richard Burdett).

185. Pulse Height Discrimination, Ratemeters and Pileup (Richard Burdett).

186. The Family of Signal Recovery Methods (Richard Burdett).

PART 13. COMMON MEASURANDS.

SECTION 1. FLOW MEASUREMENT.

187. Flowmeter Selection and Application (Michael Reader-Harris).

188. Differential Pressure (DP) Flowmeters (Michael Reader-Harris).

189. Basic Principles of Flow Measurement (Richard Thorn).

190. Calibration and Standards in Flow Measurement (Richard Paton).

SECTION 2. DISPLACEMENT AND ANGLE MEASUREMENT.

191. Displacement and Angle Sensors Performance and Selection (Halit Eren).

192. Strain Sensors (Peter H. Sydenham).

193. Specialty Displacement and Angle Sensors (Halit Eren).

194. Large-scale Metrology (Stephen Kyle).

SECTION 3. TEMPERATURE MEASUREMENT.

195. Characteristics of Temperature Measurement (Joseph McGhee).

196. Thermocouple Temperature Sensors (Jacek Kucharski).

197. Metalic Resistance Temperature Detectors (RTDs) (Dietrich Hofmann).

198. Calibration and Standards in Temperature Measurement (D.R. White).

SECTION 4. TIME AND FREQUENCY.

199. Characteristics of Time and Frequency Measurement (Michael A. Lombardi).

200. Calibrations and Standards in Time Measurement (Michael A. Lombardi).

SECTION 5. ELECTRICAL QUANTITIES.

201. Voltage Measurement (Halit Eren).

202. Current Measurement (Halit Eren).

203. Resistance Measurement (Halit Eren).

204. Capacitance and Inductance Measurement (Consolatina Liguori).

SECTION 6. VELOCITY AND ACCELERATION.

205. Theory of Vibration Measurement (Peter H. Sydenham).

206. Practice of Vibration Measurement (Peter H. Sydenham).

207. Acceleration Measurement (Peter H. Sydenham).

208. Amplitude and Velocity Measurement (Peter H. Sydenham).

SECTION 7. CHEMICAL PROPERTIES.

209. Characteristics of Chemical Measurements (Peter H. Sydenham).

210. Optical Transducers for Chemical Measurements (Ashutosh Sharma).

211. Mass Spectrometry (Peter H. Sydenham).

212. Chromatography (Brett Paull).

213. Electrochemical Measurements (David Davey).

PART 14. TEST AND EVALUATION.

SECTION 1. MEASUREMENT TESTING SYSTEMS.

214. Accelerated Testing (Patrick D.T. O'Connor).

215. Automatic Test Systems (Patrick D.T. O'Connor).

216. Test Facilities (Patrick D.T. O'Connor).

217. Instrument Evaluation (Steve Cork).

1 SOPHISTICATION OF MEASUREMENT AS THE DEGREE OF SCIENCE

The decision of whether to use existing, or to create new, measuring instruments in the study of a subject comes after measurable variables have been identified. The process is, in the physical sciences, usually considerably easier to realize than in many areas of the empirical sciences. Many stages of prior reasoning precede such a decision: this is not always recognized, especially in engineering. The process can be depicted by the chart given in Figure 1.

Knowledge seeking begins presumably because of certain inquisitive features of man's makeup that stirs up interests in directions that seem to have more relevance than others. The processes involved are complex, and, as yet, not adequately known. Paradoxically, it seems that a great deal of knowledge is used in a very general way from the onset to choose candidate paths of action to follow to gain the knowledge sought.

This process, which involves the cognitive elements of sensation, perception, apperception, advises the knowledge seeker that certain information is more relevant for study than other data. It appears that the biological senses involved provide data input to the brain, coding it with meaning to suit the required task. Two people viewing a plant leaf, for example, see the same object with similar senses, yet both could 'see' quite different attributes. Latent information available has begun to be filtered at this stage.

The assembled data is then sorted and classified according to various kinds of similarities to detect differences. Each group forms a crude measurement standard of comparison for the others. This process can often be continued until advanced knowledge is established without using measuring instruments. Linnaeus (1707–1778) was able to make a major contribution to botany by introducing his binomial classification system (see Figure 2). Darwin's *On Origin of the Species by Means of Natural Selection* of 1859 has been recognized as probably the greatest generalization yet – although gene mapping is taking that over. It was made from vast quantities of data that were all assembled with little use of measuring instruments to enhance man's natural senses.

At some stage, this qualitative form of science can be subjected to increasingly more quantitative methods. Attributes of the various classes became apparent in a way that allows instruments to be applied that give natural sensing, greater sensitivity, and greater power to move from a qualitative mode into the quantitative measurement mode. More detailed knowledge becomes available as measurements produce data that is referred against more adequate, precise, and accurate standards. Thus, it is that physical measuring instruments applied as the degree of science, which is reflected by the degree of quantification used, is improved. This line of reasoning also makes it

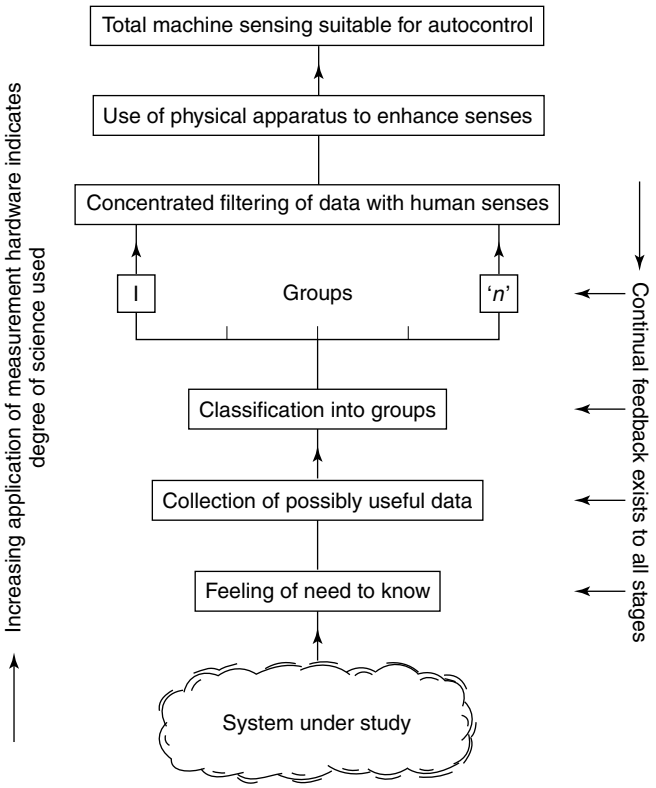

Figure 1. Simplified hierarchy of application of measuring instruments in the study of a problem.

Figure 2. Linneaus resting after a botanical ramble. He devised the binomial classification system now used, reporting it in 'Systema naturae', 1758. (Copyright © Uppsala University.)

vital that appreciation of the qualitative stages preceding proper measurement and the instruments that evolve are understood.

This sentiment is not new as the famous Lord Kelvin quote tells us. The words of Westaway (1937) are in sympathy with this. The concept expressed in Figure 1 is simplified: in practice, the stages at which hardware forms of measuring instruments are used varies widely. In some studies, they are needed at the very beginning.

Finkelstein (1975) sums up the situation in this way:

> Measurement presupposes something to be measured, and measures have to be conceived and sought before they can be found in experience. Both in the historical development and logical structure of scientific knowledge the formulation of a theoretical concept, or construct, which defines a class of entities and the relations among its members, providing a conceptual interpretation of the sensed world, precedes the development of measurement procedures and scales. It is necessary for instance to have some concept of 'degree of hotness' as a theoretical construct, interpreting the multitude of phenomena involving warmth, before one can conceive and construct a thermometer.
>
> As measurement procedures are developed, and knowledge resulting from measurement accumulates, the concept of the measured class becomes clearer and may to a substantial extent become identified with the operational procedures underlying the measurement process.
>
> In some cases the concept of an entity arises from the discovery of mathematical invariances in laws arrived at by measurement, and the entity is best thought of in such mathematical terms, but in general one attempts to arrive at some qualitative conceptual framework for it, if possible.

As the subject matter becomes better known and enables unattended sensing by an observer, as needed for control or monitoring purposes, the use of measuring instruments to enhance human senses may not be appropriate. Hardware sensors then totally replace man's senses.

It is logical, therefore, to expect all of man's endeavors that require measurements to be made (most of them!) to trend steadily toward greater use of measuring instruments. Certainly, time has proven this to be so. But this is also a consequence of man's method of survival on earth. Unlike lower animals, man has the ability to modify his environment to suit his biological structure. He does this usually by the use of technological developments, which rarely operate in the same way as natural equivalents or are made with the same materials. A comparison of natural and man-made vision sensors is given in Figure 3. The knowledge man possesses is being built up of a component about the natural world plus a component about the structures that man has created. Measuring instruments are the means by which man's creations operate and these too are creations of man. The relationship between measurement and knowledge has been explored (Sydenham, 2003).

2 MEASUREMENTS AND THE BODY OF KNOWLEDGE

The sum total of knowledge is termed the *body of knowledge*. As knowledge is a characteristic of man, not of

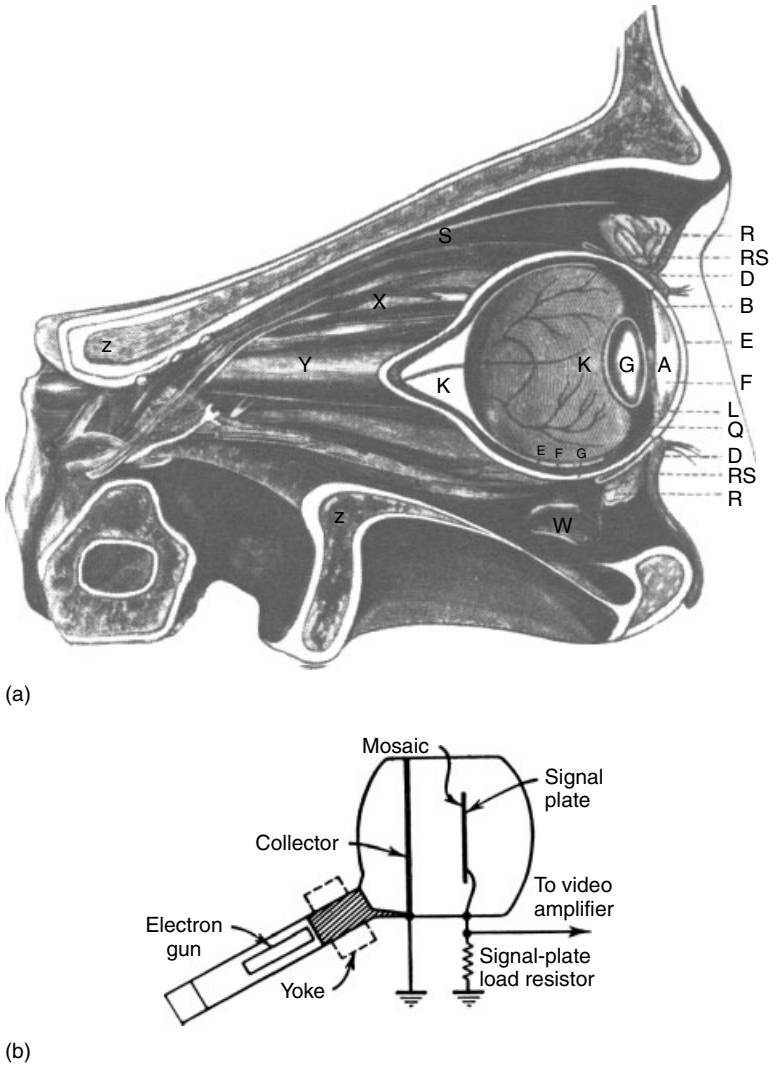

Figure 3. Man's creations generally use different materials and techniques as do natural systems. Here, imaging sensors are contrasted (a) Longitudinal section of eye (Reproduced from *Cyclopaedic Science*, Pepper J.B., (1874), Copyright Frederick Warne) and (b) RCA iconoscope – early form of television camera tube from Kloeffler (1949) (Courtesy RCA Ltd, USA).

existence, it began at zero magnitude and grew with time. No method has yet been devised to measure its magnitude in objective ways but it clearly is enlarged continuously with the passage of time.

It is formed of two groups: that about the natural world and that about the unnatural systems created by man. Man's creation grows, the natural world changes; the extent of the latent information available for conversion into knowledge therefore grows continuously.

As the body of knowledge grew, various workers of the past tried to summarize all that was known. Today, that must be recognized as an almost hopeless task. Collectively, all knowledge must be stored in a manner whereby it is retrievable. The danger of converting latent information back into another form of latent storage via the knowledge conversion state is real; what lies in the literature is not all recoverable in an easier manner than that by which it was first generated!

To retrieve knowledge, it is grouped into convenient classifications. Convenience is a term in which time of action is most important. The memory span of man, especially short term, is very limited, so it has been suggested (Harman, 1973) that major groupings usually total around seven. These in turn are subdivided, giving the various epistemological groups.

Measurements assist in gaining knowledge and knowledge, in turn, assists new forms of measurements to be conducted. A closed-loop mechanism can be observed in the development of measurements; Figure 4 depicts this.

Over the past few decades, the trend toward recognition of the interdisciplinary studies that replaced the specialisms that came to us previously has highlighted the

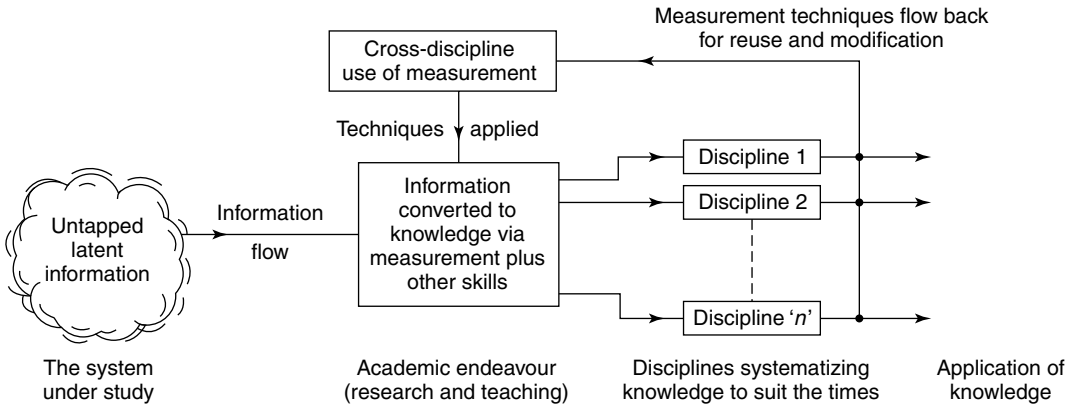

Figure 4. Relationship of measurement principles in ordering the body of knowledge.

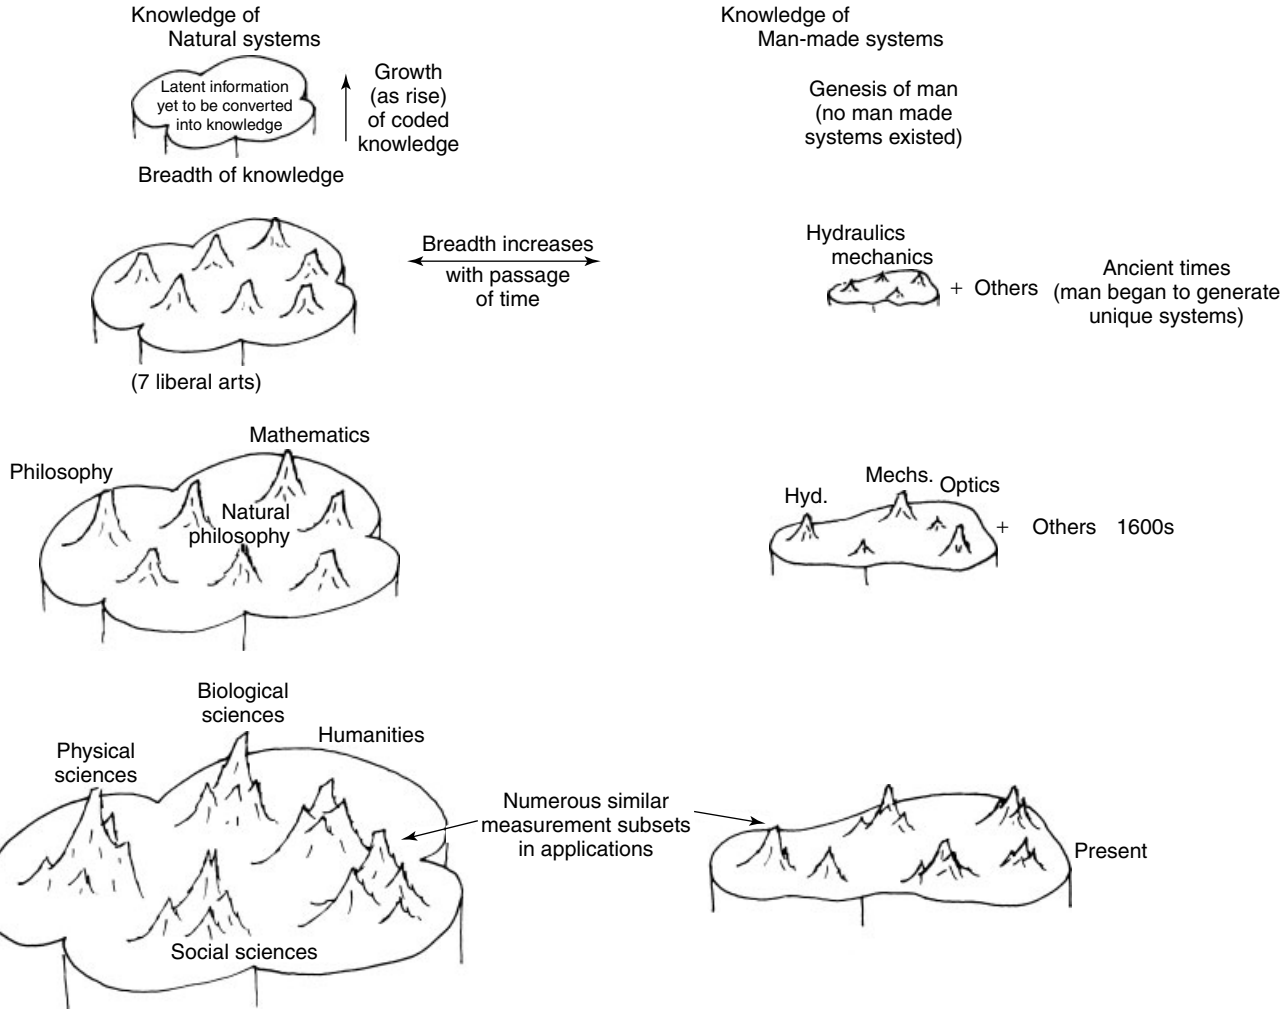

Figure 5. Epistemological mountains in the two plains of human knowledge. Measurement techniques are now duplicated on most contemporary mountains.

fact that not only does such a feedback process exist but it is also often duplicated (a needless waste of effort, therefore) and is often cross-fertilized between epistemological groups.

The Dewey cataloging system gives librarians a set of numerical codes, each having a linguistic description of what subject matter each number represents. Of over 40 000 numerical assignments, some 600 clearly relate to the

measuring process. These are distributed widely over the whole body of knowledge, as classified by that system. Pictorially, this means that most clusters of knowledge possess subclusters concerned with measurement method as depicted in Figure 5.

At present, information scientists – those people that work on the storage, coding, and retrieval of knowledge – consider that the major clusters are changing to reflect the interdisciplinary attitudes. New clusterings are emerging, one which may well be that of the relatively new discipline of measurement science, the pursuit of means to convert latent information into meaningful knowledge by rigorous and objective procedures of philosophy and practice.

1 DEFINITION OF INSTRUMENT SCIENCE

A science is an organized body of knowledge (Finkelstein, 1994). What then is Instrument Science? To answer this question, we must define what an instrument is. When posing the question, '*what is an instrument?*' (McGhee, Henderson and Sankowski, 1986), most people have a visceral feeling for the answer. According to the McGraw-Hill Encyclopaedia of Science and Technology, an instrument is a *SYSTEM, which refines, extends, or supplements* the *HUMAN faculties of sensing, observing, communicating, calculating, controlling, and perceiving*. In other words, instruments are human-made elements embedded within human-machine systems, which help humans to acquire information, by the process of sensing, and to handle data, by performing information handling operations. Using this definition as the key, an implicit use of taxonomy led to the proposal that ordering in instrumentation should involve functional and structural *reticulation* (McGhee, Henderson and Sankowski, 1986). This statement is similar to another definition by Peter Stein (1969) who asserted that *Measurement* combines '*INFORMATION transfer about*' and '*ENERGY transfer from*' a '*process*' using '*SYSTEMS,*' which are made up of '*components or TRANSDUCERS*' forming a '*STRUCTURE or network*'.

A definition that encompasses all of these ideas is given in Figure 1. The systemic nature of measuring instruments demands a holistic approach in design and analysis. It is apparent that the ordering of *information machines* depends upon the holistic relations among specific sensor *structures* performing diverse *functions* within different *energy* domains for the *acquisition, capture, communication*, or *distribution* of *information* in a variety of *signal* forms.

The diagrammatic summary definition given in Figure 1 is based upon the functions performed by measurement systems, the structures that allow them to perform the function, and the energy form from which the information is acquired. It may be regarded as the study of the methods and techniques of extending the human abilities to handle information using information machines. Since information is predominantly carried by signals, measurement is concerned with the acquisition, handling, analysis, and synthesis of signals in measuring instruments. It may also be considered as the measurement analogy of data communications.

To assist with the generalizations that make measurement scientific, it is essential to develop a unified metrological description of every constituent component making up a measurement system. A unified approach allows the evaluation of the metrological characteristics of each element. Thus, the formation and analysis of all contributory factors, and in particular, the measurement errors can be performed (Solopchenko, 1994). Signals, which are acquired using various forms of sensors, are handled using diverse forms of metrological components. These may be conditioners, amplifiers, and filters used in conjunction with suitable multiplexing methods.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

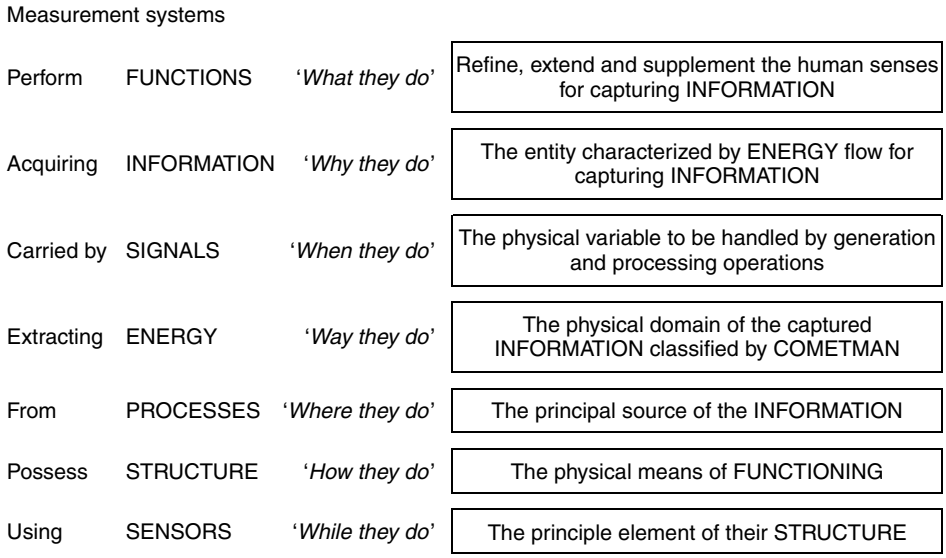

Figure 1. A substantive definition of measurement.

When instruments, which have the primary structure of systems, are viewed from this position, the field of Systems Science and Engineering (M'Pherson, 1980, 1981; Sandquist, 1985), with its related disciplines associated with large-scale systems, must play an important part in their exposition. This systems approach, which possesses holistic or totality features, offers a number of advantages. A principal benefit places instruments within a hierarchy of both systems and machines by structure, function, energy form, and information. McGhee, Henderson and Sankowski (1986) have stated that these aspects are revealed by the methods of reticulation or subdivision. As it happens, reticulation also reveals the places occupied by other types of subsystems within this hierarchy. Thus, advantages are accrued by using this approach in the study of instrumentation. Commencing from this standpoint, the systems approach is essential for the study of instrumentation. Some broad principles of Systems Engineering for instrumentation are adapted for the boundary view of human–machine systems in **Article 68, Setting the System Boundaries, Volume 2**.

2 THE NEED AND STARTING POINT FOR ORDERING IN INSTRUMENT SCIENCE

Every field of scientific activity requires organization or ordering. An essential starting point in the ordering of Instrument Science is the application of a relevant taxonomy (Flint, 1904; Durand, 1899; Broadfield, 1946; Körner, 1970; Knight, 1986; McGhee and Henderson, 1991; McGhee *et al*., 1996; McGhee and Henderson, 1993; Thomson, 1926) using objective methods to ensure that the ordering is justifiable. Such schemes of classification have been compared to nominal scales of measurement using an algebraic formulation (Watanabe, 1996). The following quotation (Knight, 1986) indicates the fundamental importance of classification in all of the applied sciences:

> We are apt to think of classification as a sort of 'natural history stage' through which all sciences pass in their youth before they grow into something handsomer, more mathematical and explanatory... classification is a highly theory-laden activity.... What one thinks one is classifying may make a big difference to the system of classificatory categories one uses.

It is apparent that classification is of basic importance for all activities in the applied sciences.

It has been noted that a taxonomy of Instrument Science will be erroneous if it is based upon its ends (McGhee and Henderson, 1993) as this will only lead to a cataloging of instruments. Indeed, only by organizing the constitution of the topic on the basis of contributory disciplines can Instrument Science be arranged according to its basic nature and inherent characteristics. Considering the nature and scope of the disciplines constituting the taxonomy, analysis, design, and utilization of instruments and instrument systems provides a clear view of the contributory disciplines of Instrument Science (Finkelstein, 1994; Finkelstein and Grattan, 1993, 1994; Measurement, 1994; Sydenham, 1982, 1983; Sydenham and Thorn, 1992) within Instrumentation and Measurement Technology (I&MT).

3 HOW INSTRUMENT SCIENCE IS ORGANIZED

Instrument science must be *holistic* by always using the '*whole-life-whole-system*' approach characterizing the *SYSTEMS ENGINEERING* method (M'Pherson, 1980; McGhee, Henderson and Sankowski, 1986; Sandquist, 1985). Thus, it is seen that instruments and instrument systems perform a diversity of information handling functions allowing the acquisition, capture, communication, processing, and distribution of information about the states of equilibrium and motion of solids, liquids, gases, and their constituent systems using a variety of physical sensing structures in different energy forms. McGhee and Henderson (1991) have suggested that this is the starting point, not only for ordering in Instrument Science but also as the fundamental context for ordering in all of the applied sciences.

The question then arises as to how the science of measurement should be organized into identifiable bodies of knowledge. A method for the organization of knowledge in the biosciences called *Taxonomy* or *Classification Science* provides the answer to this question. This method can be adapted for the organization of measurement. Observation and recording are the embodiment of the scientific method, which is of profound importance in the understanding and utilization of the physical universe and its resources. This aim is achieved through the measurement of the states of equilibrium and motion of solids, liquids, gases, and the systems they constitute (McGhee, Henderson and Sankowski, 1986). Instruments are the means by which these human faculties may be improved and supplemented (Finkelstein, 1994). However, the acquisition of information, or, more generally knowledge, requires some process of ordering or organization. In the case of instrumentation, this ordering of *information machines* depends upon the holistic relations between various instruments. The basic theoretical mechanism, which allows the organization, is the field of taxonomy or classification science. Although this science is well known in the biosciences, it is not so well known, or for that matter understood or applied, in the engineering sciences. This opinion has been expressed on a number of occasions in the references quoted in McGhee, Henderson and Sydenham (1999). It is well worthwhile to provide some basic information on the nature and scope of taxonomy for use in measurement. The systemic nature of instruments implies a holistic approach in their ordering.

Since the time of Plato and Aristotle, many attempts have been made to organize the sciences into hierarchical groupings. A scientific approach for the ordering of science is provided by *TAXONOMY* . Although this science has been used implicitly by bioscientists for centuries (Daly and Linsley, 1970), its intrinsic rules and principles were not studied deeply until the nineteenth-century French philosopher, Durand (De Gros), examined its constitution. Thus, a clear distinction is drawn between the ordered organization of the theory of Taxinomy (its original spelling) itself and its principal applications in a specific field. It has been claimed that the word Taxonomy (from the ancient Greek taxis meaning order) was first used by the seventeenth-century Swiss botanist Augustin Pyrame de Candolle (1778–1841).

What is the nature and scope of taxonomy or classification science? In the view of Durand, the most elementary form of all classification is the series that depends upon the increase or decrease of some *variable* of the scheme of ordering. Hence, any legitimate scheme of instrument classification must ensure that all of its divisions are always determined by one common principle. Instrument classification will thus be erroneous if it is based upon its ends, as this merely leads to a catalog of different kinds of instruments. Rather, instrumentation should always be arranged according to its basic nature, its inherent characteristics, and not upon anything lying outside itself. In other words, the science of classification in instrumentation is not about the sum of the ends of instrumentation but rather about coordinating the science of instruments in such a way as to give it an organized or systematized structure.

4 ORDERS OF CLASSIFICATION

The significant contribution Durand made to the science of taxonomy was the proposal that there are four principle orders or problems of classification. These orders are summarized in Table 1. In the *First Order,* described as *Generality* or *Resemblance*, is embodied what many other theorists of classification have called the 'likeness' of one thing with another thing. The *thing concept* is fundamental to the whole of categorical ordering, not just in bioscience. It is also important in the earth sciences (Von Engelhardt and Zimmermann, 1988) for the classification of minerals, in technology transfer (Zhao and Reisman, 1992), and in KNOWLEDGE ENGINEERING (KE) (Chandrasekaran and Goel, 1988; Gomez and Segami, 1991; Mill and Rada, 1990; Yasdi, 1991). Hence, this concept also has central importance in instrumentation. Likeness, of course, is that *relation* between several concrete things that unites them. Thus, the application of classification by zoologists and botanists in the discrimination between genera and species is a good example of the way in which the problem of generality and resemblance is approached.

In taxonomy, there is an important tendency to group things on the basis of their *Composition* or *Collectivity*. Durand distinguished this as the *Second Order* of taxonomy. While this order is concerned with the relationship of the part to the whole and vice versa, the *Third Order* of

Table 1. A summary of the four orders or problems of taxonomy.

Taxonomy, the science of classification (Putting *things* in a *scientific order*)		
Problem or Order	Definition and Aspects	Comment
Generality or resemblance	1. Concerned with the *likeness* of *separate things* 2. *Likeness* is that *relation* between *things* that *unites* them 3. The *thing concept* is fundamental to all *Categorical Ordering* (*i.e.* Taxonomy)	Also called the *Metaphysical Order* because terms are concerned with *theoretical* or *fictitious* things
Composition or collectivity	1. Concerned with the *relationship* of a *part* of a *thing* to the *whole thing*	All other orders are concerned with the actual things to be classified
Hierarchy	1. Concerned with the *relation* between *heads* or *central members* of *groups* of *things*	Related to the *order* of *composition/collectivity,* especially in the places occupied in each *order* relative to other things of the *same order*
Genealogy or evolution	1. Concerned with the *kinship* of *one thing* with some *other thing*	Hinges upon *notions* of *kinship* by *relationships* of • *ascent* • *descent* • *collaterality.*

taxonomy, called *Hierarchy*, takes account of the relation of rank between the heads or central members of groups of things. In their turn, these are related in the order of composition, but address each concrete thing in the assessment of the place it occupies in each order relative to the other constituents of the same order. Perhaps the most important *Fourth Order* in Durand's theory of taxonomy, especially in bioscience, is that known as *Genealogy* or *Evolution*. This order hinges upon the notions of kinship through the relations involved in the characteristics of *ascent, descent,* and *collaterality*. As with the orders of *Composition* and *Hierarchy, Genealogy* and *Evolution* are also concerned with the actual objects or events that are to be classified. Although there have been minor developments of this theoretical constitution of taxonomy, it is still fair to say that the basis laid by Durand has not been significantly altered. As this theory of taxonomy was formulated in the context of bioscience, it requires modification before being applied to instrumentation.

Another important aspect of taxonomy is the development of a system of nomenclature, which is unambiguous. In bioscience, the binomial nomenclature is due to the eighteenth-century Swedish botanist, Carolus Linnaeus (1707–1778). For example, in plant kingdom classification, the first category of the ordering is called a division. This is followed by subdivision followed by class, order, family, genus, species, and subspecies. It seems logical and convenient to use the same ordering for machine kingdom grouping, although it may cause some controversy. Adapting the basic phenetic and phyletic methods used by bioscientists allows functional and structural grouping in instrumentation. Phenetic discrimination uses similarity and difference in form or physical feature, while phyletic techniques are based upon evolutionary criteria.

A summary of taxonomy for instrumentation (McGhee and Henderson, 1989) points out that it has three objectives and three functions that emphasize its importance. Thus, the three objectives of classification are:

1. the concrete discrimination between different things;
2. the consensus regarding standards for the principles of description;
3. the bringing of order or systematization.

Similarly, the three functions of classification should allow

1. the organization of the means of communication and retrieval of the descriptions used;
2. the acquisition of new information in the extension of descriptions;
3. the highlighting of unifying factors between entities without diminishing the importance of any existing differences.

The materials of taxonomy in Instrument Science are the diverse types of instruments and their operating principles. Assembling the various instrument types is the main activity of classification in Instrument Science because it allows the possibility for further study. The grouping of instruments from the lowest levels of sensors into progressively larger groups so that a hierarchical ordering by function, structure, and energy form, constitute the final ingredients of discrimination and ordering in Instrument Science.

1 MEASURES OVERVIEW

Measurement is found everywhere; it seems to be a necessary part of human living (Klein 1975; Ellis 1973). It is the process by which we seek to qualify and quantify an issue. It is a key part in the generation of knowledge for that issue. For example, in order to decide if the greenhouse watering system needs to be turned on, the moisture content of the soil is measured, resulting in a number that is compared to a standard value to decide if it is needed.

Measurement is not always well set up. The well-experienced measurement scientist or engineer will easily be able to point to the inefficient way in which much of measurement activity is practiced.

We need to be clear about such questions as:

- What is the purpose of the measurement?
- How does measurement advance the issue in question?
- Is it being done appropriately?
- Is the result expressed appropriately?

2 THE MEASUREMENT SITUATION

Throughout the recorded history of man, there has existed recognition of the connectivity between measurement and the acquisition of knowledge that, in turn, can be related to the advancement of man in general – Sydenham (1979); Bud and Warner (1998).

Measurement can be used to support two kinds of knowledge gathering situations:

- **Controlling a known situation**

A temperature controller in a food storage container uses the measurement value to switch the cooling on and off as needed. Here, the physical process is well understood; the need is to control the flow of cooling as the temperature varies.

- **Investigating a subject under research**

The need here is to glean new knowledge. For example, a theory has been proposed that suggests a relationship between two variables in an illness exists that would suggest a cure. A series of experiments is designed in which measurements are made under controlled conditions to reveal if the relationship holds.

A key statement about the relationship between measurement and knowledge is that of Lord Kelvin. In 1883, in a lecture at the Institution of Civil Engineers, he stated:

> 'In physical science a first essential step in the direction of learning any subject is to find principles of numerical

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

> reckoning and methods for practicably measuring some quality connected to it. I often say that when you can measure what you are speaking about, and express it in numbers, you know something about it; when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind: it may be the beginning of knowledge, but you have scarcely, in your thoughts, advanced to the stage of science, whatever the matter may be.'

This statement is expressing elements of the thinking paradigm known as *reductionism*, the main method by which we gather knowledge in the so-called hard sciences.

Reductionism appears to have come down to us from the contribution of Descartes. In 1693, he stated in his *Discourse on Method* – see Hutchins (1952):

> '.....divide each of the difficulties that I was examining into as many parts as might be possible and necessary, in order to best solve it.'

He suggested that the human mind sorts out its problems and finds solutions by breaking them down into successively smaller elements, until the stage is reached where they are adequately understood.

Descartes suggested four rules for 'properly conducting one's reason':

- Avoid precipitancy and prejudice
- Accept only clear and distinct ideas
- Conduct orderly progression from the simple to the complex
- Complete analysis with nothing omitted.

This is the basis of the measurement methodology outlined in Section 8.

In addition to being used for the 'hard science' physical situation measurements, it is also used in the 'soft science' situations to obtain qualitative knowledge where measurement is vital to such situations – for example, audits of the performance of people and processes.

Studies on the general nature of measurement are available. A few are now selected to show the range of approaches taken.

Finkelstein has covered a large range of fundamental topics. His paper, Finkelstein (1999), is a good summary of how far the ideas have been taken in formal mathematical terms.

Sydenham (1979) is a review of the role of measurement, which attempted to delve into the reasons and processes.

The place of measurement in science is covered by Kariya (1999) and IMEKO (1999). It gives a balanced overview of the hard science involved along with the necessary early stages of idea formulation and expression of what it is about as a process of learning.

Hofmann (1999) makes the link between measurement and practical needs in society.

Yang and Butler (1997) approached the problem of creating a universal framework from the epistemological perspective, suggesting it be modeled as a knowledge-oriented system. They propose that an object-oriented model (Yang and Butler 1998) be used for representing measurement systems.

3 MEASURES AND METRICS

The nature of inquiry used to gather knowledge can be very different across the various disciplines – see Brown, Fauvel and Finnegan (1981). Mathematicians, scientists, engineers, social science, management, and so on, do not have the same belief systems and often use different ways of thinking to solve their problems. They, however, all make measurements of some kind to support their knowledge-development processes.

It often comes as a surprise to the 'hard science' trained scientist or engineer that not all situations can make use of reductionist techniques.

Stumbling blocks for reductionists in accepting the softer sciences and humanities approaches are the:

- apparent lack of sufficient rigor of understanding and expression;
- use of many less familiar terms and words like 'paradigm', 'metaphor', 'holistic', and so on;
- inability to be as precise about ideas as are the laws of physics;
- inability of humanities practitioners to clearly identify the parameters and relationships of their areas of work;
- lack of applicability of the reductionist approach – that surely should be used; after all, it has and still is serving much of science and engineering very well.

The humanities paradigm is known as the *phenomenological approach*. Here, the observer does not metaphorically dismantle, by reductionism, the system of interest to separate its subsystems and then build it up again after changes have been made. Instead, the humanities viewpoint is one of metaphorically getting inside the system of interest, inserting intervention actions to see if current understanding is correct, and the ability to change the system as required. A relevant branch of this is called the *soft system methodology* (SSM), Checkland (1981).

In sharp contrast, reductionism requires all of the system of interest to be first bounded to form a closed system that is then dismantled to be built up again in its new form. The sort of problem that does not lend itself to this paradigm is one in which the boundaries of influence are

unclear, preventing the creation of an adequately closed system model.

There is also another reason why reductionism often fails in the complex systems arena. Success in understanding and problem solving is predicated by the assumption that the solutions for the subsystems resulting from reticulation can all be integrated back into the needed whole. One difficulty is that even slight variations in interface specification of those subsystems parts can have a significant impact on the performance of the whole – to the point where the performance of the new whole differs markedly from expectations.

The reductionist concept for problem solving is not totally accepted – it does have a severe philosophical problem.

A fundamental difficulty is what philosophers call the 'dual body' problem. Behavior of the physical aspect of the human system is well explained by the laws and rules of physics. The human mind, however, seems to behave quite differently. Its behavior defies reduction to formal description and use of the same method of scientific investigation.

Methods of inquiry, and even the scientific process of knowledge discovery, are not taught in most engineering and science courses. A result has been the widening divide between the thinking styles of the Arts/Humanities and the Sciences, existing on the modern university campus.

Many myths about measuring exist – see Sage and Rouse (1999) pg. 584–586 – some are:

- Measurement made with hard quantified measures will lead to the soft issues also being understood – not so; soft systems are different from hard systems and need different approaches in their measurements.
- Measurement is for bean counters and the data cannot be translated into useful improvements – not so, provided it is done well, see Section 8.
- Measurement is about the past and is not relevant to the different future – not so; applications can mature as projects change, by the application of sound and relevant measurement.
- Measurement encourages a box ticking culture – not necessarily so, provided it is done well and not using simple-to-measure, yet nonuseful, data.
- Measurement stifles creativity – not so, as measurement is about knowing about things in an objective manner.
- Measurement thwarts productive human activity – not so, if done appropriately.
- The more the measurement the better the productivity will become – not so, for again it is a matter of devising a good measuring system that truly addresses the requirements.

4 TERMS

Whatever process of measuring is being implemented, a confusing range of terms are used to describe the measures used.

The 'thing which is to be known' within a measuring situation is today, in the engineering world, often called a *measurand*.

A commonly found general term for measures, used extensively in the process performance arena, is the metric (Blanchard and Fabrycky (1998); Sage and Rouse (1999)).

This term is found, where a set of measures (metrics) are established to collectively gain insight into how well the whole process is working. This term is not as frequently used in the physical sciences, for the word 'metric' there is associated with the metric system of units.

Another measures term often used in systems management is the technical performance parameter (TPM) – this is explained later.

Many other terms will be encountered that mean much the same thing – tracking variable or parameter, indicator, index, score board value, and so on.

Measure terms that have specific and different application include:

- measure of effectiveness (MOE)
- measure of performance (MOP)
- system performance parameter (SPP)
- technical performance parameter (TPP).

Where these fit into a hierarchy of measurement is explained in Section 8.

The development and application of truly effective sets of metrics is a skilled task based much on experience in the application area. It is easy to generate the measures for the clearly evident physical measurements such as temperature, speed, and load-carrying capacity. It is often not so easy to decide an effective parameter for more elusive, many to one mapping situations, such as in setting up a measuring system for the quality of a social reform program.

At the single-measurand level, seek to choose the measure with best overall effectiveness. It will not always be obvious; the process involving the measure needs to be understood. For example, in jam making, a rapid change in the pH is a far better indicator of when it is optimally cooked than is the viscosity of the mixture.

Setting up a truly effective metric is not always easy; simple ones are often chosen that, while providing a seemingly comfortable quantitative number, add little to the overall picture being sought. For example, the rate of progress of a software task could be measured as 'lines of code completed in a unit time' compared against the envisaged number of lines used as the norm. This is, however, far too simplistic

as the quality of the code and the number of errors to be subsequently corrected can completely overwhelm the time used to prepare the code for the usable standard.

As the choice and use of metrics is based in considerable experience, a company will often be protective of its metrics database and not release it to the general public for, over time, it develops to have intellectual property value.

In reality, it is the high-level measures that are of real interest, physical variables being but a part of 'many to one' mappings of measures.

5 SOME METRICS

Thousands of metrics exist. A well-organized systems design operation will have a progressively updated database of metrics that has been developed to suit its own kind of industry.

Unfortunately, these tend to not be developed in reusable ways that would permit follow-on projects to extract them from a well-setup library. Also, they are often held in confidence and tied into a project.

They mature as the staff uses them, and for this reason alone the best way to develop effective ones is to ensure they are reused over projects in a controlled manner.

A measure stored in a metric database needs to have the following information recorded:

- Metric/measure name
- Symbol used to represent it
- Acronym used, where applicable
- Synonym usage explanation
- Definition of its purpose
- Brief description of its uses
- Use in multimeasures mapping sets
- Previous projects in which it has been used
- Person who authored the entry
- Level of confidentiality assigned
- Authorizing person
- Persons who accessed it in past use.

With so much to set up to ensure traceability, soundness, and uniqueness, it is not surprising that good metric databases are not readily available.

The following short collection of metrics is a motivational starting point.

5.1 Physical measurands

- Velocity
  - Time lapsed
  - Mass
  - Force
  - Temperature
  - Viscosity
  - Tensile strength
  - Strain

and so on.

5.2 General systems use

- Time to market
  - Time to completion
  - Number of items produced
  - Sales made
  - Sales returns
  - Defects rate
  - Repair time
  - Mean time between failure (MTBF)

and so on.

5.3 Customer responsiveness

The following are from Sage and Rouse (1999), pg 569. These require many-to-one measurement mappings to arrive at a measured quantity – see Section 8.

- Product features added
- Product quality
- Customer satisfaction
- Speed of response to customers
- Market expansion
- Product uniqueness
- Listening to customers
- Customer visits
- Sales improvements
- Innovation
- Organizational acceptance to customer evolution

5.4 Innovation measurement

Some of the lists provided in Sage and Rouse (1999), pg 570 are now given:

- Number of innovative small parts
- Service innovations
- Number of pilots and prototypes
- Number of benchmarked ideas adopted
- Measures of word-of-mouth marketing
- Number of innovation awards.

5.5 Software development

- Lines of code
  - Rate of completion of lines of code
  - Efficacy of coder
  - Error rate per 1000 lines of code
  - Recursion time
  - CPU needed
  - Speed of execution of standard benchmark operation
  - Latency time
  - Number of branches
  - Compilation time
  - Reset time
  - Cyclometric complexity
  - Level of cohesion
  - Level of coupling

and so on.

5.6 Defence systems

While extracted from defence material, Hoivik (1999), these may also be relevant to civil projects and situations.

- Quantity of x
- Quality of x
- Coverage of x
- Survivability
- Lethality
- Sea, air, and land worthiness
- Warhead size
- Speed
- Range
- Altitude of operation
- Evaluability
- Weight
- Power
- Computer throughput
- Memory size
- Cooling capacity
- Target location accuracy
- Reaction time
- Receiver sensitivity
- Ranging accuracy
- Range
- Hardness to damage
- Damage tolerance
- Drift rate of guidance unit
- Radiation hardness
- Engine power
- Rate of turn
- Climb rate
- Payload
- Subsystem x weight
- Number of crew needed
- Firing rate

and so on.

6 FORMS OF COGNITIVE ENTITY

When measuring, it is important to differentiate between the terms data, information, knowledge, and wisdom when used in relation to knowledge gathering via measurement. This issue is addressed in more depth in **Article 13, Signals, Information and Knowledge, and Meaning, Volume 1**; **Article 23, Principles of Semiotics as Related to Measurement, Volume 1**; **Article 24, Principles of Epistemology as Related to Measurement, Volume 1**; and **Article 39, Characteristics of Data, Information, Knowledge, and Wisdom, Volume 1**.

It is useful at this stage to classify the four levels of the development of a cognitive entity. Using the Oxford Universal Dictionary, 1968, we get the following definitions:

- Data:
  'a thing given or granted: something known or assumed as fact and made the basis of reasoning or calculation.'
- Information:
  'the action of informing' stemming from
  'to put into form or shape.'
- Knowledge:
  'the fact of knowing a thing, state, etc.' stemming from 'to recognize or identify.' Also, 'an organized body of information'.
- Wisdom:
  'the quality or character of being wise' stemming from 'having or exercising sound judgment or discernment.'

These give some useful clues about the terms, but we really need an explanation that is better related to measurement systems. Here, follow the author's definitions Sydenham (1986).

Data: Raw symbols that are obtained from a measurement system and that have no assignment of meaning associated with them. They are just simply numbers, letters, ikons, cuneiform stabs in clay, and so on. An example is the symbol set of '10'.

Information: This is data that has associated, either tagged with it or held elsewhere, a small amount of cognitive material that gives it a certain meaning. Reduction of 'raw data' into 'engineering units' is an example. An example is '10 m'. The assignment of a tag that has a cognitive meaning; here, the distance unit 'm' for the

unit of length, the meter, creates useful information from the number symbol.

Knowledge: This is sets of information put into a context of a particular use. Representational information is organized into a coherent model structure. As with 'beauty', what constitutes knowledge is in the mind of the beholder.

It possesses specificity of application. For example, the raw data from a strain gauge on a wing of an aircraft for a given location and time, and with known units, constitutes a segment of knowledge.

Wisdom: This is a higher level of cognition than knowledge. It is a set of knowledge components having associations between entities. For example, the pattern of strain gauge readings across the aircraft wing may have peculiarities that suggest, to the expert mind, that it is in an unsafe state.

A level is reserved for the highest level of, as yet unfathomable, intelligence.

These entities form the intelligence tree shown in Figure 1. It is clear how measures lead to an increase in wisdom.

Fashions in the use of terms change. Overall, what used to be called *information* often tends to be called *knowledge* now. The fact is the various cognitive entities have yet to be consistently used.

7 THE SCIENTIFIC PROCESS

An understanding is needed of how quantifying measurement can contribute to increasing the available knowledge on a topic. This is explained by the scientific process used as the basis of reductionist thinking.

This stems from as early as the sixteenth century and has gradually become the norm. In 1931, Bertrand Russell published his understanding of the basic process steps of the scientific method.

'In arriving at a scientific law there are three stages:

- The first consists in observing the significant facts
- The second in arriving at an hypothesis, which if it is true would account for these facts
- The third deducing from this hypothesis consequences which can be tested by observation.'

The scientific method relies on:

- reducing the complexity of the variety of the real world to a manageable state;

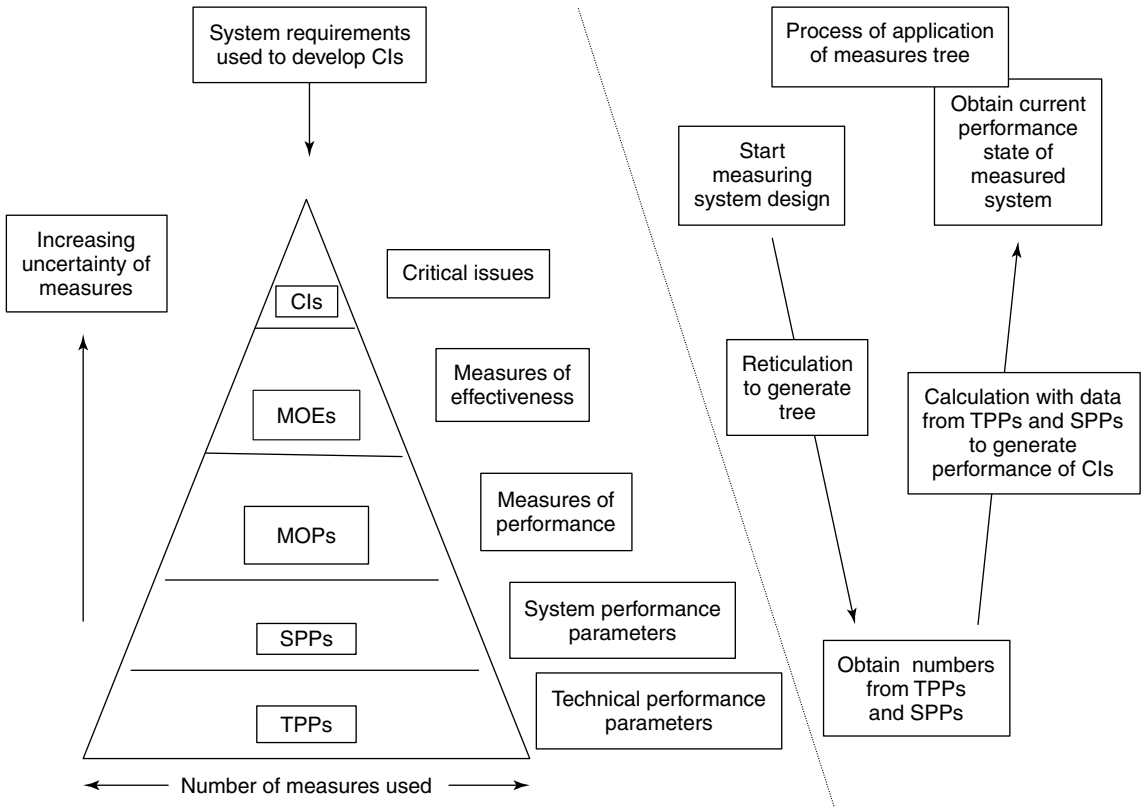

Figure 1. Intelligence tree shows relativity of the various cognitive variables and relationship to measures triangle.

Table 1. Stages of the measurement process and the role of measurement in its execution.

Generalized scientific method	Role of measurement theory and practice
Develop hypothesis	
1. Identify question/problem	1. Develop test objectives
2. Formulate hypothesis	2. Estimate performance
Experiment	
3. Plan the experiment	3. Develop test method
4. Conduct the experiment	4. Collect test data
5. Analyze the results	5. Calculate the measures
Verify hypothesis	
6. Check the hypothesis	6. Compare results
7. Refine the hypothesis	7. Rerun tests or extrapolate

- performing analysis or experimentation on simple models of the world to examine a hypothesis;
- validating a hypothesis by looking repeatedly to see if it can be disproved – the 'null hypothesis' basis. It is actually not achieved by showing it to be always true, as is commonly understood (infinite testing needed there!);
- building knowledge, therefore, by eventually refuting the hypotheses and forming an improved one.

The scientific process of inquiry and its stages are summarized as Table 1. Alongside are given the various functions of measurement in that process.

Areas of measurement are needed to undertake all stages of this knowledge-gathering activity. Measurement is, therefore, a key part in its application. Poorly undertaken measurement can lead to incorrect knowledge, or more usually the case, to less precise knowledge, possibly giving rise to misinformation or negative knowledge.

The process acquires new data from measurements made, and the observer uses that data to draw conclusions about the hypothesis being developed by evaluating the data in the context of the hypothesis.

So far, we have discussed the role of measurement in the scientific process. It is an easy step to see that this process is applicable to any measurement situation itself for a measurement activity is an experiment to see what you have. This is the time to review how that data flows into evaluation of the hypothesis.

8 HOW TO APPLY MEASURES

We need to ask a fundamental question. What is the holistic purpose of making a measurement?

In the closest inward looking boundary, it is to satisfy the need of the person requesting the test. This is, however, far too restricted a horizon to take because that test is being done to integrate into a much larger problem situation.

The scientifically executed process is the only way by which measures are obtained that are as objective as possible. The physical experiment performed in measuring is the only way to obtain verified data on the physical world.

A single measurement entity is being measured as part of a large array of measurements needed for evaluation purposes of a system of some kind. Examples might well be to assess the airworthiness of a new aircraft or to see if a medical intensive monitor unit is operating within all critical performance parameters.

The above sample lists of metrics show that for a project numerous things can be measured. The question needing an efficient solution is how can one set up an optimal measuring system when time, access, and cost, usually, severely limit the number of measurements that can be made.

9 THE MEASURES TRIANGLE AND ITS PARAMETERS

What is needed is a plan to set up and use many scientifically executed physical measurements that are integrated, in a traceable manner, to form decisions that map into a few high-level measures about the overall system.

This leads to the concept of the measures triangle. Figure 2 shows the various levels and types of measures that form this measures treelike diagram.

To set up a system's measurement plan, the first thing to do is to identify the critical issues (CI) from the system requirements documentation. CIs are those high-level issues that, will make the development fail if not achieved.

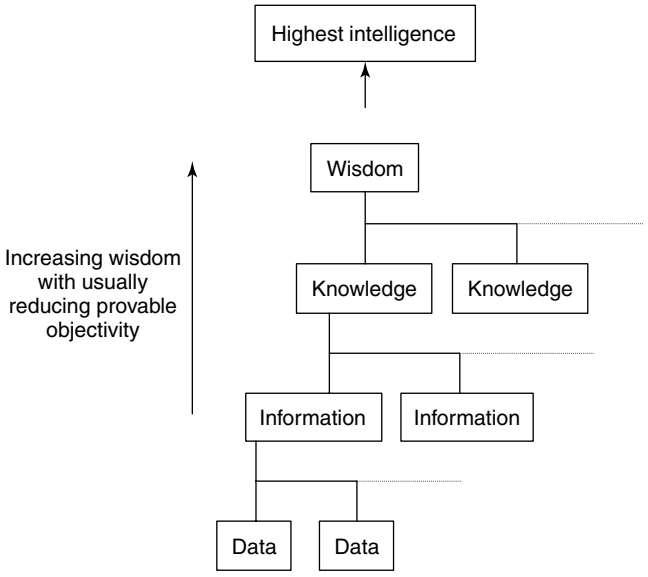

Figure 2. Measures triangle and its levels of measures.

Each CI is then broken down to obtain its measures of effectiveness (MOE). These are expressed in terms of what is to be achieved, for example, the requirement states that 'the customers must be satisfied' so that MOE needs measures of customer satisfaction to be set up. That it may not be immediately obvious how to measure it is not an issue at this stage of the reticulation. One should not start from what can be measured, but from what should be measured – a commonly ignored requirement!

The MOEs, in turn, reticulate down to give measures of performance (MOP). These break down the MOE into the MOP that, when combined, lead to the MOE value. Customer satisfaction could be measured in terms of the return rate of customers, from a direct survey of them using a written survey instrument, or from use of a video camera that records their demeanor as they pay for the goods. MOEs and MOPs cannot be measured directly.

This in turn gives the number of returns per customer; consolidated survey results grade; and an image interpretation as the system performance parameter SPPs to measure.

The final level is the technical performance parameter (TPP) wherein physical measurements are possible. SPP measures will often go directly to the TPP level as is the case here for return rate: a counting exercise. The paper survey will, however, not necessarily need TPP measures as it will be done by discussion and box ticking in a form. The paper survey is already able to yield some SPP values. The customer demeanor grade has to be determined from image processing set up to measure various indices. This needs a physical measuring instrument to obtain a set of TPPs that map into the SPP of customer demeanor.

In this way, from each CI, a tree of measures is generated. A measuring system design has been generated. Of these layers, only the TPP is hard data obtained by use of the defendable scientific process. The measures on the other layers invariably contain some degree of subjective decision making.

Once all of the TPP and SPP data has been obtained, the values are fed upward inside the tree to give the various other measures their value, by direct calculation up the tree. In this way, traceability results for all measurements and only essential measurements are performed.

When the first draft of the system is available and representative figures can be inserted for each measure, judgment can be exercised to see which measures are not significant; these can be omitted to reduce the measurement effort needed.

As the calculations rise up the trees, the integrated knowledge becomes less accurate in its nominal value and will have increasing uncertainty. This situation cannot be avoided unless all decisions are made entirely with physical measurements and with nonfuzzy logical combination. This ideal of perfect measurement appears to be a goal but it, usually, would be too costly, would take too long to organize, and more often than not, would not be feasible to build.

At any point in the tree a nodal value can be extracted, and its measure calculated from data below it. The widely used technical performance measure TPM is, in effect, such an extraction, but it has little recognition of where it fits into the traceable hierarchy from data measurement to proof of requirement satisfaction, for it is usually generated from experience without use of a measures tree.

A more detailed explanation of test and evaluation of large systems with many variables is provided in Sydenham (2004).

10 CASE STUDY OF THE GENERATION OF MEASURES

A simple example of how a measures tree is developed from the CI is the generation of a suitable measuring system for automatically monitoring the quality of loaves of bread coming from a bread baking line. This results in a fully physical measurement situation.

Figure 3 shows a set of reticulated measures that allow the appropriate TPPs (the actual measurements of physical variables) to be measured and their values integrated into the result that each loaf is acceptable, having met all requirements that are extracted as CI. If the integrated measure for a loaf is not acceptable, then the out-of-limit measurements will show where action is needed for correction.

A measures tree can be set up for a measuring system engineering development project. As the development progresses, the respective measures are monitored and used, with the best estimates of the time, to yield the overall value of merit for progress of the project.

This methodology can become very complex in large systems developments for the following reasons:

- CIs can exceed the 100 to 1000s;
- reticulation needs time to decide good breakdown sets of variables;
- measurements cannot always be made in a timely manner;
- uncertainty of measurements is variable;
- nature of measure, such as statistical distribution, are different, making combination problematic;
- measures are often taken from similar prior tests and need careful application;
- required measurements cannot be made because of a reduced budget, too little time, lack of test object, or lack of a test facility;

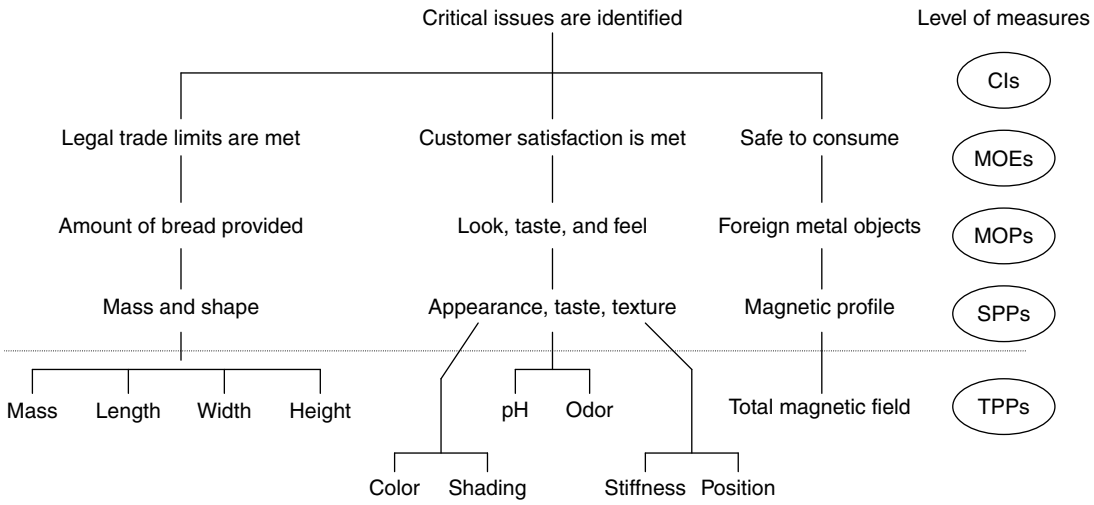

Figure 3. Development of a measuring system for loaves of bread from an automatic bakery.

- prior history, inherited data, and poorly defined processes are forced into the program.

For these reasons, many large programs do not get well-organized measures, with subsequent lack of confidence and timeliness in delivery.

Small programs need to tailor the measures tree concept to suit their budget. An example is Pratt (2004).

1 COST ISSUES

Measurements are made using physically existing equipment. The instruments must be created from the basic materials and applied using the labor of people. Material and labor resources have never been unlimited or freely available to a measurement user. Priorities must be decided in situations appearing to need measurement equipment.

A measuring instrument does not stand alone as far as its costs are concerned. The cost of measurement should not be assessed by looking only at the purchase or manufacturing cost of the apparatus used. Here, attention is drawn to the real cost of the individual measurement, for too little attention is often given to this aspect of measuring instruments.

To provide a balanced economic statement, it is necessary to consider the worth of a measurement in terms of the cost-to-benefit ratio for making the measurement.

The cost of measurements and their worth has not been a subject that many writers have felt they wanted to openly address. In general, measurement is seen as a low value item (around 2–8%) in a much larger overall budget of a system and thus needs little attention. It is considered by many that making a measurement is straightforward and simple to set up using available systems off the shop shelf.

Costs to produce and sell a measuring system are, however, very much the concern of the manufacturer who needs to set a realistic selling price, and to a nation, for it is a significant factor in a national economy due to the high gearing effect of good measurement practice.

This account begins first by looking at the cost of the apparatus, broadening outward through the cost of making a measurement, and then to the cost of measurement to a nation.

2 THE COST OF AN INSTRUMENT

The cost of finally making a measurement is formed from several subcomponent costs:

- C_i – cost to investigate the measurement need by the customer
- C_m – cost to research need, design, manufacture and market the measurement system hardware and software
- C_s – cost to set up the measurement in its application ready for use
- C_m – cost of maintenance and spares holdings
- C_a – cost to apply the measurement.

Costs to decide what is needed and to locate and purchase the instrument system C_i are often absorbed into other

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

project budget lines and thus can be transparent. They, however, can be considerable. Paradoxically, the less expensive the system needed, the higher the relative costs can be for locating a suitable unit; sellers will often assist with this cost where the price tag is large.

The cost C_m of designing and making the instrument system is built up from many parts, such as researching the need, design development, embellishment, paper work about specifications, use and service, packing, delivery, and many more contingencies. Figure 1 depicts the factors involved in costing the making of an instrument. Manufacturers well understand the issues and costs involved.

In classical antiquity, many of these cost factors did not arise. How to use the instrument was usually self-evident. Rarely were more than one of exactly the same model made; often the maker was the user, so he or she did not need to be concerned with records and sales. As the instruments were made by craft artisans, they usually had more decorative embellishment than was needed to be adequately functional.

The time taken to make a piece of measuring equipment has changed over time. It was not uncommon for instrument makers up to the seventeenth century to spend not months but years on manufacture. Harrison produced his four prize-winning chronometers of the eighteenth century as the result of devoting most of his life to the task. Originally, instrument making was more akin to the production of fine arts products of today than to the fierce open competition of an industrial market.

The introduction of production manufacturing methods changed this situation greatly. Markets widened, production run numbers rose, and cheaper means of producing the desired performance were realized.

The measuring instrument manufacturing market game has the feature that its players seem to be doing their best to work themselves out of a job! As soon as a significant new principle or technique is discovered that could cause major sales, the manufacturers move to produce it for sale first at a relatively high price. Demand grows with reduced price, so means are sought to stimulate demand, leading to larger production runs sizes. This tactic, if successful, drops the price, which saturates the market; the manufacturer must again look for another product.

Some makers will make adequate profits in this cycle and will return again to play another round. Many, however, do not get their timing and marketing methods right. They end up with an abundance of out-of-date products that cannot be sold at even the cost-to-produce price. Companies can go to the wall if this happens too often. Many an instrument firm has poured funds into developing a certain class of

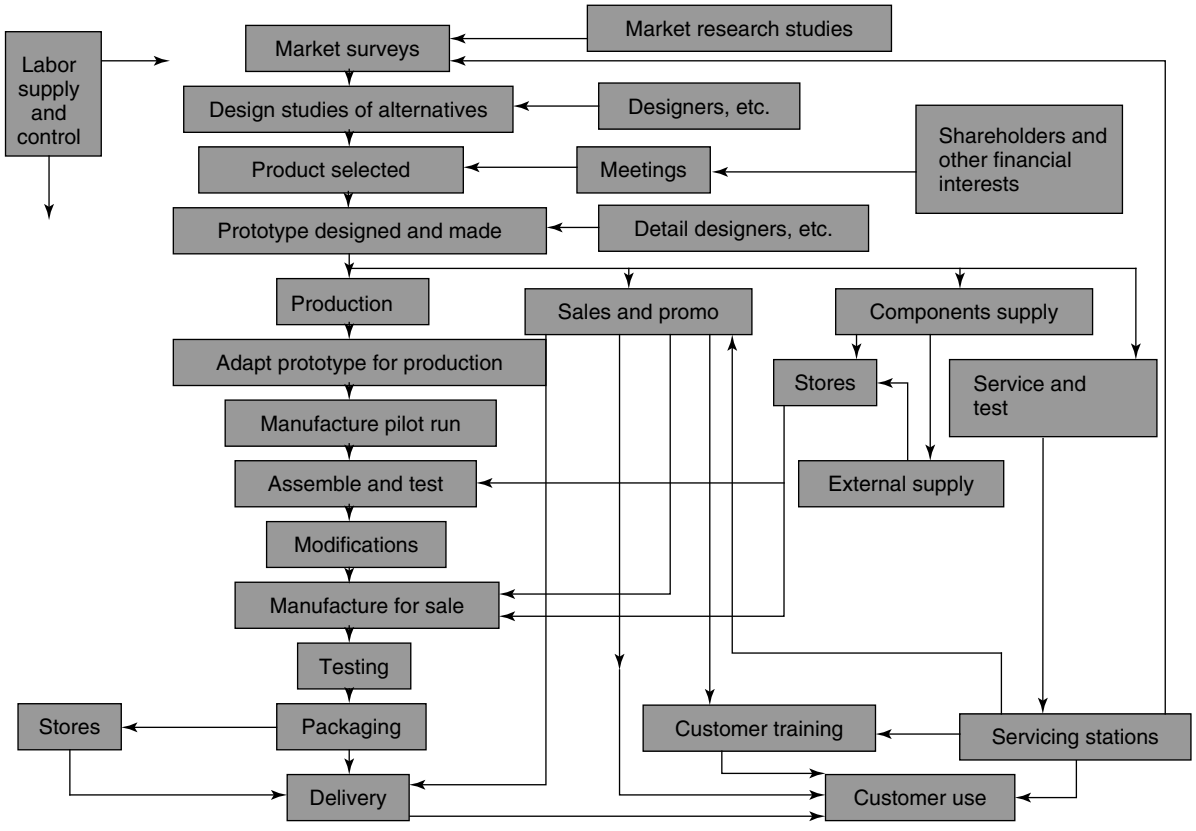

Figure 1. Factors involved in costing the manufacture of an instrument.

instrument only to have other makers systems sell better than theirs.

The instrument market has the following specific features:

- Production volume is small to medium, rarely large.
- Cycle time to develop is only a matter of months or so.
- Costs to produce have fallen dramatically as development by the whole group of this industry increased.
- Useful life of the physical aspect of a product is comparatively long.
- Information Technology (IT) content changes rapidly but the basic principle remains reasonably static.
- Purchasers expect ultimate reliability for minimal cost.
- Applications are not well worked out.
- Users expect 'fit and forget' to apply despite the low price paid.
- Users expect spares to be available for decades.
- Companies making instruments and measuring systems change hands a great deal.

Furthermore, as the per-unit production cost is lowered to make the system more affordable, the reliability of the components, and thus that of the system, are often sacrificed.

Another feature that the instrument maker has to contend with is that systems designers consider it reasonable and normal to call up specials when specifying the measuring apparatus required. One-offs are product lines that the firms must produce to maintain customer faith yet they often cost far more than the customer thinks should be paid. People have become used to the idea that their electric toaster works as the designers suggest it should, yet they would not always agree to make the same degree of compromise in using the instrument makers suggestions of what are reasonable basic units to work with.

Just as the knowledge about measuring systems has to be restructured for future, more efficient use, so must the range and number of marketed instrument variations be restructured.

It is generally acknowledged and understood that the cost of the instrument itself can be assessed from a long list of the production component costs, as shown in Figure 1. Management must budget for a manufacturing price to decide sales potential and profit margins. The same, however, cannot be said of users when they assess the cost of a measurement to their organization or enterprise. The truth is rather startling: the real cost of a measuring instrument is usually many times the purchase price of the apparatus.

3 ANALYZING THE COST OF MAKING A MEASUREMENT

Assessment of the real cost of a measuring instrument should be on the basis of considering what costs would have been avoided, or incurred through lost benefit, if it had never been considered – the economists call this the 'opportunity cost'. Figure 2 shows the total costs that comprise the cost of making a measurement.

To begin the costing process, it is necessary to first include the cost of the time spent in deciding what has to be measured (C_i). Too often this stage is seen as barely existing because the measurand, the parameter to be measured, appears obvious. It is the writer's experience that many users give too little emphasis to this very basic step, ending up measuring the wrong entities.

Having decided the variable(s) concerned, it is then necessary for the designer to devote time to generating sound specifications for the method selected. For example, assume the task has been defined as one of measuring the temperature of a product because that seems to indicate when it is ready to be transferred to another process – as in jam making. Is temperature really the best parameter to monitor? If so, what must be the precision, accuracy, absolute value, shape of sensor, and so on? To ascertain when jam is cooked sufficiently, it is better to measure the pH, and not the temperature! Making these requirement decisions incurs time and monetary costs.

Consider next that the specific instrument principle and the specifications have been chosen. The measurement task has still barely begun, for it is then necessary to locate trade information of available products so that a specific purchase can be organized. Tenders are called – or firms contacted – to obtain quotations, data sheets, delivery information, installation details, and so forth. At this juncture in costing of the real cost of a measurement, one must not forget to also include the time spent in preparing budget submissions and filing the records of this investigative work.

Eventually, the stage is reached where a purchasing decision can be made. That, too, takes up more time by skilled staff. It is unlikely that these above mentioned stages can be passed through in less than a minimum of a few hours of effort for even the simplest of measurements. Extensive measurement systems take months, sometimes many-years, of work to reach this stage.

The instrument system has then been selected and the order placed for supply; the cost of the ordering procedure should be included. Delivery is then awaited. If all proceeds perfectly, the instrument arrives on time without the need to make enquiries about late delivery. More often than not it is necessary to chase delivery, adding more cost.

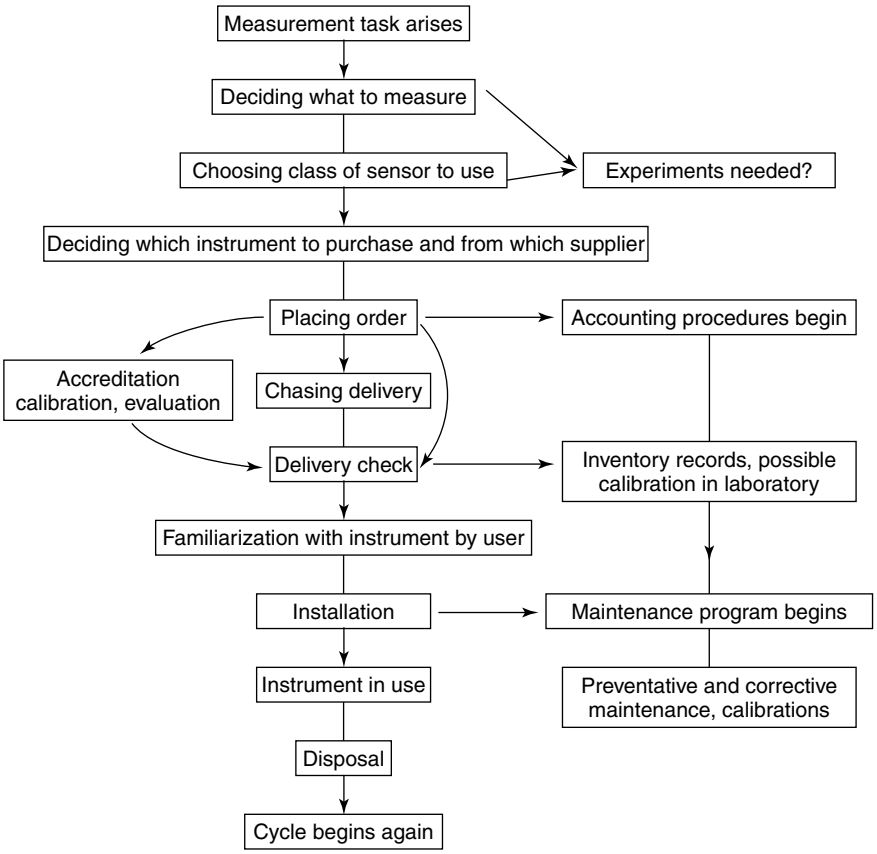

Figure 2. The cost of a measurement far exceeds the purchase price of the instrument.

Upon receipt of the system, the wise purchaser will carry out an immediate overview delivery check to ascertain that it is undamaged, is generally within specifications, contains the necessary documentation (which might be yet another cost to consider), and that it will suit the purpose intended. Soon after that a more extensive test is needed; if performed properly, this can take many hours and will need the use of expensive test equipment, therein also placing a cost into the overall account.

If things are found to be wrong at delivery time, additional effort will have to be devoted to getting it corrected through the purchase agreement or perhaps, which is often quicker and perhaps cheaper, having it repaired in-house.

In parallel with this acceptance stage is the need for the user to become familiar with the instrument operation. It may need attendance by staff at a training course, or be simply a case of reading the operating instructions. Whichever it is, still more time must go onto the costing sheet. The resources expended on this should not be underestimated, for a complex piece of measuring equipment may require the user to spend much unproductive time learning to apply it. Errors in its use in the early stages will also give rise to costs that have to be met somewhere.

Installation is then needed. This requires the organization of varied skills. It may necessitate inventory records to be created along with an instrument dossier and a spare parts reserve to be set up. Plant drawings usually need to be updated with instructions written and issued to operators.

Costs of the measurement continue to mount. To ensure that the instrument is performing properly, it will be necessary for it to have a service program, a calibration program, and a maintenance program in operation, as well as a possible method of monitoring the measuring system if its role is in a key area. To remove an instrument, take it to a calibration laboratory, carry out a calibration, and return it to duty will take a minimum of another two or three hours of work, but it can even take many days!

Too often the decision is made to purchase the instrument offered at the lowest price. This is oversimplifying the purchase decision; the fact remains that most instruments will need some unpredictable service during their useful life. The cost of this kind of service is high, for it usually occurs when labor repair costs are at their highest penalty rate. Furthermore, the emergency technician may not be familiar with the system and has to learn at the owner's expense.

Eventually, the measuring system has provided a useful and satisfactory life; its costs to the user go on. At some

stage, effort has to be expended to establish a replacement schedule and the choice of its replacement, and these can be complex issues. The model of instrument used originally will often have been superseded by something that may not be quite the same in some aspects that are critical to the application; it may not be possible to get a replacement at all.

Finally, the last of the costs associated with the measuring system parts is its disposal. It may be possible to recoup some of the aforementioned costs through sale of the instrument, but the opportunity cost of a well used, now superseded instrument is more likely to be a debit, not a credit. This cost often does not arise until years after installation, for most large complexes tend to store old instruments for many years before they are finally discarded, finding their way into a museum collection or being dismantled for use as pieces of some other plant.

4 CALCULATING THE COST OF MEASUREMENT

Any genuine attempt to estimate the cost of a measurement must include all of the above factors. The overall cost issue to be studied is one of establishing what resources were tied up by the existence of the measuring system that might have been used elsewhere if it had not been considered. A detailed costing on the above-given basis can lead to a satisfactorily quantitative assessment of which measuring system to purchase and in which way to use it to make the measurement needed.

All of the above costs are concerned only with the choice, purchase, installation, and maintenance of the correct measuring system. The cost of the whole measurement can continue to rise if the right decisions have not been made.

Much of measurement conducted is, unfortunately, not entirely productive. A wrong measurement has often been the cause of disastrous losses to the enterprise. A serious malfunction in the commissioning stage of a new ship can cost the builder thousands of dollars per hour. Incorrect operation of a weapon of war has a cost that goes without saying.

5 BALANCING THE COST-BENEFIT FACTORS

The total of all of the above costs has to be weighed against the benefits of making the measurement when it is expressed in monetary terms. Whereas it is reasonably clear and straightforward to obtain the cost of making the measurement, it is not so clear how to assess the value of the benefits of making it.

This can be done by conducting a risk analysis, for example along the lines of developing a safety case – *see* **Article 99, Safety Organization, Volume 2**; **Article 100, Safety Analysis Methods, Volume 2**; and **Article 101, Assessing and Demonstrating Safety, Volume 2**. Some simple examples should assist one to understand what can be at stake.

A large blower was used to aerate sludge in a mineral separation process. The 100-kW blower had a temperature sensor installed to shut it down when its internal lobes overheated, for that could cause it to seize and burn out the motor. The cost of the blower unit was around $200 000 installed, and the inexpensive and somewhat crude temperature sensor used was a mere $200. As might reasonably be expected, the blower was eventually seriously damaged when it overheated at a time when the sensor had not operated properly. Lost production and repairs cost as much as a new blower unit. In this case, the outlay of a mere 0.1% of the purchase value on protection seems to be too low. Lost benefit can be expected to be one of the higher costs.

A second example is found in the factory of a permanent magnet manufacturer who had taken over an old plant. These magnets are cast from a molten NiCo alloy that melts at a temperature higher than that of steel. The actual pouring temperature and subsequent annealing process are crucial to the final field strength of the magnet.

The whole manufacturing process, with its casting, several annealing and curing steps, takes some 10 days before it is learned from tests how well the magnets will perform. Along with the process, several measurements are made of critical parameters. At the end of the process there existed a final inspection station used to test and certify the quality of each magnet.

First, the process relied on a very old uncalibrated infrared radiometer and a set of record cards that had been inherited, giving the different temperatures needed (as indicated by that radiometer) for the various shapes of magnet cast. As no independent calibration of the radiometer existed, if it should fail, it would be virtually impossible to decide what temperatures to use in future.

Next, the final inspection area that was set up inside the dirty foundry area was a dark mess. The force measuring system for the magnet test was red with rust and its measuring instrument dials were hardly readable. This was the station audited by the customer! It was rejected, as it was not a suitable testing process for them to accept; they then did their own tests with a higher rejection ratio.

The manufacturer decided he was unable to make the investment in improvements and eventually was forced to close down.

A third example situation was that of a temperature controller installed in a greenhouse used for plant research in a

university. After 5 years of apparently stable temperatures in the greenhouse, the thermocouple controller system was overhauled.

It was found that the thermocouple circuitry was not in the control regime expected, owing to an incorrect change to the circuit card to hopefully reduce the indication span. This had reset the recorder's chart zero point to where it was expected to be, but in doing so the changes had increased the chart span to 400 °C, full scale, instead of 40 °C. It seemed to behave as expected but it was then seen to be recording the temperature of the control room, not that of the greenhouse. The cost of this incorrect measurement would be hard to assess but it is clear that the research findings for the previous 5 years were subject to much uncertainty.

The benefits of a measurement need to be carefully investigated using an objective standpoint and methodology that leads to monetary values. These can then be weighed against the monetary cost to make the measurements.

6 THE NATIONAL MEASUREMENT SYSTEM MATRIX APPROACH

The cost of measurement also can be of importance at the whole country level; measurement has been identified as an important factor in a national economy. This discussion now considers the cost to a nation of making measurements.

Studies of the cost of national measurements were given in-depth consideration in the 1970s. Prior to that, costing was certainly performed on the annual budgets of such institutions as the national measurement laboratories and similar identifiable groups, but little attempt was made to go beyond this small section of the total national cost devoted to measurement.

The term *National Measurement System* (NMS) came to the fore when the then National Bureau of Standards (NBS), USA, (now the National Institute of Science and Technology (NIST)) conducted a major nation-wide study of the value of the United States' NMS.

Development of their study can be followed in the National Conference of Calibration Laboratories (NCSL) Newsletters from 1972, through to 1978. Minck (1977) defined the NMS as 'consisting of all national activities and mechanisms that provide physical measurement data to allow the creation of the objective, quantitative knowledge required by our society'.

Previously, Huntoon (1967) had developed the concept of the NMS in a paper. The NBS study reached the final report stage in 1975 after 151 separate studies had been made. The report contained 27 documents. Two key readings are NBSIR 75–925 'Final summary report study of the National Measurement System, 1972–1975' and NBSIR 75–949 'Structure and function of the National measurement system'.

The report included a major impact matrix (Figure 3), showing the measurement relationships existing for 25 groups of societal needs. It graphically portrays the dynamics and the degree of such interactions and, in doing so, well illustrates the great complexity and widespread use of measurements in our modern lifestyle.

This NBS study was catalytic; many countries now maintain NMS activities. Owing to the importance of the NMS to national economic welfare, they are now usually cared for by departments of trade or industry.

Information in the UK system is found on DTI (2003). The Australian one is explained in NSC (2003). Taiwan's is discussed in NML Taiwan (2003). Others are to be found from a web search.

Interestingly, the organization that began the NMS movement, NIST, does not list any NMS activity, as such, on its current information service, NIST (2003).

7 GUIDANCE TO MANAGEMENT ON THE COST-BENEFIT OF MEASUREMENT

Very little has been done to find and develop means by which management can be guided in budget decisions concerned with the use of new, or existing, measuring equipment. Easy to reveal are the simple benefits of money saved by implementing a better-controlled process, or by labor costs saved by the use of a more advanced measuring technique. More difficult to quantify in an adequate manner, but often equally as important, are such factors as

- general improvement of the standard of a product resulting in increased sales;
- increased reliability of a product;
- less wastage in manufacture;
- potential to produce a product that was otherwise impossible to make;
- improved performance of the product;
- improved working relationships between those groups of a nation that impact together in an area of measurement; and
- increased confidence by others in a nation's products, with subsequently improved exports.

At present, measurers are not yet able to measure the worth of measurements to the same degree as they can assess the cost of measurement. Perhaps this is the reason many measurement budget decisions generally do not allocate finance to measuring equipment in proportion to

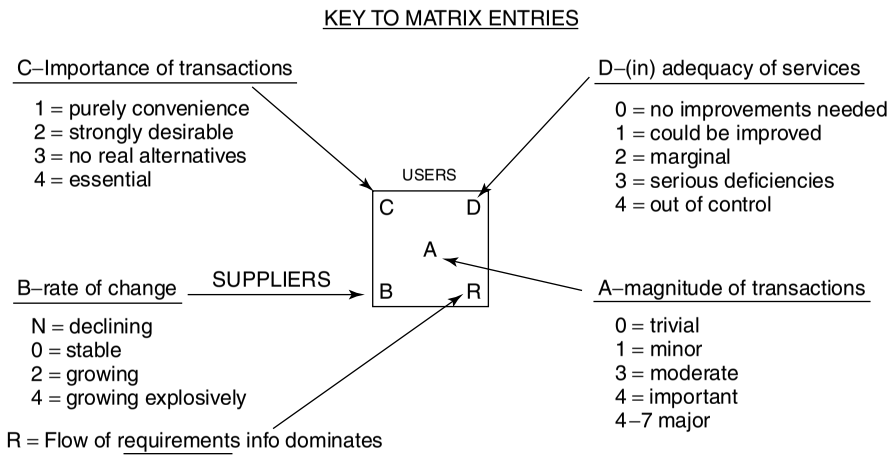

Figure 3. (*Continued*).

the money expended on the whole system. Comparatively little money goes into calibration, education and research of the basic fundamentals of measurement using scientific principles and its technology. 'Fit and forget' measurement technology might be the desire of management but, as with all uses of technology, it is not a reality. Measuring instruments are no exception and they are certainly not perfect.

Throughout history, there have been occasions when the governing power of nations have considered that certain measurements or measuring instruments would be of great benefit to the nation.

In 1598, the Spanish monarch, Philip III, offered a large sum of money to any person who could produce a timekeeper that would reduce navigational inaccuracies across the Atlantic Ocean regions. In England, Harrison was awarded £20 000 from the British Government who had offered this huge reward, in 1714, for a similar reason.

On another occasion, James Cook took the voyage to southern regions of the globe to measure the transit of the planet Venus in June 1769. This too was concerned with improving navigational accuracy. Here, it was the Royal Society of London that induced the King and the Admiralty to expend a considerable sum of money conducting this one measurement.

In summary, it is relatively easy to make a case for spending money on measurement for clear-cut scientific, knowledge-seeking reasons. The long-term less quantifiable benefits, however, are often seen in their historical perspective as being more significant than the originally argued case; these are the benefits that management would like to be able to cost in money terms.

1 GENERAL REMARKS ON HUMANS, MACHINES, AND INTERFACES

From the earliest times, humankind has attempted to control its environment. This compulsion has required the extension of the human abilities to sense the environment and so to perform useful work upon its materials and substances. Human-made implements and artifacts are the means by which these faculties are extended. A generic name, which includes all of these items, is embodied in the concept of *machines*. There are two main kinds of machines. The first, which extends the human ability to do useful work, may be referred to as *energy handling* or *energy transforming machines*. A second group of machines to extend human sensing, given much emphasis by the present revolution is *information handling*, constituting what may be called *information transforming machines*. Information handling machines may also be referred to as *information machines* in short or also as *technical instrumentation*.

2 THE OVERALL HUMAN, MACHINE, AND ENVIRONMENT MODEL

The important interfaces between humans, machines, and their environment are illustrated in Figure 1 (McGhee *et al*., 1996, 1998). The human biosystem is a complex combination of muscles and senses. Muscular activity is associated with effort and effort with work. The practical limitations on the ability of human muscle power to work have led to the extension of almost all humans working in complex industrial societies using machines that amplify the human ability to gain mechanical advantage. Simple examples of this are the spades, pickaxes, and spanners used in such diverse activities as cultivation, road repair, and motor mechanics. More sophisticated examples used in the same activities, which allow orders of magnitude increase in the mechanical advantage, are tractors, mechanical diggers, and pneumatic spanners. The impact that these *energy handling* machines have had upon human activity is mirrored in those machines allowing extension of the human abilities of sensing and perception. For example, although humans can sense hotness relations through the tactile and visual senses, they require extension when the objects under observation are either very hot or very cold. Thus, the need arose for inanimate implements to extend this human sensing ability. So it is with the other human senses as well.

Because of the inextricable link between humans and their environment, and between humans and machines, the ordering of these interfaces helps to explain the links given in Figure 1. Firstly, there is always a direct link between

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

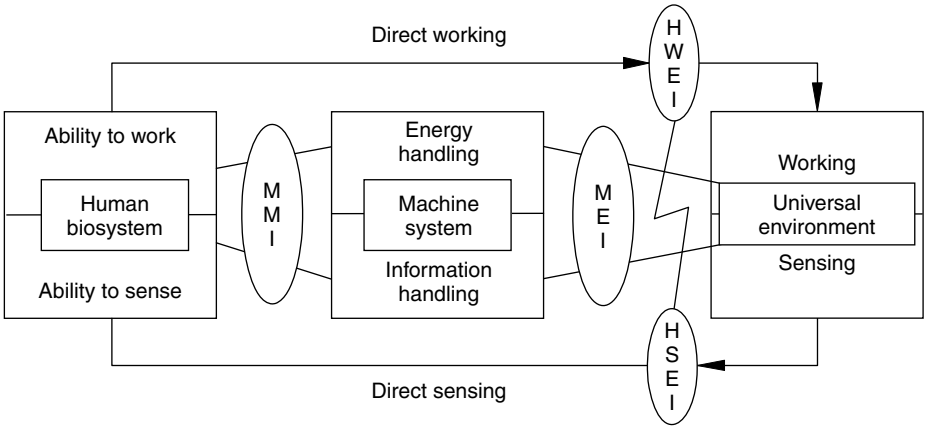

Figure 1. Interfaces between humans, machines, and the universal environment.

humans and the universal environment. This interface has two component parts. One of these, which may be called the *human-working environment interface*, or (HWEI), explains the activities undertaken by humans in performing useful work as part of the process of providing sufficient resources for survival. Related to this, to a greater or lesser extent, is an interface called the *human-sensing environment interface*, or HSEI. This embodies the interacting link between the human senses, which interface with the universal environment for the purposes of gathering information. From the beginning of the machine era to the present day and beyond, an interface has existed between humans and machines. Known as the *human–machine interface*, or MMI, it provides the basis for humans to use machines to extend their abilities to perform useful work by acquiring some form of mechanical advantage, as well as supplementing the human abilities of sensing and perception. The third interface, allowing machines to interact with the universal environment, is called the *machine environment interface*, or MEI.

These interfaces between humans, machines, and their environment give a clear picture of the primary links between them. It also indicates that instruments should be studied, analyzed, and designed on the basis of how humans interact with them and how they interact with the environment within which they extend the human abilities to handle information.

3 HUMANS AND TECHNICAL INSTRUMENTS – AN EVALUATION AND COMPARISON

It is instructive to compare the human sensing system with human-made technical sensors. This comparison is summarized in Figures 2 and 3 (McGhee, Henderson and Sydenham, 1999), which are freely adapted from Hofmann (1982). The five human senses of seeing, hearing, tasting, smelling, and feeling, which involve some 122 million sensing receptors, can be classified by the energy form of the observed variable using the COMETMAN acronym. The origin of this acronym and the classification of energy are given in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. From the information processing point of view, humans can process information at a rate of around 100 bps with an unconscious information transfer rate of around 1 Gbps from some 4 million nerve strings linked through the human nervous system to the cortex or brain stem.

Figure 2 shows that a biological sensing system is characterized by

- an abundance of sensors also called *receptors*,
- a very large number of message channels,
- a parallel processing capacity,
- a complex interacting structure with fusion of sensors,
- an ability to learn and adapt.

In the case of technical sensor systems, it is their clear function to extend and enhance the human senses. Although they execute this intention in most cases, Figure 3 shows that they are nevertheless characterized by

- a limited range of basic sensors,
- a small number of message channels,
- a series processing of information,
- a transparent physical structure, which is neither complex nor interacting, nor is there extensive fusion of sensors,
- an as yet underdeveloped ability to learn and adapt.

It is fair to say that the advent of large-scale integration of both analog and digital processing circuits, accompanied by the use of microprocessors with large memory capacity,

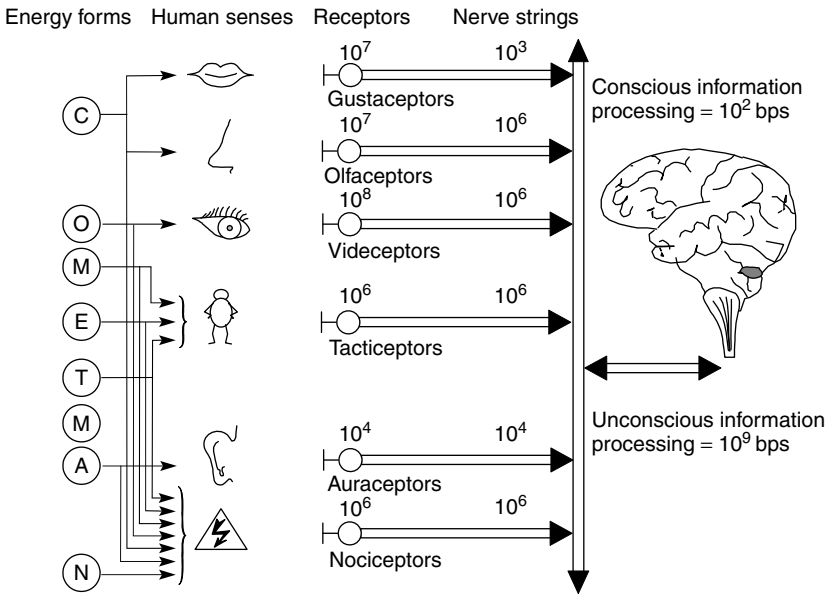

Figure 2. The human biological sensing system including sight, hearing, tasting, smelling, touching, and pain.

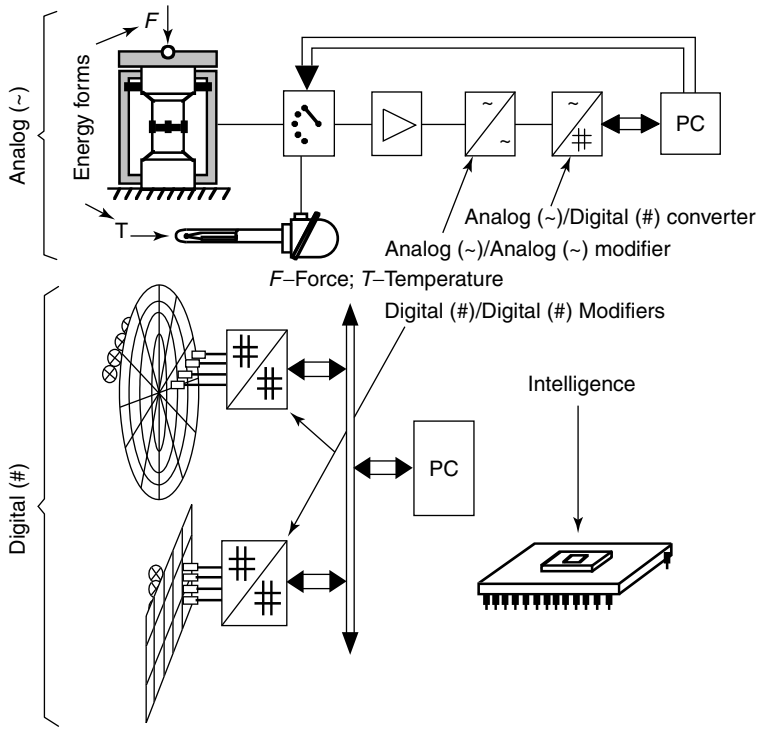

Figure 3. Technical sensor systems.

has led to tremendous changes in *technical instrumentation*. Even so, there is broad scope for further development.

Figure 3 shows that almost all of the measuring system is actually handling data, even in the strictly analog parts of the instrument such as the sensor, where an information-bearing signal is converted into another signal in a different energy domain. Hence, measurement technology should perhaps be renamed as *data measurement* or DM. In contemporary measurement, because of the influence of computers, there is an inexorable trend toward the use of a minimum number of analog components. For this reason, it seems appropriate to view measurement technology as data measurement. Data measurement is to measurement as data communication is to communication.

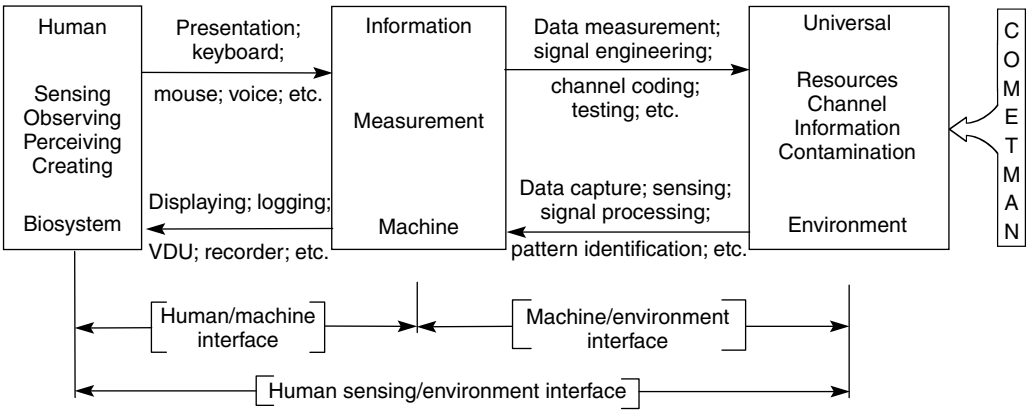

Figure 4. Block diagram of human and measurement information machine in a universal environment.

4 HUMAN AND INFORMATION MACHINE MODEL – THE CRUCIAL AND CENTRAL MEASUREMENT LINK

Information technology, or IT, has produced radical changes through the pervasive influence of the personal computer, or PC. Each increase in the system clock frequency and corresponding improvement in the information machine input/output, or I/O cards opens up endless measurement applications.

From the functional point of view, the relationship between the information machine aspects of Figure 1 are given in more detail in Figure 4 (McGhee, Henderson and Sydenham, 1999). The human faculties of sensing, observing, perceiving, and creating are visualized as being extended using a measuring information machine. Information flows from the human through the MMI, which consists of the PC keyboard, the human voice, the mouse, and so on. In the reverse direction, information is communicated to the human using various types of displays, Visual Display Units (VDUs) as well as data loggers and recorders. The measuring information machine enhances the human faculties by assisting in the generation of suitable coded interrogating signals for testing purposes. This process is one of the aspects of *data measurement*. Technical sensors, of the same general diversity as in Figure 3, enhance the human abilities to capture information associated with the flow of energy in the universal environment under observation.

5 THE TWO PROBLEMS OF MEASUREMENT

It is important to notice the distinction between the two main types of measurement in the above model of measurement. Measurement in technical science has two main purposes. The first purpose is to acquire data about the static or equilibrium properties of real objects or events. The second is to acquire data about the dynamic behavior of these real objects or events. These may be referred to as *direct* and *inferential* measurement respectively (Finkelstein, 1994; McGhee, Henderson and Sydenham, 1999). They may be referred to as the two problems in measurement. Both require the use of sensors to measure the states of equilibrium and motion of solids, liquids, gases, and the systems they constitute. A primary goal in both these measurement processes is to take account of errors, their sources, and their quantification (Solopchenko, 1994; McGhee, Henderson and Sydenham, 1999). The first measurement problem is to acquire data regarding the static or equilibrium properties of some real object or event. Acquiring data about the dynamic behavior of these objects or events is the second problem. Thus, real systems, objects, or components may be measured from two different points of view known as *direct measurement* and *inferential measurement*.

6 DIRECT AND INDIRECT MEASUREMENT

Direct measurement *per se* involves the process of directly *sensing* those active observable quantities characterizing the flow of energy and information (Finkelstein, 1994). Figure 3 (McGhee, Henderson and Sydenham, 1999) shows a typical structure for direct measurement using only two analog sensors and two digital sensors for simplicity. A load cell is used to measure an applied force F, while an electrical temperature sensor is used to measure a temperature, T. Optical methods for digitally measuring linear and angular positions are also shown. The instrumentation also includes a diagrammatic representation of multiplexing, amplification, and conversion under the control of a PC.

Indirect measurement uses directly measured quantities to compute the value of another, ostensibly nonmeasurable variable. The measuring instrument captures a signal carrying information about the flow of energy or matter associated with the system or event. Signal processing is used in both cases to extract the information.

7 INFERENTIAL MEASUREMENT

Figure 5 gives a block diagram of the inferential measurement problem. All systems may possess any one, or a combination of the characteristics associated with storage, transformation, transmission, or dissipation of energy. These system characteristics determine the dynamic behavior of the process whose dynamic properties can only be verified by measurement with the help of interrogative testing, also referred to as *inferential measurement* or *identification.* The dynamic characteristics of a system can be described by models. A model of a physical process is a representation of its style, form, or pattern. Hence, inferential measurement or identification consists of constructing a model of a dynamic system. Modeling is based upon input and output observations or measurements, as well as on prior knowledge. Dynamic models have significance in many engineering and nonengineering systems. Frequently, they play a vital role in the proper analysis and design necessary for the efficient operation of the modeled system. Models are used in physics, biology, astronomy, engineering, economics, sociology, psychology, medicine, ecology, agriculture, as well as others. A boundary view of the identification problem is given in **Article 68, Setting the System Boundaries, Volume 2**. Modeling and model building as an essential ingredient of sensor science is justified in **Article 107, Principles of Sensor Science, Volume 2**. Two-space, three-space, and tetrahedron modeling of sensors is described in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. Signal/Energy matrix modeling of sensors is considered in **Article 110, Signal/Energy Matrix Modeling, Volume 2**.

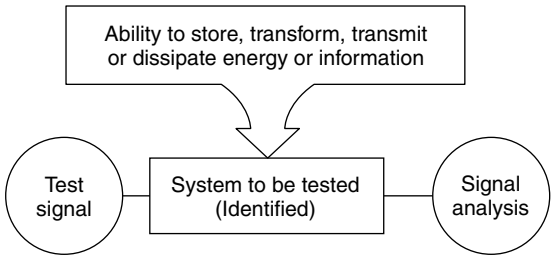

Figure 5. A block diagram illustrating inferential measurement.

Humans have a compelling urge to sense and test. Classifying and synthesizing signals is a very important activity in inferential measurement. In its engineering context, measurement can lead to improved design, since physical processes become better known. This knowledge also leads to more efficient energy utilization and product quality by allowing effective control.

1 BOUNDARY PERSPECTIVE OF HUMAN–MACHINE SYSTEMS

As defined in **Article 5, Humans in the Real World, Volume 1**, instruments are human-made systems. Between men and machines there is an ever-present relation, whose manifestation alone does not constitute a system. Systems are understood to have an opaqueness and obscurity of structure, characteristic of complexity. Although complexity is a necessary property, its possession is insufficient for an object to be classified as a system. The object must also have a purposeful function. Hence, a system is a purposefully directed labyrinth of complex operations. It will be seen later that a system also possesses recursive properties. Measurement occurs within the context of systems (**Article 5, Humans in the Real World, Volume 1**). An exemplary aspect of this systems approach is the totality of the considerations, which are taken into account. Thus, systems are examined on the basis of the bilateral influences and effects, which occur between them and the wider system within which they operate.

The primary functions of instruments inextricably link them with humans (**Article 5, Humans in the Real World, Volume 1**). A human–machine system is the context within which men and machines are united in the execution or pursuit of aims. Hence, human–machine systems provide an appropriate starting point for the introduction of instrumentation. These systems do not exist in isolation. The environment, within which they function, regards them as subsystems of itself, the wider system. Hence, the bilateral impacts of this linking must be considered. A boundary perspective of these systems, shown in Figure 1 (M'Pherson, 1980; McGhee, Henderson and Sankowski, 1986), allows a distinction between the three groups of inputs and outputs.

Inputs and outputs in human–machine systems may be grouped as *Resources*, *Information*, or *Contamination*.

2 RESOURCES

Manpower, Money, Machines, and Materials are often called the 4M's of systems. *Manpower* is remunerated by a *Money* resource, which is also used to purchase *Machines* and *Materials*. Actuators and tools (forms of *energy handlers or transformers*) are machines that supplement the human capacity to do work. Those that extend the human faculties of sensing and perception, belong to the general class of *information machines*. Raw materials support production at all stages and levels. The transformation of input resources into consumable output resources is an aim of human–machine systems. Electrical power is the most common form of resource for modern instrumentation.

3 INFORMATION

This could be considered as the most important in the measurement context. There are three main classes of

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

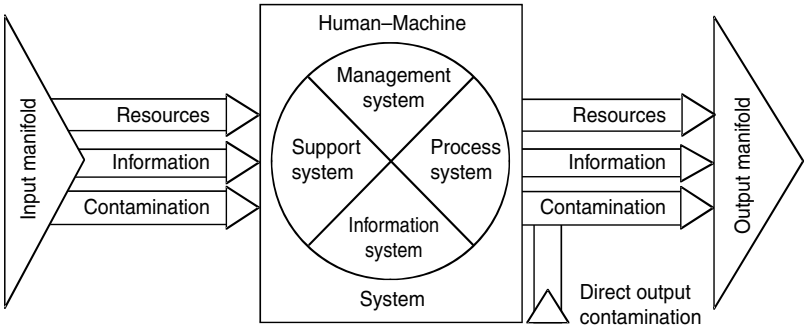

Figure 1. Boundary perspective of a human-machine system.

information. *Subjective information* is the most nebulous since it is embodied in those human perceptions resulting from intuitions, opinions, and feelings. As has been stated above, technical instruments extend the human faculties of sensing and perceiving and so enable humans to acquire *Objective information* about the physical universe.

The theories of Shannon and Weaver (1972), which permit the treatment of information handling processes with a higher level of abstraction, provide the means of quantifying objective information. In this theory, there are two coding theorems, which, although developed for communications instrumentation systems, are also important for the other instrumentation systems. One theorem states the important principles for an economical, coded representation of source data, that is, each source alphabet should contain the minimum number of alphabet symbols. Although this alphabet should be used as economically as possible in the formation of code words, the code words must still be uniquely and instantaneously decodable, thus ensuring no ambiguity. The other theorem refers to the coding of source coded signals for transmission through interference generating channels. A pretransmission coding of these signals should be such that their statistics optimally match the statistics of the communications instrumentation channel, so allowing high fidelity information transmission. Hence, two levels of coding are evident. The limits, beyond which it is impossible to advance, are usually referred to as *Fundamental Limits* in all physical processes (IEEE, 1981).

Fuzzy information, which was first formulated by Lotfi Zadeh (1984) in the 1960s, provides a means of quantifying the possible meanings for the same group of symbols. It may be concluded that fuzzy events should be treated as independent, 'fuzzy Shannon sources'. The average information of these 'fuzzy Shannon sources' has one component associated with the randomness of the two events in a binary alphabet. The other specifies the average information resulting from the fuzziness of the fuzzy set relative to its ordinary or binary set.

4 CONTAMINANTS OR INFLUENCE EFFECTS

Contamination is properly regarded as implying impurity and interference. Three types of contaminants (or influence effects) are (i) *disruptions*, which could have drastic or catastrophic effects due to natural disasters, for example, climate, (ii) *social factors* such as wars, strikes, or prohibitions and (iii) *failure of resources* due to impurities and effluents from various sources.

Bilateral Power Flows occur along the interconnections that link a human–machine system with its environment. Apart from feedstock-power flows, which are essential for correct operation of the system, other types of power flow can cause interference within the system resulting in poorer system performance. This type of contamination may be referred to as a *disturbance power flow*. In most situations, as mentioned above, a limitation, called a *fundamental limit*, exists. These are of interest in all systems. As they are of special interest in information theory, they are of interest in all information handling processes. If the information handling operation is measurement, then *fundamental measurement limits* exist due to the equipartition of energy, which is the most common source of *fundamental fluctuations*. McGhee, Henderson and Sankowski (1986) give a list of references.

Components that are used to build systems, are not immortal. The aging of the physical elements gives rise to a change in their material properties, which can affect performance. If burnout occurs, then this type of failure may cause a disruption. Parameters of the system, which are instrumental in determining the performance of the system, give the system '*parameter-sensitivity*'. *Sensitivity analysis* (Frank, 1978; Lojek, 1982) provides a means of assessing the effects of all impacts and parameters upon the performance of systems. In general, all of these sources of contamination must be considered in instrument systems. The boundary perspective of human–machine systems provides a basis for highlighting all effects impacting upon systems. Hence, it indicates the importance of a detailed

consideration of all causes and effects at the boundaries of any system (Sandquist, 1985).

5 THE INFORMATION/ENERGY TETRAHEDRON

It is also possible to visualize the range of possible information and energy forms for the groups of inputs discussed above. A way of providing this view is shown in Figure 2 (McGhee *et al*., 1996, 1998) using the COMETMAN acronym. This acronym is one of the ways of classifying energy types described in much fuller detail in **Article 109, Structure and Energy in Sensor Systems, Volume 2**.

A spatial representation for the boundary inputs and outputs of a human–machine system in its most general form requires a multidimensional space. As there is a total of three groups of inputs and three groups of outputs, the representation becomes too complex for graphical illustration. Each of the input and output groups may be specified as information bearing signals or energy flowing forms. Figure 1 greatly simplifies the possibilities by visualizing the output energy/signal form for an information machine, or more specifically a measurement system. In such a system, the main output is an information output, which also corresponds to the resource output. Although contamination is also produced at the output, it is not necessary to consider it for the present purposes.

Along the base plane of the spatial representation introduce a topological grouping consisting of three axes. Each of these axes is taken as representing one of the three input groups with their COMETMAN classification. This organization of inputs on the base plane may be regarded as *the input triangle*. Such a name is appropriate, as illustrated by the *input triangle* given by the dotted lines in Figure 2. Here the support energy form is electrical, the contamination energy/information is chemical, and the measurand energy form is mechanical using a sensor like a resistance strain gauge. The chemical contamination could be responsible for parasitic electrochemical potentials at the contacts in the electrical circuit. Each point on the *input triangle* axes may be joined to an energy/information form on the output axis. When the output is in the form of an information bearing electrical signal, the dash-dot line combinations shown in Figure 2 allow the link between all three input forms and the output form to be clearly seen. The geometrical shape, which is outlined by the dotted and the dash-dot lines, has one base plane surface and three inclined surfaces. This represents a tetrahedron or four-faced object. This way of representing the boundary impacts on systems may be called the *information/energy tetrahedron* when used in the context of systems. When used in the context of sensors it may be called the *sensor effect tetrahedron*.

Illustration of the manner in which the contamination inputs influence the output may be extended to cover contamination from other energy forms. The dot-dot-dash lines in Figure 2 show the case when the contaminating energy form is due to the influence of temperature on the wire of the strain gauge. The deep perception allowed by the *information/energy tetrahedron* given in Figure 2, which is

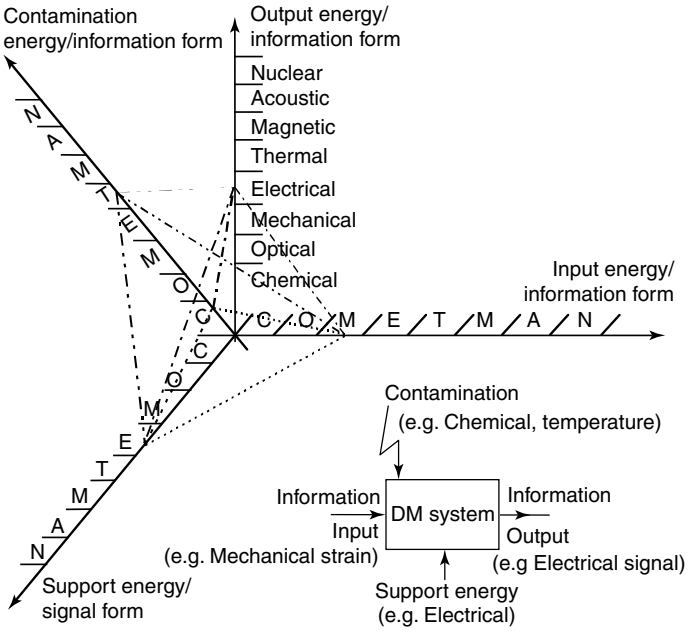

Figure 2. The information and energy tetrahedron.

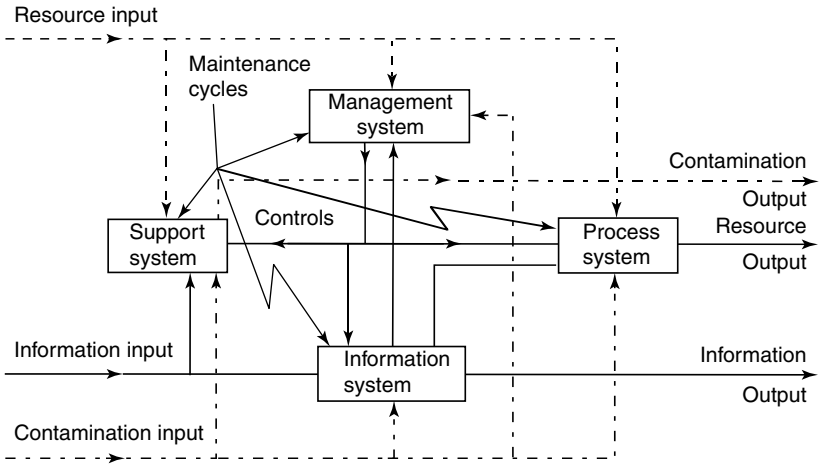

Figure 3. Interconnecting substructures in a human-machine system.

fairly straightforward, is still realistic and comprehensive. The use of the information/energy tetrahedron in sensor systems is given a fuller treatment in **Article 109, Structure and Energy in Sensor Systems, Volume 2**.

6 SUBSTRUCTURE OF HUMAN–MACHINE SYSTEMS

Human–machine systems may be divided into the four main subsystems that are indicated in Figure 2 and described by McGhee, Henderson and Sankowski (1986), M'Pherson (1980) and McGhee *et al*. (1996). The interconnection between these subsystems is shown in Figure 3. A *Process system*, which can produce a useful resource output, provides the means by which the aim of the human–machine system is realized. Controls and instructions, generated by a *Management system*, with the aid of an *Information system*, are required for the proper coordination and execution of all system functions at all levels. The *Information system* is responsible for acquiring and processing all of the information required to permit effective operation of the complete system, through the management system. Supplying feedstock and energy is the responsibility of a *Support system*, which also provides the human–machine system with its functional means of repair and survival. Survivability means that the system will continue to operate in a hostile environment and will complete its mission or operation. Survivability in the context of microprocessor based real-time operating systems is important. An ability for structural modification may be required. Reliability analysis provides a method of assessing the probability that a system will complete its mission successfully.

1 THE BASIC CONCEPTS

Measurement can be defined in the wide sense as a process of empirical, objective assignment of symbols to attributes of objects and events of the real world in such a way as to represent them, or to describe them.

Description, or representation, means that when a symbol, or measure, is assigned by measurement to the property of an object, and other symbols are assigned by the same process to other manifestations of the property, then the relations between the symbols or measures imply, and are implied, by empirical relations between the property manifestations.

Objective process in the definition of measurement means that the symbols assigned to a property manifestation by measurement must, within the limits of uncertainty, be independent of the observer.

An empirical process in the definition of measurement presented above means, first, that it must be the result of observation and not, for example, of a thought experiment. Further, the concept of the property measured must be based on empirically determinable relations and not, say, on convention.

This wide definition of measurement is often disputed by those who consider the paradigm of measurement in the physical sciences as normative, or, at least, they require measurement to be a numerical representation in which reflects an order.

For this reason, it is convenient to distinguish between strongly and weakly defined measurements. Strongly defined measurement is defined as a class of widely defined measurement, which follows the paradigm of the physical sciences. In particular, it has precisely defined empirical operations, representation by numbers, and well-formed theories for broad domains of knowledge.

Measurement that constitutes representation by symbols of properties of entities of the real world, based on an objective empirical process, but lacks some, or all, of the above distinctive characteristics of strong measurement, may be termed weakly defined (Finkelstein, 2003).

It remains to explain the terms *theory of measurement* and *philosophy of measurement* as used in this introduction.

Measurement theory is the study of the logical and epistemological basis of representation of property manifestations by symbols.

Measurement philosophy is the study of the basic concepts underlying measurement, embracing measurement, as defined above, and concerning the relation of measurement to language, reasoning, knowledge, and the like.

2 OUTLINE OF THE HISTORICAL DEVELOPMENT OF MEASUREMENT THEORY

The practical pursuit of measurement arose in the earliest stages of the material culture of man. However, it was based on an intuitive understanding of the process.

The ancient Greeks were the first to investigate the philosophical foundations of measurement. The schools of Pythagoras, Plato, and Aristotle were concerned with the nature of number, quantity, and their relation to the real world.

The Middle Ages saw much scholarly study of the theory of measurement, though scholars were not concerned with the application of measurement to observation of the physical world.

The rise of modern science, from Galileo, through Newton to Lagrange and Maxwell, put mathematics at the heart of physics, applied measurement to physical observation, and developed comprehensive mathematical theories of domains of physics. These developments were, however, not accompanied by analysis of the fundamental concepts of measurement.

Helmholtz (1887) laid the true foundations of the modern theory of measurement in a thorough logical analysis of the epistemology of counting and measuring. Hölder (1901) further developed this.

Campbell (1920) provided a lucid and thorough analysis of the fundamental basis of the measurement of physical quantities and his theory became generally accepted.

The classical theory of measurement from Helmholtz to Campbell was concerned with physical measurements. The theory was inapplicable to the social and psychological sciences. A report of a committee of the British Association for the Advancement of Science, published in 1940, which considered quantitative methods, rejected the possibility of psychological measurements.

These rigid positions of the classical theory of measurement were broken down by work in the social and psychological sciences. The concern of the social sciences with the concept of utility led to an axiomatic theory of utility that supported development of a new measurement theory. In psychology, Stevens (1951) carried out much fundamental work on developing an appropriate analysis of the nature of measurement.

The proceedings of a conference in the United States in 1959 (Churchman and Ratoosh (1959)) presented a review of the classical approaches to measurement as extended to needs of the social and behavioral sciences.

Modern formal measurement theory may be said to be based on the work by Tarski (1954) on relational systems and model theory, broadly describable as concerned with the representation by symbols of a formal language.

Suppes and Zinnes (1965) provided an early, clear exposition of the theory, in the development of which Suppes has been one of the key workers. The representational theory of measurement was then developed and well documented in a group of important books published between 1971 and 1990. The principal works are those of Pfanzagl (1968), a very detailed and thorough account of the representational foundations of measurement in three volumes by Krantz *et al*. (1971, 1990) and the important treatises of Roberts (1979) and of Narens (1985)

The representational theory has now been accepted widely in the social and behavioral sciences. However, while it embraces physical measurement, the theory has not found a recognized place in the theory and practice of physical sciences.

Modern measurement theory has been debated in the measurement and instrumentation technology community since the 1970s.

Representational measurement theory has not progressed significantly in recent years, as it seems to have proved adequate for the purposes for which it has been developed.

However, the rapid development of symbolic computation and soft computing has offered prospects for the further development and extension of general symbolic representation.

3 NATURE AND PROPERTIES OF MEASUREMENT

The properties of measurement arising from its definition as a process of empirical, objective, assignment of symbols to properties of objects or events of the real world in such a way as to describe them will now be analyzed and discussed. They are an explanation of the primacy of measurement in science.

Measurement provides an objective description of the measurand. It is thus invariant in rational discourse. The description is not merely a matter of opinion or feeling.

Measurement is based on a well-defined empirical process of observation. It is thus a basis of justified, true belief; in other words it is the basis of true knowledge.

Measurement is not naming. It provides descriptions of relations of the property manifestation measures to other manifestations of the same property. The value of a measurement process depends upon the richness of the relations it can represent.

Measures are descriptions of great conciseness. A single number tells us what it would take many words to express.

Measurement gives, further, a description that is precise, pinpointing by a single number a particular entity, where a verbal description indicates a range of similar but differing things.

Measurement is description by a well-defined symbolism. A measure of a property gives us an ability to express facts and conventions about it in a formal symbolic language. Without the convenient notation of such a language, the complex chains of induction and deduction by which we describe and explain the universe would be too cumbersome to express.

It follows from what has been said that description by symbols is not good in itself. The only value of measurement lies in the use to which the information is put. Science is not just the amassing of numerical data; it depends upon the way in which the data are interpreted, analyzed, and organized.

Finally, measurement describes measurands by symbols, which can be realized as signals. They can be acquired, processed, and effectuated by information machines.

1 PHILOSOPHICAL AND MATHEMATICAL BASIS OF THE FORMAL THEORY OF MEASUREMENT

The formal theory of measurement has its origins in the needs of psychology and decision sciences. However, its form has been influenced by developments in philosophy.

The approach of the theory is in its essence based on two philosophical movements: logical positivism and the philosophy of logic.

Logical positivism was an important philosophical movement initiated in the so-called Vienna Circle of philosophers in the early twenties of the twentieth century. It sought to base all knowledge on empirical observation and logical deductions from them. Central to it was the verification principle: the notion that the meaningfulness of statements lies in the specification of the empirical steps required to verify them. In that view, data obtained by empirical observation are foundational and knowledge is built bottom-up from them. Closely allied to it is the view of operationalism in the philosophy of science, which defines concepts in terms of precisely defined empirical operations. While those views have run their philosophical course by the sixties of the twentieth century, they remain influential in scientific thinking.

The other movement on which the formal theory of measurement is founded is the development of modern logic. From the work of Boole in the mid-nineteenth century, it developed mathematical formalisms, such as the notions of symbolic representation, sets, relations, mappings, and the like to represent valid reasoning. It culminated, with respect to measurement, in the work of Tarski (1954), on model theory, concerned with the representation of extralinguistic systems by symbolic systems.

The theory of measurement defines the concept of measurand quality as an empirical relational system based on empirically observed data and relations. It maps it into a symbol system based on the notions of sets and relations. It considers the representation of the quality system by the symbol system and its uniqueness. The foundation of the underlying concepts of measurement on empirical observation gives this theory of measurement a strong validity. The expression of the concepts and reasoning in the formalism of mathematical logic gives it its rigor.

The formal theory of measurement is presented here concisely. Detailed presentations are given in Krantz *et al*. (1971, 1990), Roberts (1979). A wider discussion is given in Finkelstein (2000).

2 THE CONCEPT OF QUALITY

Measurement presupposes something to be measured. Both in the historical development and logical structure of scientific knowledge, the formulation of a theoretical concept

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

or construct, which defines a quality, precedes the development of measurement procedures and scales.

The basic notion is that of a manifestation of a quality, an abstract, a single-sensed aspect of an object or event, such as, for example, the smell of a substance. Observation of the real world leads to the identification of empirical relations among these single manifestations. Examples of such relations are similarity and difference. As a result, the concept of a quality is formed as an objective rule for the classification of a collection of empirically observable aspects of objects into a single set, together with the family of objective empirical relations on that set. The resulting relational system is a quality, and each single member of the set is termed a manifestation of the quality.

We can thus see that there is a difficulty in the measurement of such qualities as beauty. The existence and meaningful use of the word beauty indicates the usefulness of the concept. However, there is not an objective rule for classifying some aspect of observable objects as manifestations of beauty. Similarly, there are no objective empirical relations such as indistinguishability or precedence, in respect to beauty. The basis for measurement of beauty is thus absent from the outset.

When there exists a clearly defined quality, as a set into which its manifestations can be objectively and empirically classified, together with a set of empirical relations, then we can always find some symbolical relational set by which it can be represented.

Consider some quality and let q_i represent an individual manifestation of the quality, so that we can define a set of all possible manifestations as

$$Q = \{q_1 \ldots\} \tag{1}$$

Let there be on Q a family R of empirical relations R_i

$$R = \{R_1, \ldots, R_n\} \tag{2}$$

Then, the quality is represented by an empirical relational system

$$Q = \langle Q, R \rangle \tag{3}$$

Finally, let us explain the concept of an empirical quantity. If there is an order relation in the quality relational system, enabling us to order quality manifestations in a way that has formal similarity to the relations equal, greater, and less, then the quality is termed a quantity.

In some cases, the concept of a quality arises from invariances in numerical laws arrived at by measurement. It will be considered in connection with indirect measurement.

It is usual that once a scale of measurement is established for a quality, the concept of the quality is altered to coincide with the scale of measurement. The danger is that the adoption in science of a well defined and restricted meaning for a quality like intelligence may deprive us of useful insight that the common natural language use of the word gives.

3 REPRESENTATION

Consider some quality represented by a relational system

$$Q = \langle Q, R \rangle$$

Consider a numerical relational system defined as follows. Let N represent a class of numbers

$$N = \{n_1 \ldots\} \tag{4}$$

Let there be on N a family P of relations

$$P = \{P_1, \ldots, P_n\} \tag{5}$$

Then,

$$N = \langle N, P \rangle \tag{6}$$

represents a numerical relational system.

Commonly, N is just the real number line.

The representation condition requires that measurement be the establishment of a correspondence between quality manifestations and numbers in such a way that the relations between the referent property manifestations imply and are implied by the relations between their images in the number set. Formally, measurement is defined as an objective empirical operation M

$$M: Q \longrightarrow N \tag{7}$$

so that

$$n_i = M(q_i) \tag{8}$$

such that $Q = \langle Q, R \rangle$ is mapped homomorphically into (onto) $N = \langle N, P \rangle$.

The above homomorphism is the representation condition.

Firstly, it implies that if q_i is related to q_j by an empirical relation R_k, that is $R_k(q_i, q_j)$, and P_k is the numerical relation corresponding to R_k, then $R_k(q_i, q_j)$ implies and is implied by $P_k(n_i, n_j)$.

Measurement is a homomorphism rather than an isomorphism because M is not one-to-one, it maps separate

but indistinguishable property manifestations to the same number.

$$S = \langle Q, N, \mathrm{M} \rangle \tag{9}$$

constitutes a scale of measurement for Q.
$n_j = M(q_j)$, the image of q_j in N under M is called the measure of q_j on scale S.

4 SOME DIRECT SCALES OF MEASUREMENT

An attempt will now be made to analyze some qualities as empirical relational systems and to explain the logical basis of deriving a scale of measurement for them. Extensive measurement is the basis of measurement in the strict sense and will be considered in detail.

The extensive scales of physical measurement are based on establishing for the quality Q of empirical objects, for which a scale is to be determined, an empirical ordering with respect to Q of the class Ω of all objects possessing elements of Q, together with an operation o of combining the objects, elements of, which has, with respect to Q, the formal properties of addition. Such scales are known as extensive.

The above will now be stated more formally.

The basis of a scale of measurement of Q is the definition of the set Q.

Secondly, there must be an operational procedure that establishes on the set of objects Ω possessing Q an empirical equivalence relation $\sim$ and a transitive empirical relation $\prec$ with respect to Q such that $\langle Q, \sim, \prec \rangle$ is an order system.

Finally, consider objects $\omega_1, \omega_2, \omega_3, \omega_4 \in \Omega$ exhibiting property manifestations $q_1, q_2, q_3, q_4 \in Q$.

For an extensive measurement scale, there must be an operation $\circ$ for combining ω_1 and ω_2 with respect to q_1 and q_2, which we shall denote by $q_1 \circ q_2$, with the same formal properties as addition.

For all $q \in Q$,

1. $q_1 \circ q_2 \in Q$
2. $q_1 \prec q_1 \circ q_2$
3. $q_1 \circ q_2 \sim q_2 \circ q_1$
4. $q_1 \circ (q_2 \circ q_3) \sim (q_1 \circ q_2) \circ q_3$
5. if $q_2 \sim q_3$, then $q_1 \circ q_2 \sim q_1 \circ q_3$
   if $q_3 \sim q_2$ then $q_1 \circ q_3 \sim q_1 \circ q_2$
6. if $q_1, q_2, q_3, \ldots$ bear to each other the relation $\sim$, and $q_1 \prec q_1'$, then there is a number n such that $q_1' \prec q_1 \circ q_2 \circ q_3 \ldots \circ q_n$

With these definitions, the empirical relation system $\langle Q, \sim, \prec, \circ \rangle$ has a structure with the same properties as the numerical relation system $\langle \mathrm{Re}, =, <, + \rangle$.

With an empirical ordering operation and an 'additive combination' thus established, one proceeds to the setting up of a scale. A single object with $s_1 \in Q$ is chosen as standard, assigned the number 1, and chosen as the unit of the scale. Another object with the equivalent property is then found and combined by additive combination to produce the standard 2. This is repeated to produce an extended series of integral standards. Fractional standards are generated by combining two equivalent standards, which when combined are equivalent to s_1, and assigning them the number 1/2, and so on. A property empirically observed to be equivalent to s_I is assigned the measure i.

Consider now a matching scale. Such a scale is based on the establishment on the set of quality manifestations Q of an empirical indifference relation $\sim$.

Given $\langle Q, \sim \rangle$, a set of differing elements $s_i \in Q$ are selected to form a standard set $S = \{s_1, s_2, \ldots, s_n\}$. Numbers (or other symbols) $n_i \in N$ are then assigned to each $s_i \in S$, the same number n_i not being assigned to two differing elements. The fundamental measurement operation M of the scale consists of an empirical operation in which measurands $q_i \in Q$ are compared with members of the standard set S. If $q_i \sim s_i$, then it is assigned the number n_i. An example of this form of scale is a color code in which the relation 'matches' constitutes the empirical indifference relation.

Consider now ranking scales. In such a scale, an empirical order system $\langle Q, \sim, \prec \rangle$ is established on Q. A set of differing standard objects having $s_i \in Q$ is then selected and arranged in an ordered standard series $S = \langle s_1, s_2, \ldots, s_n \rangle$ according to $\langle Q, \sim, \prec \rangle$. Numerals are assigned to each s_i say i, in such a way that the order of numerals corresponds to the order in S, of standards to which they are assigned. Any $q_i \in Q$ can then be compared with the elements of S in the same way as in nominal measurement. If q_i bears the relation $\sim$ to any $s_i \in S$, it is assigned the numeral i. If an entity is not equivalent to any $s_i \in S$, one can determine between which two standard elements it lies in the empirical order system.

The best example of a ranking scale of measurement is the Mohs scale of hardness of minerals in which each material successively only scratches those higher than it in the sequence.

5 UNIQUENESS: SCALE CLASSIFICATION AND MEANINGFULNESS

The requirement that the fundamental measurement procedure of a scale should map the empirical relational system Q homomorphically into the numerical relational system

N does not determine the mapping uniquely. There is an element of arbitrary choice in the setting up of scales of measurement. In the case of scales based on additive combination, for instance, the choice of the unit standard is arbitrary. In the case of a ranking scale of measurement, the actual numbers assigned to the standards are arbitrary subject only to the requirement that they should be in the required order.

The requirement of homomorphism thus defines a class of scales that may be called equivalent. The class of transformations that transform one member of a class of equivalent scales into another is called the class of admissible transformations. The conditions that admissible transformations must satisfy are known as the uniqueness conditions.

We can classify scales by the classes of transformations admissible for them. Let m be numbers representing measures on a scale and let m' be the corresponding numbers on the transformed scale: $m' = F(m)$. The generally accepted classification of scales is as follows:

If F() is any 1–1 substitution, the scale is nominal.
If F() is any monotonic increasing function, the scale is ordinal.
If $F() = am + b$, $a > 0$, the scale is interval.
If $F() = am$, $a > 0$, the scale is ratio.

The problem of the meaningfulness of statements made about a quality in terms of its measures is important. Such a statement is meaningful if its truth is unchanged by admissible transformations of the scales of measurement; in other words, if it reflects the empirical relational system on which the scale is based and not just the arbitrary conventions of the scale.

Thus, as a very simple example, it is meaningful to speak of the ratio of two masses, since that ratio is invariant with respect to changes of the unit of mass. It is not meaningful to speak of the ratio of two hardnesses measured on the Mohs scale, since that ratio would be changed by a monotonic increasing transformation of the scale.

Another view of meaningfulness that can be taken is that only such statements involving measures are meaningful, which can be logically traced to the empirical operations on which the measurement is formed.

6 UNCERTAINTY

The above discussion of measurement has been given in terms of deterministic relations and mappings. However, all empirical observations are accompanied by scatter and bias.

The basic empirical observation process is unable to establish exactly the required relations such as indifference and order, on which the scale of measurement is based. Thus, for example, the empirical indifference relation is assumed to be an equivalence relation, which is reflexive, symmetric, and transitive. In practice, there is a least detectable difference, which means that $a_1 \sim a_2$ does not exclude $a_1 \prec a_2$, or $a_1 \succ a_2$.

Thus, there is uncertainty in the empirical relational system on which the representational measurement is based.

The problem can be dealt with using the concept of probabilistic relational systems, or employing fuzzy logic representation.

1 MEASUREMENT AND OTHER FORMS OF SYMBOLIC REPRESENTATION

Measurement is only one form of representation of entities by symbols. It is closely related to other forms of symbolization.

The formal representational theory of measurement based on model theory, outlined here, can be extended to the more general case of representation by symbol systems (Finkelstein, 2000).

A symbol will be defined here as an object or event, which has a defined relation to some entity, for the purpose of eliciting a response appropriate to that entity in its absence.

Let Q be some set of entities and let R be some set of relations on Q constituting a relational system:

$$Q = \langle \mathrm{Q}, \times R \rangle \tag{1}$$

Note that Q may now be a set of any objects, events, abstract entities, and so on, and R need not be empirical.

Now, let Z be a set of objects or events to be used as symbols and let P be a set of relations defined or existing on Z to constitute a symbol relational system:

$$Z = \langle \mathrm{Z}P \rangle \tag{2}$$

With F a mapping from R onto P, and M a mapping from Q into (onto) Z, such that M and F map homomorphically into (onto) Z, then,

$$C = \langle Q, Z, \mathrm{M}, \mathrm{F} \rangle \tag{3}$$

Let $\mathrm{z_i} = \mathrm{M}(\mathrm{q_i})$ be the image of $\mathrm{q_i}$ in Z under M. Then $\mathrm{z_i}$ is termed the symbol of (or for) $\mathrm{q_i}$ under C, and $\mathrm{q_i}$ is termed a *referent* or meaning of $\mathrm{z_i}$ under C. C is termed the *symbolism* or *code*.

We may extend the concept of general symbolization to the concept of language.

A language L may be defined as a *subset of all finite strings*, that is, concatenations of elements of an alphabet or set of symbols, A. In the context of the symbolization C, the alphabet consists of the elements of Z and P, supplemented by function symbols.

A grammar, or syntax, G, is a set of rules, which, operating on the alphabet A, can generate all the strings of L. An alphabet and grammar constitute a compact description of a language.

All the considerations of the formal theory of measurement can be generalized to the symbolization of any relational systems by any general symbol system and descriptive language.

Formalisms such as symbolic logic and the like enable general symbolic descriptions to be effectively handled. The capability of computers to manipulate general symbols has made general symbolic representation technically important.

2 SPECIAL PROPERTIES OF MEASUREMENT AS A FORM OF SYMBOLIC REPRESENTATION

Measurement, widely defined, can then be viewed as a special form of general symbolic representation. It is, therefore, useful to review those properties of measurement that distinguish it from other forms of symbolic description. It is useful to note here again the distinction between strongly defined measurement that is based on representation in the language of mathematics and weakly defined measurement that may employ representation by more general symbolism.

Measurement is not mere naming, but provides information about the relation of a particular manifestation of a quality and other manifestations of the same quality.

Measurement is an objective description. The symbol assigned to an entity, given the representation relation, is independent of the observer, within the limits of uncertainty of the representation relation. The objectivity of measurement makes measures invariant and indisputable in logical discourse.

Measurement is an empirical process. This means first that it must be the result of observation and not, for example, of a thought experiment. Further, the concept of the property measured must be based on empirically determinable relations and not, say, on convention. The truth of descriptions based on measurement is thus empirically justifiable.

The utility of symbolic descriptors depends upon their conciseness and the compatibility with further processing. Strongly defined measurement yields measures that are numbers, and may be manipulated mathematically. Weakly defined measurement may yield measures that are more general symbols. Their utility depends upon their compatibility with further processing. While mathematical processing of data is particularly powerful, there are effective ways of processing other symbolic descriptions.

As stated above, measurement is not mere naming. It is the representation of a measurand relational system in the real world, by a symbolic relational system. The utility of measurement depends upon the richness of the measurand relational system and the power of the symbolic relational system. In strongly defined measurement, the measurand relational system is embedded, in general, in a well formed and complete theory of a domain. The symbolization in strongly defined measurement is in the language of mathematics, with powerful capabilities of manipulating the descriptions. In weakly defined measurements, the symbolization of the domain may not be complete. Further, the relations representable in the symbolization may be few, so that the measurement is not powerful. Thus, in nominal scales, it is only possible to represent the indistinguishability, or difference of two entities, and no other relations between them.

3 MEASUREMENT AND INFORMATION

If z_i is a symbol of or for q_i under C, then information about q_i given z_i can be denoted by $J(q_i|z_i)$, where

$$J(q_i|z_i) = \langle z_i, C \rangle \tag{4}$$

A measure provides information about the measurand.

In information theory, we consider an information transmission channel that transforms symbols x_i, elements of a symbol set X, acting as inputs into symbols y_i, elements of a symbol set Y, constituting outputs. The transformation is in general many to many.

The quantity of information I about an input x_k provided by the occurrence of an output y_i is given by

$$I(x_k; y_i) = \log \left[\frac{P(x_k/y_i)}{P(x_k)} \right] \tag{5}$$

where $P(\,)$ represents probability. The base of the logarithm defines the unit of the scale.

The definition of quantity of information given by information theory and the definition of information based on symbolic representation theory are consistent, and indeed similar. The information theoretic definition presupposes the concepts of representation by symbols. In both, information is knowledge about an entity provided by an image of the entity under a mapping. Information theory thus deals with a restricted class of problems.

Measurement is then an information process. Measuring instruments are information machines.

Information machines are machines or systems of machines that have as their function the acquisition, processing, outputting, and effectuation of information. They operate by transforming input symbols into output symbols by defined transformations.

The signals that carry information in measuring instruments may be viewed as sequences of symbols. Regarding digital data as a sequence of symbols is intuitively obvious. Analog signals are not so obvious. However, we may view a continuous analog signal $s(t)$ as a sequence of Dirac unit impulses. The elements of the sequence are then symbols.

With regard to symbol processing in information machines, we may regard the processing as a prescribed mapping

$$T: Z_i \longrightarrow Z_o$$

from an input symbol set Z_i (symbolism C_i) into or onto an output symbol set Z_o (symbolism C_o).

More generally, we may view the transformation as a prescribed mapping of sentence in an input language L_i into sentences in an output language L_o.

$$T: L_i \longrightarrow L_o$$

The treatment of measurement as an information process and of measuring instruments as information machines is the basis of systematic approaches to measurement and instrumentation science and technology.

4 MEASUREMENT AND KNOWLEDGE

The result of a measurement constitutes knowledge.

The classical view is that knowledge consists of a set of propositions that are true, that a subject believes to be true, and that the subject is justified in believing to be true. The main problem in this view of knowledge is the nature of the justification of the belief.

There are theories that provide a basis of justification. Two significant theories in the present context are based on causality and reliability. According to causal theories, knowledge consists of true belief that bears a true relation to the fact in question. According to reliability theories, knowledge requires that it be acquired by a reliable process or method.

A measurement result is a statement in the form

$$z_k = \langle z_l, S \rangle \tag{6}$$

where z_k is the symbolic designation of the measurand, z_l is the symbol assigned by or to the measurand by the measurement process, and S is the scale on which the measurement is carried out.

Knowledge obtained by measurement satisfies the conditions of valid knowledge, meeting the requirements of the theories discussed above. The fact that measurement is a precisely defined empirical and objective process ensures that it bears a true relation to the fact in question. These properties also make data that is based on measurement reliable.

We may distinguish between declarative and procedural knowledge.

Declarative knowledge is knowledge about 'that', and has been discussed above.

Procedural knowledge is knowledge about the 'how'. It is essentially expressed as transformational rules for declarative knowledge.

Knowledge based on measurement is essentially declarative knowledge. However, the implementation of the measurement process is based on procedural knowledge.

The application of knowledge takes, in general, the form of a problem solving or design process.

In such a process, the basic operations are an analysis of requirements, leading to a value model or objective function, possibly multidimensional. Following the generation of candidate solution concepts, which are commonly knowledge-based symbolic models, the candidates are analyzed in terms of the value model. On the basis of an analysis of the thus derived values of the solutions, one or more of the candidates are chosen by a decision process to be accepted for further development, or implementation.

The value model is based on a measurement-like process of assigning numbers to attributes. The value model is however subjective, reflecting the view of the decision-maker. It is not measurement.

1 DEVELOPMENT POINTS OF THE REPRESENTATIONAL THEORY OF MEASUREMENT

The formal representational theory of measurement is based on direct measurement; the representation of particular attribute manifestations on the basis of an objective empirical process that involves no theory either in the formation of the concept of the measurand quality, or in its representational process.

The formal representational theory accords with the philosophical perspectives of logical positivism and operationalism, which base all valid knowledge on empirical observations and logical deductions from them. While both these points of view have received much philosophical criticism, they remain an important basis for the approach of the sciences.

Representational theory provides a sound basis for the foundations of measurement in all its aspects. It nevertheless requires extensions to deal satisfactorily with a number of problems.

The first is the problem of indirect measurement. The exposition of the representational theory that is outlined here – *see* **Article 7, Introduction to Measurement Theory and Philosophy, Volume 1**; **Article 8, Formal Theory of Measurement, Volume 1**; and **Article 9, Nature and Properties of Measurement, Volume 1** – considers measurement scales formed by direct mapping from a quality relational system to a numerical relational system. Frequently, however, scales of measurement for qualities are constructed indirectly through a relation of the quality to be measured and other qualities, for which measurement scales have been defined.

The second problem is that of establishing measurement scales for domains of knowledge for which there are complete, well validated, and grounded theories. The basic representational theory does not rely on any theories concerning the measurand. However, the establishment of measurement scales in domains for which valid theories exist is generally based on the underlying theory.

Finally, we have the problem of qualities that have a number of components, or dimensions. The component qualities may be directly measurable in the sense considered above; however, the measurand quality may not. The formation of measures based on such multidimensional qualities is an important practical problem.

The three problems outlined above will be considered in terms of the representational theory.

A more extended discussion is provided in Finkelstein (2000) and the literature cited therein.

2 INDIRECT MEASUREMENT SCALES

In direct measurement, scales are formed by direct mapping from a quality relational system to a numerical relational system. Frequently, however, scales of measurement for

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

qualities are constructed indirectly through a relation of the quality to be measured and other qualities for which measurement scales have been defined. The reason is, generally, the impossibility of setting up a satisfactory measurement scale directly.

In its simplest form, consider a case in which every object that manifests the quality to be measured exhibits a set of other qualities that are measurable. Then, to each manifestation of the measurand quality, there corresponds a set of measures of the associated qualities. These associated or component measures can be arranged in an ordered array. If manifestations of the measurand quality have identical arrays of component measures, and if and only if they are indistinguishable, then the array of component measures characterizes the measurand.

If we can combine the various component measures or, in other words, map them into a single number so that numbers assigned to the quality manifestations by this process imply and are implied by empirical relations between the quality manifestations, then this sets up an indirect scale of measurement.

Consider as an example the scale of measurement of density of homogeneous bodies. Each such body possesses mass m and volume v (where m and v are assumed to be measures on already defined scales). It is an empirically established law that objects of the same material, and hence conceptually of the same density, have the same ratio (m/v). When different materials are ordered according to our concept of density, they are also ordered according to the respective ratio m/v. Hence, a scale of measurement of density is based on the ratio of mass to volume.

A few observations should be made here. The function m/v that maps measures of mass and volume into measures of density is not unique in its order preserving properties with respect to density. For instance, $(m/v)^2$ would be an equally valid derived measure of density. The form of m/v is chosen to result in the greatest simplicity of mathematical relations involving density. The properties of the function m/v are an idealization of real observations.

3 MEASUREMENT BASED ON THEORY

Consider then the establishment of concepts of quantities and of measurement scales in domains of knowledge of the world, for which there are complete, well validated, and grounded theories.

Physics is one such domain. It is the paradigm for the strong definition of measurement. It is proposed to consider measurement in domains for which there are good theories in terms of the processes of establishing measurement in physics.

The classical theory of measurement was developed to give an account of measurement in the physical sciences. In terms of this classical theory, measurement in the physical sciences is based on the establishment of direct extensive scales of measurement for a number of physical quantities as described here. These quantities are used as the base of a system. Scales for other physical quantities are obtained as derived scales, that is, indirect scales in terms of the base quantities, in the form of multiplicative monomial functions of the base quantities.

This theoretical view does not account for the way in which measurement units and scales for physical quantities are established. For example, the unit of length in the SI system is now defined in terms of the velocity of light in vacua defined as standard. The scale of temperature is defined in terms of thermodynamic theory. Thus, the paradigm of measurement that involves no theory either in the formation of the concept of the measurand quality, or in its representational process is inappropriate.

The situation of physics is that it consists of a number of axiomatized theories such as Euclidean geometry, classical mechanics, thermodynamics, electromagnetism, and so on. The scales of measurement of classical physics are based on the acceptance of these theories as representations of the real world and defining the units on that basis rather than on individual axiomatization and establishment of scales of particular physical quantities.

It is now proposed to outline this formally in terms of the processes and notation of formal representational theory.

It is proposed here to define the term theory in the formal terms of model theory. A theory T is then defined as a set of sentences of the language L. It may be possible to present T as an axiomatic system in which all sentences of the theory are clearly derived from a set of axioms that is considered to be true. A fully formalized axiomatic system consists of

1. primitive symbols, (Z), in the notation adopted above;
2. rules for the formation of well-formed expressions (G);
3. axioms;
4. rules of inference;
5. a code C establishing the definition of the symbols and the interpretation of symbols and sentences.

In the strongly defined measurement of physics, L is the language of mathematics. This establishes the rules for the formation of well-formed expressions and the rules of inference. The symbols Z are numbers.

Measurement scales establish a code C constituting the definition of the symbols and the interpretation of symbols and sentences.

4 SYMBOLIZATIONS THAT ARE NOT MEASUREMENT

The concepts of representational theory can be extended to assignments of numbers, or other symbols, to properties of objects in such a way as to describe them, but where the symbolic descriptions are not measurements.

One example is classification of industries by a standard industrial classification. Assignments, on such a classification, of numbers to enterprises are objective and based on an empirical observation. They represent the relation of the enterprise to others symbolized using the same classification. However, they are not measurement to the extent that the system of classification is not based on an objective empirical system of relations of industries.

An important class of the descriptive assignment of numbers, the measurement status of which is problematic, arises in educational testing. Marks in examinations may be objective, and are based on an empirical process, but it is problematic what they measure, other than the performance in a particular test. It is doubtful whether, when marks are treated as measures on a ratio scale, they are not, in fact, measures on an ordinal scale. This affects the meaningfulness of statistics on marks, such as calculations of averages and the like. The conflation of marks, such as the calculation of weighted sums of marks, contains an element of subjectivity in the conflation scheme, which probably disqualifies such conflated marks from being considered measurements.

As a final example of descriptive numerical assignments that have doubtful measurement status, it is important to consider utility evaluation in formal decision making.

Problems of decision sciences were an important stimulus to the development of wider concepts of measurement. Formal concepts of utility, with considerable power, have been developed. However, it appears, that utility, however strongly defined, is only a description of the subjective judgment of the decision maker. It is not a measure of any objectively defined characteristic of the object evaluated.

1 MEASUREMENT THEORY IN PHYSICAL SCIENCE

Measurement in physical science is generally strongly defined. It is based on the mapping of empirically observed relational systems in a physical domain into a symbolical relational system of mathematics (*see* **Article 7, Introduction to Measurement Theory and Philosophy, Volume 1**; **Article 8, Formal Theory of Measurement, Volume 1**; and **Article 9, Nature and Properties of Measurement, Volume 1**).

In strongly defined measurement

1. definition of the quantities is based on the theory;
2. empirical relational system is also defined by the theory;
3. symbolic relational system is rich;
4. theory for the domain is complete.

However, there are problems in physical measurement that present theoretical problems: they arise in measurement of properties for which there is no adequate theory and also in quantum and relativistic physics.

In technological measurements of physical properties of objects or materials, there often arises the requirement to characterize properties for which there is no adequate theory. For example, in testing of food we may need to describe empirically and objectively the ease with which a fat can be spread on a surface. In mining practice, there arises the need to characterize the hardness of a stratum that has to be worked upon. In such problems, the measurement scales formulated are weakly defined. There is, however, always the endeavor to investigate the relevant materials and phenomena in order to model them in terms of established theory and to produce strictly defined measurement scales.

Special problems arise in quantum and relativistic physics, which cannot be handled by the theory of measurement presented here. In quantum physics, the interaction between observer and observed system imposes a limit on the certainty of the joint measurement of the attributes of the system such as position and momentum. This imposes a fundamental difficulty on the measurement theory. The theory of relativity also has a large impact on the theory of measurement in the physical sciences. In terms of the view presented here it attempts to represent reality using a theory different from those used in classical measurement as, for example, in classical mechanics. The rejection of the concept of simultaneity and an upper limit to velocity are examples of such differences.

There are thus fundamental developments in the application of measurement theory to the physical sciences to be undertaken.

A more extended discussion of the problems is given in Finkelstein (2000, 2003).

2 MEASUREMENT THEORY IN SOCIAL AND PSYCHOLOGICAL SCIENCE

It is to be noted that it is the requirements of social and psychological sciences, which have led to the replacement

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

of the restrictive classical theory of measurement by the more comprehensive modern wide definition.

The social and behavioral sciences are very much concerned with such attributes or qualities as utility, standard of living, alienation, intelligence, and the like. The first problem in attempting to measure them is the difficulty in establishing an adequate objective concept of these qualities based on empirical relations. The conceptual framework is often absent.

When a scale of measurement for a quality such as 'standard of living' is formed, there remains a fundamental problem of establishing that the measure and concept correspond. For example, index figures that are often adopted for the purpose of measuring standard of living are disputed by those whom they do not suit, as not measuring what they consider to be the meaning of standard of living.

The empirical operations involved in establishing scales of measurement in social and behavioral judgment, commonly involve responses by human observers. These are, for example, required to judge whether two stimuli, such as light intensities, pitch of sound, and so on, are indistinguishable. As another instance, they are required to give an ordinal ranking to a number of alternatives. The data thus derived may be sufficiently consistent for a population of observers to consider their objective; they are nevertheless subject to considerable random scatter.

The scales of measurement, the social and behavioral sciences being frequently based on determination of equivalence and order only, are then only nominal or ordinal.

Commonly, some conceptual quality such as the 'alienation' of a work force in terms of measurable quantities, such as worker-days lost through disputes and absenteeism is difficult to establish. The difficulty again is the establishment of agreement between the concept of the quality and the measures adopted.

There are no wholly axiomatized theories in the social and behavioral sciences, which correspond to, say, classical mechanics or thermodynamics.

Measurement in social and psychological science is thus generally weakly defined. Such measurement has one or more of the following features:

1. It is based on a concept of the quality that is often fuzzily defined – *see* **Article 12, Fuzzy Approaches for Measurement, Volume 1**.
2. There is significant uncertainty in the empirical relational system that it represents.
3. The symbolic relational system has limited relations defined on it.
4. There is no adequate theory relating the measurement to other measurements in the same domain.

Finally, it may be stated that in these sciences it is by no means universally agreed that the clear formation of concepts in terms of empirical observation, is possible or desirable. Nor is there agreement that the search for data, through measurement, advances knowledge and understanding. The opponents of quantification would say that human nature and behavior are too variable to enable the methodologies of the physical sciences to be applicable to them.

A more extended discussion of the problems is given in Finkelstein (2000, 2003).

1 DEFINITION OF FUZZY SENSORS

Introduced by Zadeh in 1965 the fuzzy subset theory is now a common tool in main domains. The basis of this theory and its symbology is first defined. A fuzzy subset A of a set X is a set that can contain partially some members of X. Any member x of X has a membership degree to the set A. This membership degree is denoted $\mu_A(x)$, and μ_A is the membership function of the fuzzy subset A.

The main objective of a sensor is to convert the physical state of an entity into an information entity (Mari, 2001). Fuzzy sensors are defined as sensors producing a fuzzy subset as their information entity. The idea of using fuzzy subsets in process control systems arose from Chang and Zadeh's (1972) study of fuzzy mappings.

This section provides basic definitions of the three general stages involved in fuzzy information systems (Foulloy and Galichet, 1995).

Fuzzification is an interface that produces a fuzzy subset of information from the measurement; it is a mapping from the set of measurements X to a set of fuzzy subsets associated with the input, denoted $F(Y)$.

The inference resulting is an interface that produces a new fuzzy subset from the result of the fuzzification, using, for example, a set of rules. The result of the inference is a fuzzy subset associated with the output. It can be represented by a mapping from the set $F(Y)$, associated with the input, to a set of fuzzy subsets associated with the output and denoted $F(Z)$.

Defuzzification is an interface that produces a crisp output from the result of the inference, that is, it is a mapping from the set $F(Z)$, associated with the output, to the set U.

The set Y related to the input can either be the set of numerical values, that is, X, or the set of linguistic values, that is, LX. In the same way, the set Z related to the output can either be the set of numerical values, that is, U, or the set of linguistic values, that is, LU. Therefore, the previous definitions can be used to provide an efficient classification, that is, a typology of fuzzy information handling in four classes as shown in Figure 1.

From the preceding typology, three types of components can be introduced:

- Fuzzy sensors provide a representation of the measurements by means of fuzzy subsets; they perform the fuzzification.
- Fuzzy actuators are components that are able to act on the physical world depending on the fuzzy subset they receive; they perform the defuzzification.
- Fuzzy inference components produce new fuzzy subsets from fuzzy subsets they have received, thus performing fuzzy reasoning.

This article focuses on linguistic fuzzy sensors that deal with linguistic fuzzy subsets and on numerical fuzzy sensors

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

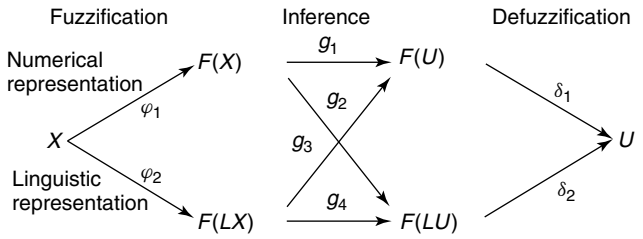

Figure 1. Typology of fuzzy processing in measurement and control systems.

that deal with numerical fuzzy subsets. Linguistic fuzzy sensors can be represented directly by means of the φ_2 mapping (see Figure 1). They can also be represented indirectly by means of the composition of several mappings as long as the resulting information is a fuzzy subset of linguistic terms.

In many situations, information sought is not available from a single entity, but from many different complementary entities. In measurement theory, this case corresponds to the so-called conjoint measurement. Here, it will be called the *aggregation of complementary information*, and is presented in Sections 4 to 8.

2 NUMERICAL FUZZY SENSORS

The basic idea developed in the design of numerical fuzzy sensors is to take into account and manipulate the measurement uncertainties. Mauris, Lasserre and Foulloy (2001) propose a theoretical well-founded approach, compatible with the ISO Guide on the expression of uncertainty, for building a fuzzy subset that is interpreted as a possibility distribution that represents the uncertainty associated with a measurement.

According to the ISO Guide prepared jointly by the International Organization for Metrology; BIPM (Bureau International des Poids et Mesures); IEC (International Electrotechnical Committee); ISO (International Organization for Standardization); and the OIML (International Organization of Legal Metrology), the expression of measurement uncertainty must satisfy certain requirements in order to be widely used at the practical level. The Guide recommends use of a parametric representation of the measurement uncertainty that

- characterizes the dispersion of the observed values; for example, the standard deviation or a half-width of an interval at a given level of confidence,
- can provide an interval of confidence, which contains an important proportion of the observed values,
- can be easily propagated in further processing.

Thus, the ISO Guide proposed to characterize the measurement result by providing the best estimation of the measurand (i.e. in general, the mean value) and the standard deviation. In fact, it simplifies the probability approach by considering only the first two moments (mean value and variance) of the probability distribution.

Nevertheless, the Guide distinguishes two categories of uncertainty according to the method used to estimate their numerical values: those that are evaluated by statistical methods called type A, and those that are evaluated by other means called type B. Note that for the latter, probability approaches are not more natural than the interval approach, when the uncertainty expression comes from experts (Reznik and Dabke, 1999).

In this article, we consider the fuzzy and possibility theories as an alternative to the conventional probabilistic approach (Kendall and Stuart, 1977), and as an extension of the interval calculus (Moore, 1966). Many methods, more or less justified, are proposed in the fuzzy literature to represent measurement uncertainty (Geer and Klir, 1992; Ree and Jager, 1993). The basis of this approach is to represent measurement uncertainty by a fuzzy subset (interpreted as a possibility distribution) built to be compatible with the ISO Guide.

The foundation of this approach is the notion of confidence interval. Let us first recall this notion: let p be a probability distribution, and let it be a 'one point' estimation (for example, the mean value of the probability distribution) of the 'real' value.

An interval is defined around the 'one point' estimation and corresponds to the probability for this interval to contain the 'real' value. Such an interval $I_{1-\alpha}$ is called a confidence interval of confidence level $(1 - \alpha)$ (95%, 99% for example); it is the risk level, that is, the probability for the real value to be outside the interval.

Mauris identified each confidence interval of level $1 - \alpha$, with each α-cut of a fuzzy subset F, which thus gathers the whole set of confidence intervals in its membership function. Figure 2 represents this situation.

3 LINGUISTIC FUZZY SENSORS

Where numerical values are commonly used to represent measurement results some applications would better manipulate symbolic values or linguistic terms. For example, a rule-based decision system uses linguistic terms in its rules. The advantage of using linguistic terms instead of numerical ones is to reduce the number of symbols involved. Zadeh (1971) subsequently introduced the concepts of fuzzy meaning and the descriptor set that are extensively used in fuzzy sensors designs. They provide

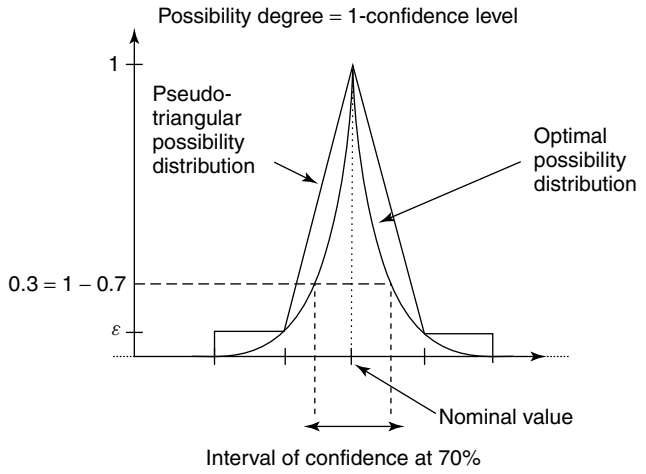

Figure 2. A numerical information entities as a possibility distribution.

a simple means for representing measurement results by a fuzzy subset of linguistic terms. The conversion from numeric to linguistic representation presented in the following is called the *linguistic fuzzy description* or, more simply, the *fuzzy description*.

Let X be the universe of linguistic discourse associated with the measurement of a particular physical quantity. In order to linguistically characterize any measurement over X, let W be a set of linguistic terms, representative of the physical phenomenon. Denote R the relation defined on $X \times W$ that formalizes the link between items of the universe of discourse and the linguistic terms of the lexical universe.

Two mappings can be defined from this relation. The first one is a one-to-one mapping m, called the *meaning* of a linguistic term. It associates any term w of W with a subset of X,

$$\forall w \in W, m(w) = \{x \in X | xRw\} \tag{1}$$

The other one is a one-to-one mapping d, called the *description* of a measurement, which associates any measurement x of X with a subset of W.

$$\forall x \in X, d(x) = \{w \in W | xRw\} \tag{2}$$

Since the two mappings are defined from the relation, we have obviously the following equivalencies:

$$xRw \iff x \in m(w) \iff w \in d(x) \tag{3}$$

Consider now that the relation R is a fuzzy relation on $X \times W$. It is characterized by its membership function denoted μ_R. The grade of membership $\mu_R(x, w)$ characterizes the strength of the link between x and w. Then, the previous

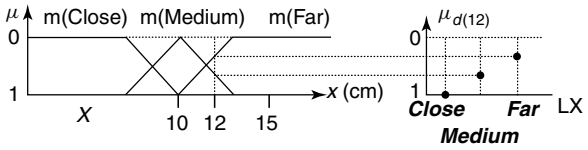

Figure 3. Fuzzy meaning and fuzzy description mechanism.

concepts can be extended to the fuzzy case. It leads to the fuzzy meaning of a term and the fuzzy description of an object state, respectively defined by

$$\forall w \in W, \ \forall x \in X, \mu_{m(w)}(\mathrm{x}) = \mu_R(x, w) \tag{4}$$

and,

$$\forall w \in W, \ \forall x \in X, \mu_{d(x)}(w) = \mu_R(x, w) \tag{5}$$

Equivalencies given in (3) become equalities between grades of membership as follows:

$$\forall w \in W, \ \forall x \in X, \mu_R(x, w) = \mu_{d(x)}(w) = \mu_{m(w)}(\mathrm{x}) \tag{6}$$

Figure 3 shows the link between the fuzzy meaning of each word of the set $LX = \{Close, Medium, Far\}$ and the fuzzy description of a numerical value.

4 FUZZY NOMINAL SCALES

Scales have been introduced to model the link between physical states and information entities created by the measurement. Finkelstein (1975) proposed to define any scale by the following symbolism:

$C = \langle X, S, M, R_X, R_S, F \rangle$, where

- X refers to a set of object states and R_X is a set of relations on X,
- S refers to a set of information entities, and R_S is a set of relations on S,
- M, called the representation, is a mapping from X to S,
- F is a one-to-one mapping with domain R_X and range R_S.

Knowing what kind of scale is used for measurement is very important. This knowledge defines the set of relations and operators allowed for the manipulation of information entities.

In the case of nominal scales, R_S contains only the equality relation on S and R_X contains an equivalence relation on X, denoted $\sim$. The mapping F is then simply defined by $F = \{(\sim, =)\}$. The representation respects the following equation.

$$\forall x_i \in X, \ \forall x_j \in X, x_i \sim x_j \Leftrightarrow \mathrm{M}(x_i) = \mathrm{M}(x_j) \tag{7}$$

The equivalence relation $\sim$ defines a partition of the set of object states and M associates each item of the partition with information entity. The general symbolism for a nominal scale is

$$C = \langle X, S, M, \{\sim\}, \{=\}, \{(\sim, =)\}\rangle \tag{8}$$

It was shown by Benoit and Foulloy (2003) that the fuzzy description presented in Section 3 can be interpreted as a nominal scale with the following symbolism. This scale is named the fuzzy nominal scale.

$$C = \langle X, F(W), d, \{\sim\}, \{\equiv\}, \{(\sim, \equiv)\}\rangle \tag{9}$$

where d is the fuzzy description, and $\sim$ is a fuzzy equivalence relation on X, and $F(W)$ is the set of fuzzy subsets of W.

It was also shown that a proximity relation between lexical entities can be deduced from the preceding symbolism, which means that

- a fuzzy nominal scale is not only a nominal scale; in addition to equivalence relation, proximity relation and associated pretopological operators can be used on information entities;
- the introduction of fuzziness in measurement can be made only if a proximity relation really exists between physical states.

Therefore, fuzzy nominal scales can be useful for taking into account the fuzziness of a humanlike linguistic representation, but they must be used carefully.

5 DIFFERENT TYPES OF FUZZY BLOCKS

Using the preceding approaches, it is now possible to define a set of function blocks that can be merged to create complex systems. The classification of the function blocks is based on the nature of the fuzzy subsets and the nature of the function. Fuzzy subsets can be numerical fuzzy subsets (NFS) or linguistic fuzzy subsets (LFS). Function blocks can perform the fuzzification, the inference or the defuzzification. This classification, issued from the typology presented in Section 1, distinguishes 8 fuzzy function blocks.

- Numerical fuzzification: it has a numerical entity as input, that is, a number or a vector, and an NFS as output.
- Linguistic fuzzification: it has a numerical entity as input, and an LFS as output. It performs a fuzzy description of the numerical input.

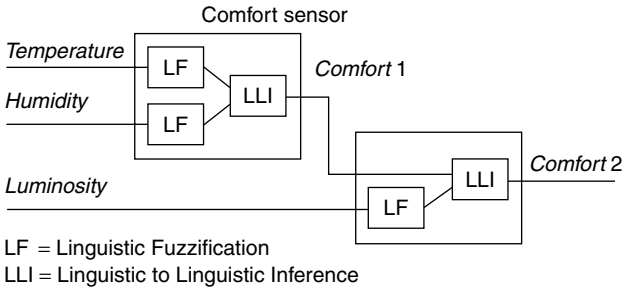

Figure 4. Fuzzy sensor made of fuzzy blocs.

- Numerical inference: input and output are NFS.
- Numerical to linguistic inference: input is an NFS and output is an LFS.
- Linguistic to numerical inference: Input is an LFS and output is an NFS.
- Linguistic inference: input and output are LFS.
- Numerical defuzzification: it has an NFS as input and a numerical entity as output.
- Linguistic defuzzification: it has an LFS as input and a numerical entity as output.

A measurement system can be created with a graph of fuzzy blocks respecting the basic constraint that each end of the connectors must have the same nature and the universe of discourse. Linguistic entities must be fuzzy subsets of the same lexical set, and numeric entities must be defined on the same numerical set. Figure 4 shows how this applies to an example system.

6 RULE-BASED FUSION OF INFORMATION

Some inference blocks use linguistic fuzzy subsets for their inputs and their outputs. As the fuzzy nominal scale concept is too young to be applied at this level, the linguistic fuzzification is usually considered as a simple nominal scale. The only relation that links linguistic entities is an equivalence relation. With an equivalence relation, the fusion of information can be made with a set of rules. Generally, most of the rules are expressed in the following manner:

$$\text{If } X_1 \text{ is } L_1 \text{ then } Y \text{ is } a$$

for example, if the size (of a shoe) is *large* then the price (of a shoe) is *high*.

In fact, the rule represents a correspondence between the variable X_1 (e.g. the size) and the variable Y (e.g. the price). The purpose of this sort of metaimplication is to infer information about Y from information about X_1.

As proposed by Zadeh (1975), the if ... then ... metaimplication could be viewed as a fuzzy relation between X_1 and Y represented by the fuzzy graph $\mu_{\Gamma 1}(X_1, Y)$. Then the image F of a fuzzy subset E of the variable X_1 is obtained by the combination/projection principle (also referred to as generalized modus ponens) according to

$$\mu_F(Y) = \mu_{f(E)}(Y) = \perp_{X_1}(\mu_E(X_1) T \mu_{\Gamma 1}(X_1, Y)) \quad (10)$$

where T is a norm and $\perp$ a conorm.

To compute $\mu_F(Y)$, we must know $\mu_{\Gamma 1}(X_1, Y)$ and $\mu_E(X_1)$.

The problem is first how to build $\mu_{\Gamma 1}$ and secondly how to define $\mu_E(X_1)$.

The most natural representation of the rules is to consider that the rules relate the two linguistic terms L_1 and a, that is, to consider that $\boldsymbol{L}_1$ and $\boldsymbol{a}$ are elements of the lexical sets LX_1 and LY and that $\Gamma 1$ is a fuzzy graph on the Cartesian product $LX_1 \times LY$.

In this case, the expression is transformed for every $\boldsymbol{a}$ belonging to LY into

$$\mu_F(a) = \mu_{f(E)}(a) = \perp_{L_1 \in LX_1}(\mu_E(L_1) T \mu_{\Gamma 1}(L_1, a)) \quad (11)$$

with $\mu_{\Gamma 1}(L_1, a)$ representing the degree of validity of the rule and $\mu_E(L_1)$ a linguistic description of the variable X_1.

Now, if we consider n rules, we have n elementary graphs Γ_i's. If we consider that every rule provides a relation, a unique graph Γ that represents all the rules could easily be built by taking $\Gamma = U_i \Gamma_i$. If we consider more complex rules of the form

$$\text{if } X_1 \text{ is } L_1 \text{ and } X_2 \text{ is } L_2 \text{ then } Y \text{ is } a,$$

we then consider X_1, X_2, Y as elements of LX_1, LX_2 and LY, and Γ is defined on the Cartesian product $LX_1 \times LX_2 \times LY$.

The expression becomes

$$\mu_F(a) = \perp_{(L_1, L_2) \in LX_1 \times LX_2}(\mu_{(E,E')}(L_1, L_2) T_1 \mu_\Gamma (L_1, L_2, a)) \quad (12)$$

It remains then to define $\mu_{(E,E')}(L_1, L_2)$.

If we make the assumption that the two variables are independent $\mu_{(E,E')}(L_1, L_2)$ is decomposable and we can write

$$\mu_{(E,E')}(L_1, L_2) = \mu_E(L_1) T_2 \quad \mu_{E'}(L_2) \quad (13)$$

(with T_2 an operator of intersection, i.e. a norm).

If we have two numeric measurements x_1 and x_2, then

$$\mu_{(E,E')}(L_1, L_2) = \mu_{i(x_1,x_2)}(L_1, L_2) = \mu_{i(x_1)}(L_1) \; T_2 \; \mu_{i(x_2)}(L_2) \quad (14)$$

Computation of (12) leads to obtaining the description of (x_1, x_2) on LY, that is, $\mu_{i(x_1,x_2)}(a)$ for every a belonging to LY.

In fact, we have built a new fuzzy sensor that is an aggregation of the two primary fuzzy sensors.

An interesting problem is the determination of the operators $\perp$ and T. This choice is implied by the structure we will obtain for the aggregated information and by the properties of the graph Γ. Such studies have been performed in the case in which Γ is a crisp graph (Benoit, Mauris and Foulloy, 1995; Mauris, Benoit and Foulloy, 1996).

7 FUZZY CLASSIFICATION APPROACHES

Another approach for fuzzy measurement is to consider fuzzy sensors as fuzzy classifiers. This approach can be chosen when the initial knowledge about the measurement is a set of examples instead of an expert set of knowledge.

The idea of similarity, naturally associated with fuzzy sets, has been used mainly in clustering analysis. Indeed, it may be more realistic for describing a data set to look for fuzzy clusters when some clusters are not well separated.

Since Dunn (1973) and Bezdek (1981), the theory of fuzzy sets has been introduced into several clustering techniques. In particular, the fuzzy c-means (FCM) and the fuzzy k-nearest neighbors algorithms (KNN), which are the generalization of the crisp ones, have been widely used. More recently, some authors (Grabisch and Nicolas, 1994), have used the fuzzy integral in classification problems. Introduced by Sugeno (1974), the fuzzy integral has been mostly used as an aggregation operator in problems such as decision making. Bezdek and Pal (1992) contains most of the seminal works on the use of fuzzy sets theory in the field of pattern recognition and classification.

The FCM clustering algorithm is the fuzzy equivalent of the nearest mean hard clustering algorithm (Duda and Hart, 1973). Data are supposed to be structured into n vectors whose dimension is $p : X_j$; $j = 1,2, \ldots, n$; each vector characterizes an object described with p attributes. We assume here that the number of clusters is known. For this preselected number c, the FCM algorithm produces c vectors, which represent the cluster centers, and for each data point c membership values, which measure the similarity of the data points to each of the cluster centers.

Let u_{ij} be the membership value of the vector X_j to the cluster i describing how close X_j is to this cluster's center C_i. The classification is obtained by minimizing the following objective function with respect to the memberships $\{u_{ij}\}$ and the cluster centers $\{C_i\}$:

$$\sum_{j=1}^{n}\sum_{i=1}^{c}(u_{ij})^m d^2(Xj, Ci)$$

where d is a distance in the space of data. The value of the fuzzy index m tunes the degree of fuzziness of the clustering. The membership values indicate how well the point has been classified. When the input is close to a particular center, the membership value to the corresponding class is close to one.

A fuzzy k-nearest neighbors algorithm was proposed by Keller, Gray and Givens (1985). The conventional KNN classification method assigns each input to one of the possible classes. First the k-nearest neighbors are found. Then the input is assigned to the class that includes the majority of the neighbors. In the fuzzy KNN classifier, the second step consists in assigning to the input a membership degree to each class. Let x be an input, $u_i(x)$ its membership to the ith class and w_{ij} the one of the jth neighbor z_j, then

$$u_i = \frac{\sum_{j=1}^{k} w_{ij}\left(\frac{1}{\|x - z_j\|}\right)^{2/(m-1)}}{\sum_{j=1}^{k}\left(\frac{1}{\|x - z_j\|}\right)^{2/(m-1)}} \qquad (15)$$

where m is an adjustable parameter that tunes the weighting effect of the distance.

Since the introduction of the Sugeno integral, different families of fuzzy integrals have been defined. We only present here the Choquet integral that we use as an aggregation operator for multiattribute classification (Grabisch and Sugeno, 1992). Let f be a function from X to [0,1], and μ a fuzzy measure on X. Assume the elements $\{x_i\}$ are ordered such that we have $f(x_1) \leq f(x_2) \leq \cdots \leq f(x_N)$. The Choquet integral with respect to μ is defined by

$$\int f d\mu = \sum_{i=1}^{N}(f(x_i) - f(x_i - 1))\mu(A_i) \qquad (16)$$

where $A_i = \{x_i, \ldots, x_N\}$ and $f(x_0) = 0$ by convention.

The $\{x_i\}$ represent the attributes that are taken into account for the classification. The $\{f(x_i)\}$ represent the individual degrees of matching with each of these features. For each class, we define one or more prototypes and a fuzzy measure on the set of subsets of attributes. This measure gives the importance of each attribute, and every subset of attributes from the point of view of this class in the classification process. This allows us to take into account the redundancy in the information collected or the dependence between two or more features. Naturally, the features, or subsets of features, whose contribution to the identification of a given class is the greatest are assigned the greatest measures with respect to this class.

8 INTERPOLATION-BASED FUSION OF INFORMATION

An alternate solution to performing a clustering is to create the fuzzy meanings with simple interpolation techniques. In this article, we consider initial knowledge about measurements. This knowledge is materialized by the meaning of lexical entities on a small subset V of the measurements set X.

Then we have to extend the meaning of each symbol on all the measurements set. In order to obtain a fuzzy partition, the measurement set is cut into n-simplexes. An n-simplex in an n-dimensional space is a polyhedra with $n + 1$ vertices. For example, a 2-simplex is a triangle and a 3-simplex is a tetrahedron. Then meanings are defined on each n-simplex respecting the fuzzy partition constraint.

First, the measurements set is partitioned into n-simplexes using Delaunay's triangulation. The points used to perform the triangulation are the elements of the set V. As any triangulation can be used to cut the measurements set, it must be chosen according to constraints associated with the measurements. The Delaunay triangulation is preferred when no constraint can be found (Benoit, Mauris and Foulloy, 1994).

The membership function of the meaning of each word is defined on each n-simplex by a multilinear interpolation. Suppose the restriction on an n-simplex of the membership function of the meaning of a word $\boldsymbol{s}$ is

$$\mu_{m(s)}(x_1, x_2, \ldots, x_n) = a_1x_1 + a_2x_2 + \cdots + a_nx_n + a_{n+1} \qquad (17)$$

The value of this function is known for the $n + 1$ vertices of the n-simplex, therefore the $n + 1$ factors ai can be calculated by the following equation system:

$$A = M^{-1}B \quad M = \begin{vmatrix} x_{1,1} & \ldots & x_{1,n} & 1 \\ \ldots & \ldots & \ldots & \ldots \\ x_{n+1,1} & \ldots & x_{n+1,n} & 1 \end{vmatrix}$$

$$A = \begin{vmatrix} a_1 \\ \ldots \\ a_{n+1} \end{vmatrix} \quad B = \begin{vmatrix} \mu_{m(s)}(v_1) \\ \ldots \\ \mu_{m(s)}(v_{n+1}) \end{vmatrix} \qquad (18)$$

The ith vertex of the n-simplex is denoted v^i, and its jth component is denoted $x_{i,j}$.

Once this process is performed on each n-simplex for each word, we obtain a fuzzy nominal scale defined on X. This scale is an extension on X of the fuzzy nominal scale on V.

With this method, the knowledge needed for the configuration of the sensor is very compact. It can be acquired by means of a system called a *teacher*, which can be a human or an expert system. During the configuration phase, the teacher and the sensor analyze the same phenomenon, and the teacher gives its description to the sensor. The sensor increases its knowledge with its measurement associated with the teacher description. Then it can build the fuzzy nominal scale. It should be noted that the description given by the teacher must be a fuzzy subset of words, which verifies the fuzzy partition condition. If the teacher is a human, then its description is generally a crisp set that contains only one symbol. Figure 5 gives the teacher's knowledge about colors that is expressed in a two-dimensional chrominance space and the fuzzy meaning of the color Red.

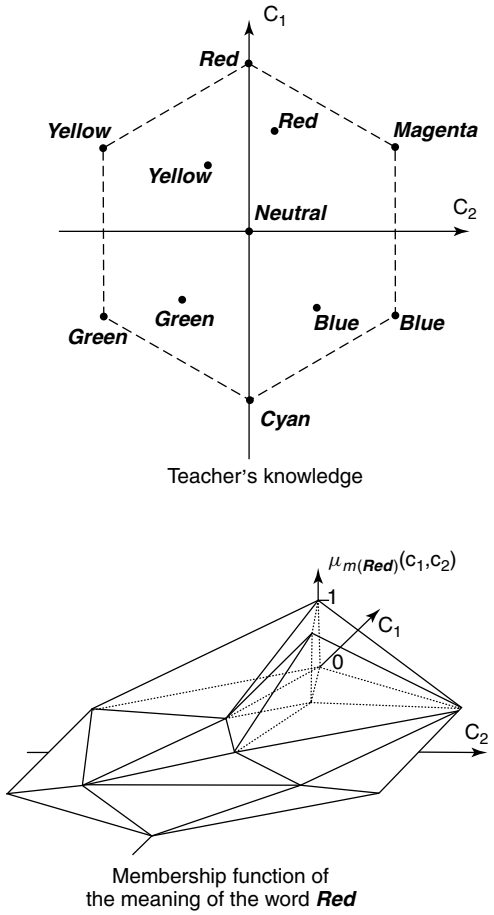

Figure 5. Teacher's knowledge and fuzzy meaning of the color red.

1 NATURE OF COGNITIVE UNDERSTANDING AND RELATIONSHIP TO KNOWLEDGE AND IDEAS

The real world exists independently of our perception, and one is aware of the outside real world through seeing, hearing, and other senses. Human perception organizes sensory stimulation into percepts of various objects and phenomena. Sufficient experience of external objects and phenomena enables one to categorize and characterize them by means of defined properties or attributes. Basic knowledge is thus formed as ideas, concepts (including conceptual relations) about these attributes and the associated matters. Figure 1 shows the basic relation of human experience or cognition.

In fact, human cognition may be split into two processes, as shown in Figure 2. The first one is essentially a perception process, while the second one involves some memory and learning of the empirical relations.

Human cognition is an empirical process, subjective to possible a priori propositions and individual experience (Yang and Butler, 1997). Although the limitation of human senses often results in unsatisfactory knowledge, human perception, and cognition always plays a fundamental role in measurement, in particular, in the definition of a measurand and its associated measurement scale.

Modern sciences have aimed at systematically organizing objectively verifiable empirical experience and knowledge as scientific knowledge. Scientific knowledge is often quantifiable, precise, concise and thus easy to process and transform. Measurement plays a central role in the acquisition of scientific knowledge. Measuring tools, that is, instruments, are used to extend and improve the power of human senses. The machine perception performed by measuring instruments transforms the identified measurable properties or attributes (i.e. measurands) into some predefined numbers or symbols through symbolic representation as in Finkelstein (1975). The information carried by these symbols can be extracted through data processing, and scientific knowledge about the observed system can then be developed on the basis of this information. Similar to human cognition shown in Figure 1, this process may be illustrated in Figure 3.

2 DEFINITION AND APPLICATION OF DATA

Data is a plural form of datum and generally refers to 'known facts or things used as a basis for inference or reckoning' (Pearsell, 1999). In information systems including

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

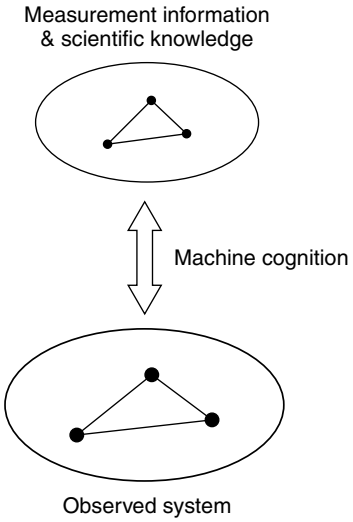

Figure 3. Machine cognition.

measurement, data may be defined as 'the quantities, characters, or symbols on which operations are performed by computers and other automatic equipment, and which may be stored or transmitted in the form of electrical signals, records on magnetic tape or punched cards, etc.', according to the Oxford English Dictionary (Simpson and Weiner, 2002). Some common examples include numbers, characters, images, and sounds.

Data are one kind of information carrier, and information is an integral part of data. Data are the mixture or fusion of carrier and information. Information or meaning can only be extracted and understood through some kind of data processing (e.g. brain, computer).

In measurement, data are usually recorded numbers or signals stored in various forms. Data have to be collected and processed before information and knowledge can be extracted. Typically, data is collected through a sampling process, both spatial and temporal, as discussed in Yang and Butler (1997, 1998). They have to be representative, that is, the information they carry should be essentially the same as or significantly close to that exhibited by the observed system.

It is often necessary to separate data collection or acquisition from data processing, although an integrated process would be more desirable and has indeed become increasingly common. The collected data that have only gone through minimum conditioning and processing are often called *raw data*.

Since computers can easily process digital data (both discrete-valued and discrete-time), raw data should ideally be in digital format. Continuous-time (typically also continuous-valued) signals become discrete-time and continuous-valued data (or sampled data) through sampling in time domain. If raw data are already discrete-time, but continuous-valued, they can be converted to digital data using an (A to D) analog-to-digital converter. The raw data can be simply continuous-time and continuous-valued signals, for example, recorded on magnetic tape, in which case both sampling and A to D conversion is required to generate digital data.

3 DEFINITION AND APPLICATION OF INFORMATION

Information may be defined as something or knowledge communicated concerning some particular fact, subject, or event. It can be separated from the person informed and can produce different responses in something, and is capable of being stored in, transferred by, and communicated to inanimate things (Simpson and Weiner 2002).

Information exists objectively and, unlike knowledge, it does not require a human subject, although it ultimately

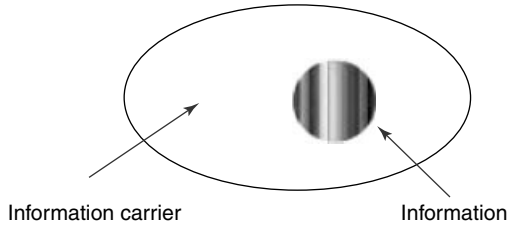

Figure 4. Information cell.

serves human beings. Information becomes knowledge once it is understood and possessed by the informed subject.

Information cannot exist on its own and it necessarily requires some kind of information carrier. Information is usually carried and conveyed by signals in various energy forms, for example, mechanical, electrical, optical, and so on. It can also be stored in various media, for example, printed text, electronic file, and even in the human brain. The relationship between information and information carrier may be generally presented as an information cell model, as shown in Figure 4.

The cell may manifest itself in various forms, for example, electronic signal, data, text, sound, image, brain, and even real-world objects. The cell body denotes the information carrier, while the nucleus actually represents the information carried and conveyed.

3.1 Information and measurement

On the basis of the information cell model, machine perception together with human perception may be represented as shown in Figure 5. Measuring instruments therefore essentially function as an information flow channel, or information machine as discussed in Draper, McKay and Lees (1952), Finkelstein (1982) and Sydenham, Hancock and Thorn (1989). Measurement is an information acquisition process, primarily concerned with the capture (or sampling), enhancement, extraction, and presentation of information. Ideally, the information should be preserved as much as possible in the measuring chain and could be easily separated or extracted from the carrier.

In measurement, information is carried and conveyed by measurement signals or recorded data. The information in a measurement is ultimately knowledge about the measured object. It is primarily concerned with the magnitudes and the relations of the measurand(s), represented on some predefined scales, as in the representation theory of measurement discussed in Pfanzagl (1968), Krantz *et al.* (1971), Narens (1985), Finkelstein (1982).

The information may be regarded as the meaning of the measurement data, and, as such, has to be extracted using various data transforming techniques. There are two distinct types of data transforming involved in a measurement process, as shown in Figure 6. The first transformation (AB) converts the measurand(s) to signals in various forms, which can then be conditioned and enhanced. The central function of this transformation is the generation of machine percepts or representation of measurand(s) in the form of numbers or symbols. The second transformation (BC) converts the symbols into meaningful information, although the latter also usually takes the form of numbers or symbols. The key process of the second transformation is calibration. The first transformation is data-driven, relating the measurand(s) to the measurement numbers or symbols, whereas the second one is information-driven, relating the symbol relations back to empirical relations.

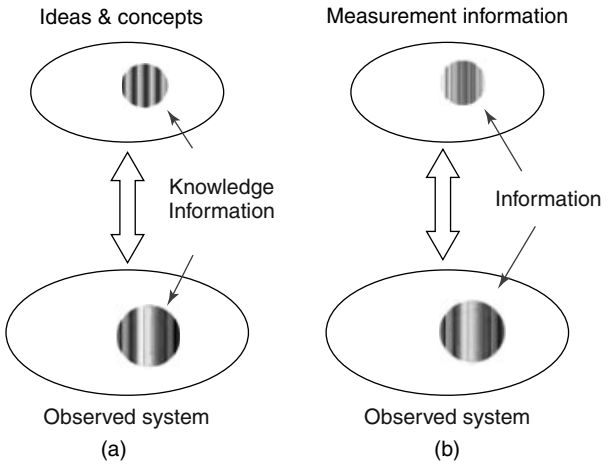

Figure 5. (a) Human machine and (b) machine perception.

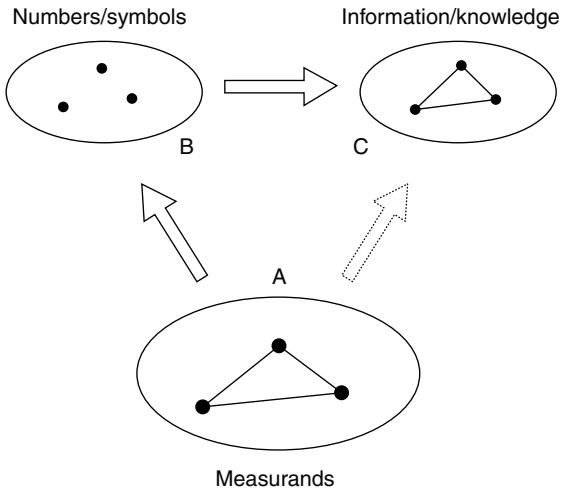

Figure 6. Extraction of measurement information.

4 DEFINITION AND APPLICATION OF KNOWLEDGE

Knowledge can be generally defined as the familiarity gained by experience of a fact, thing, or person. Knowledge is usually in reference to a subject or person, and information becomes knowledge as information is interpreted and possessed by a person (Sydenham, Hancock and Thorn, 1989). In fact, human knowledge could also be represented and stored as information.

From epistemology's point of view, knowledge can be obtained through direct and indirect experience. Ideas and concepts are formed from human perception and from the observer's direct experience of the real world. Human knowledge gained also comes from the experience of the manifestation of the information carried by the observed system.

Indirect experience can be any experience other than direct experience. For example, this may be the experience of somebody else, or one's internal experience and mental activities, that is, reasoning and deduction, which result in rational knowledge. Indirect knowledge should also include the knowledge acquired through machine perception. The role of instruments and measurement is not only extension of the range and capability of human senses but also the enhancement of indirect experience and knowledge.

Measurement starts with human direct experience, and as basic concepts of attributes or measurands are formed, some basic and fuzzy knowledge is developed. Measurement serves to quantify and improve this kind of knowledge, generating, and refining scientific knowledge, which is usually precise and easy to process and apply.

4.1 Direct and indirect knowledge in measurement

Of course, human knowledge comes from both direct and indirect experiences. Figure 7 shows the combined relations between human perception and machine perception, where the observed object or system is the key link of the two perception processes. Since machine perception and measurement may be regarded as a kind of indirect experience, Figure 7 also models the interactions between direct and indirect experiences. It is widely recognized that one's direct experience plays an important role generally in his or her cognition process, knowledge acquisition and, in particular, indirect experience.

4.2 Level of abstraction and knowledge pyramid

Both human and machine perceptions aim at extracting information and knowledge, but the two have different

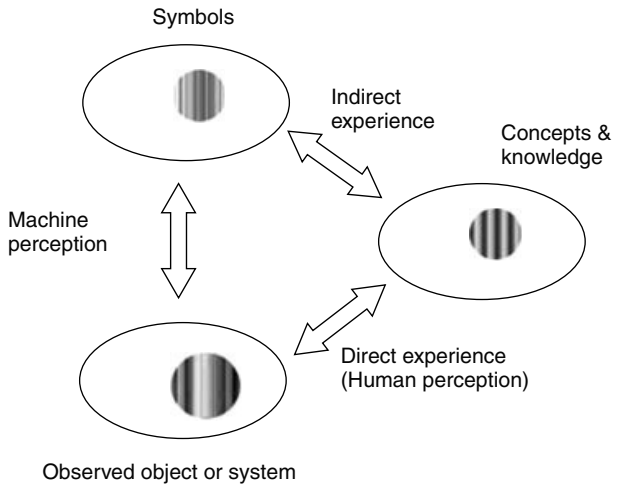

Figure 7. Direct and indirect knowledge.

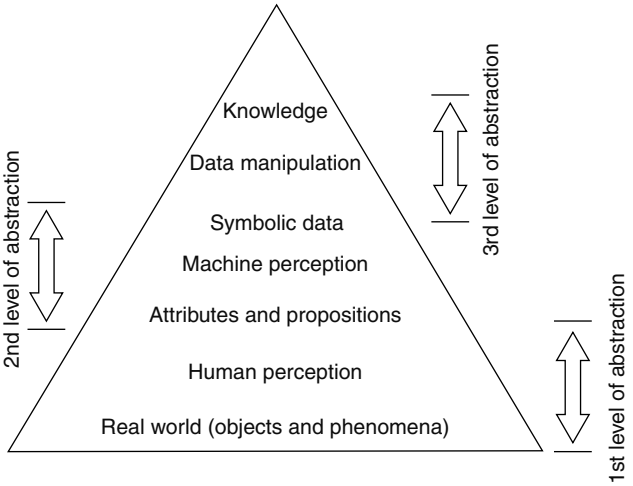

Figure 8. Knowledge pyramid.

levels of abstraction. In terms of the level of abstraction, the relationship between knowledge and human/machine perceptions can be presented as a knowledge pyramid, as in Yang and Butler (1997) and as shown in Figure 8.

The first level of abstraction is the concept of attributes and their relations formed after human perception through direct experience. The second level of abstraction transforms these attributes to predefined symbols and it represents the observed system in symbols. The third level of abstraction further transforms the symbols into information and knowledge about the observed system through general data manipulation.

4.3 Measurement and other branches of science

Measurement science requires the underpinning of some other branches of science, for example, mathematics and

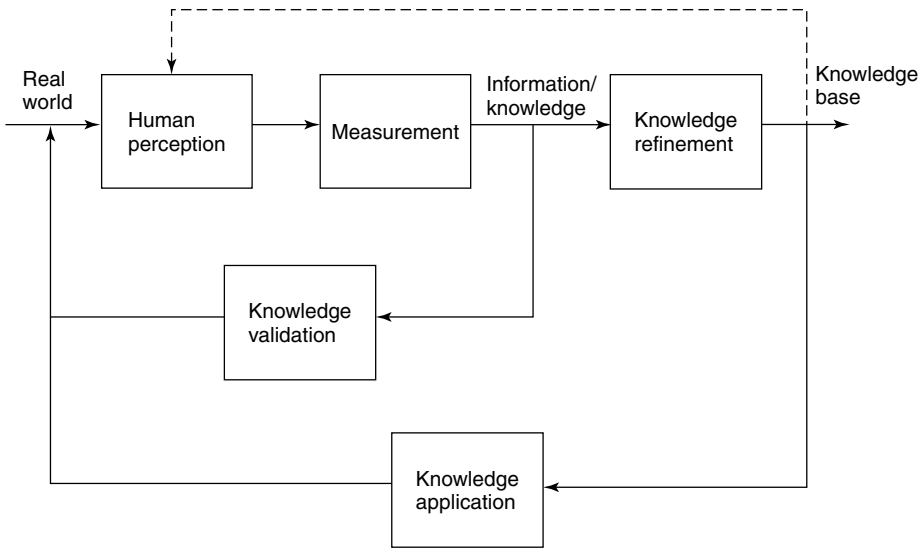

Figure 9. Measurement and other branches of science.

other fields of information science including data processing, communication, and control. Measurement also underpins many other branches of science, for example, physical, chemical, and biological science. Domain experts rely upon measurement and instrumentation to study their problems. But they work on a larger framework, as shown in Figure 9, where the knowledge obtained from measurement about the measured attributes help them understand the objects or phenomenon in the system concerned. This understanding leads to knowledge at a higher level, which may be further refined through validation and which constitutes the science of the subject domain concerned. The objective of measurement is knowledge acquisition, whereas those of the domain experts are primarily concerned with the direct practical experience, knowledge validation, and knowledge refinement (Yang and Butler, 1997).

5 DEFINITION AND APPLICATION OF WISDOM

Wisdom may be defined as special or advanced knowledge that is developed from wider experience and is often not easily or naturally associated or applied.

As discussed in the previous section, measurement extends our experience and knowledge. It often functions as part of an overall system that applies and makes use of the knowledge generated in measurement. It underpins many other branches of science. Measurement can thus be a source of intelligence or wisdom, especially in a complicated system or process in which advanced knowledge is required and/or should be applied. For instance, it can be argued that the development of our knowledge in physics generally involves some kind of measurement, including those very advanced ones representing the wisdom of mankind, for example, Einstein's relativity theory was based upon the measurement of the speed of light.

Having discussed various related concepts like data, information, knowledge, and wisdom, it is common wisdom to use simple examples to clarify the relations and differences of related concepts!

Suppose we have received the following parts of texts:

A: 'house, prices, UK, rise, fastest, annual, market, last, peaked, 25.3%, 2002, 1989'.
B: 'House prices in the UK rose by 25.3% over 2002, the fastest annual rise since the market last peaked in 1989.'
C: 'Property can be a very good investment in the UK.'
D: 'What goes up can come down, and usually quite sharply.'

Part A could best be described as data because it mainly contains individual words and their relations are not explicitly given. Part B could best be described as information with the relations between words and concepts clearly stated. Part C could best be described as knowledge derived from the interpretation of the information (Part B). Of course, additional knowledge can also be developed. Part D could best be described as wisdom.

6 DEFINITION AND APPLICATION OF A SIGNAL

Signals may be defined as 'a modulation of an electric current, electromagnetic wave, or the like by means of which

information is conveyed from one place to another', according to the Oxford English Dictionary (Simpson and Weiner, 2002). Signals are closely related to data, and in fact they become data once recorded. But by definition they have wider existence in natural and man-made systems, and thus play a more important role. Like data, they are information carriers. Information is carried by the magnitude or attributes of the variation of signals (Finkelstein, 1994).

A signal is essentially the change or modulation of an energy state, which can be detected by a human observer or instrument. Signals can be regarded as factors of energy or power, and energy as the signal carrier. Signals are generated from energy connections and interactions between the objects and matter in the system concerned. Various energy forms may be involved, for example, electrical, mechanical, thermal, optical, magnetic, and chemical. Each element of the measuring chain can be regarded as a transducer and the energy flow may change form in each transducer. Energy flow determines the signal flow in a measuring instrument.

6.1 Signal processing

Since the energy associated with a signal is influenced or modulated not only by the measurand but by other effects also, noises will always be present in a measuring chain together with signals. It is thus necessary to carry out signal conditioning and signal processing to increase the signal-to-noise ratio.

Signal processing is a technology concerned with the representation, transformation, and manipulation of signals and the information they contain, in such a way as to make them more useful in a given application. Signal processing has a long history. The last four decades have seen its extremely rapid growth, partly due to availability of the ever-increasing power of devices and computers, both hardware and software, and partly due to its prevalence in the advances of many branches of science and technology (Yang, 2001).

Signals may be represented and processed in various domains, for example, time domain, frequency domain, and time-frequency domain. The ultimate goal of signal processing is information enhancement and extraction, for example, noise reduction, classification, detection, estimation, prediction, feature extraction, and so on.

7 HUMAN AND MACHINE SIGNALS

Machine signals are predominately used nowadays, and they are generated by and also mainly intended for machines. But signals are closely related to the signs intended for humans and may be utilized as human signals. In fact, one definition refers to a signal as 'a sign or notice, perceptible by sight or hearing, given especially for the purpose of conveying warning, direction, or information' (Simpson and Weiner, 2002).

7.1 Human signals and machine signals in measurement

In instrumentation and measurement, machine signals, and human signals are closely related in several ways. Firstly, human sensation and perception based upon the direct detection or sense of human signals are an important and necessary part of measurement and knowledge acquisition. Although they tend to have limited range and power, human perception can directly lead to the understanding of measurand(s) and their empirical relations, which are the basis of measurement.

Secondly, although machine signals may be quite different from human signals, they are actually often based upon human signals. This is necessary because they should carry and convey the same information. The similarity may extend to the signal generation mechanisms and energy forms.

Thirdly, machine perception extends the range and power of human senses. Measuring instruments or machines are able to handle more signals with greater capability. They can generate quantified numerical results, which subsequently lead to refined scientific knowledge.

Finally, the output signals of a measuring instrument or machine perception often have to be presented to a human observer. Indicating or displaying instruments have been a very important part of a measurement system. As measurement is often intended for the human observer, the interpretation of the output signals becomes an integral part of measurement.

7.2 Signals and semiotics

Indeed, as measurement signals may be regarded as symbols or signs, their interpretation may be explained using a semiotic triadic model or semiotic triangle, in which the meaning of the sign is related to both the specific sign presented and the observer's empirical experience of the real-world object.

Similar explanations can be found in measurement. In fact, Figures 6 and 7 presented in the previous sections are essentially a triadic model and may be referred to as a measurement triangle, as shown in Figure 10. Further discussions on semiotic issues in measurement are given in **Article 114, Models of the Sensor Interface, Volume 2**,

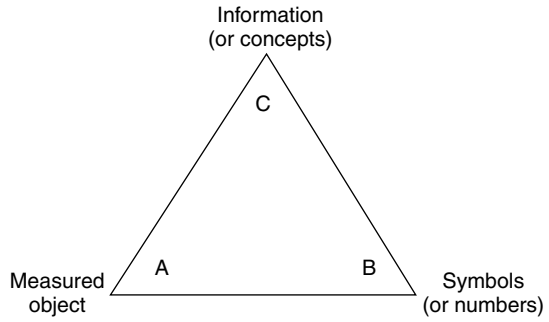

Figure 10. Measurement triangle.

but it is interesting to note here that measurement is primarily concerned with how measurement symbols (signals or data) are related to the observed object(s), whereas semiotics centers around how the symbols are interpreted. Both of them require the human observer's direct experience of the related system or process.

8 ROLE OF COGNITIVE PSYCHOLOGY

As an empirical science, cognitive psychology is concerned with mental processes and their effects on human behavior. It studies mental processes such as attention, sensation, perception, memory, language, reasoning, learning, problem solving, and decision making.

Human sensation and perception are the basis of measurement. As discussed in the previous sections, concepts, and definitions of measurands as well as their measurement scales are based upon experience and understanding of empirical relations developed from human sensation and perception.

Since human perception is subject to the limitation of human senses and direct experience, the concept of measurand and its measurement may go through continuous development and evolution. For example, the length standard has been redefined several times to reflect the latest understanding of the measurand.

The study of human sensation and perception could also provide useful examples, references, and knowledge for sensing and measurement. In some applications, sensors may even need to be integrated with human senses, for example, hearing aids.

At a higher level, the understanding of memory, language, reasoning, learning, and decision making can make a great contribution to information extraction, knowledge representation, manipulation, storing, and retrieval in measurement. It may also lead to suitable models for intelligent sensors and instrumentation.

1 THE SYSTEMS HIERARCHY OF MEASUREMENT SYSTEMS

As pointed out in **Article 5, Humans in the Real World, Volume 1**; **Article 2, Organization of Instrument Science, Volume 1**; and **Article 6, Substructure of Human–Machine Systems, Volume 1** (McGhee, Henderson and Sankowski, 1986 and McGhee *et al*., 1996), the wide view that Systems Engineering permits, highlights the placing of information and information systems within the structure of human–machine systems. The substructure of human–machine systems (**Article 6, Substructure of Human–Machine Systems, Volume 1**); (McGhee, Henderson and Sankowski, 1986; McGhee *et al*., 1996) may be represented by the hierarchical dendrograph or tree diagram given in the classification of Figure 1, where it can be seen that technical instruments, also called *instrumentation*, are clearly located as elements within the information subsystem of human–machine systems. Functional and structural characterization plays a primary role in this systems approach. Thus, the functions and boundary structure of information machines may be linked to the hierarchical structure of the complete system. Technical instrument systems, also called *technical instruments*, perform a number of different functions. Four primary functions, which are also shown in Figure 1, distinguish between instruments for measuring, calculating, communicating, and controlling.

2 MACHINES HIERARCHY OF MEASUREMENT SYSTEMS

Technical instruments are one of the two types of human-made machines. It is important to visualize the place occupied by these machines in a hierarchical classification of entities in the physical universe as illustrated in Figure 2. This will be recognized as similar to the hierarchy used in everyday situations by bioscientists and earth scientists who are interested in the ordering of the variety of living and nonliving things. The grouping of the physical and life sciences allows a clear division between these two important sciences. Two classes or groups of things, which may be called *superkingdoms*, make up the terrestrial *hyperkingdom*. The *superkingdom of living things* is made up of animals, plants, and other life-forms such as fungi and microbiological organisms. In the *superkingdom of nonliving things* it is possible to identify the separate groups or *kingdoms* of materials and machines. Materials that are important in all engineering activities may occur naturally as earth and minerals. There is also a diversity of human-made materials.

Only the *division* of the machine kingdom called the *division of information machines* is of immediate interest in this article. These machines may be grouped under

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

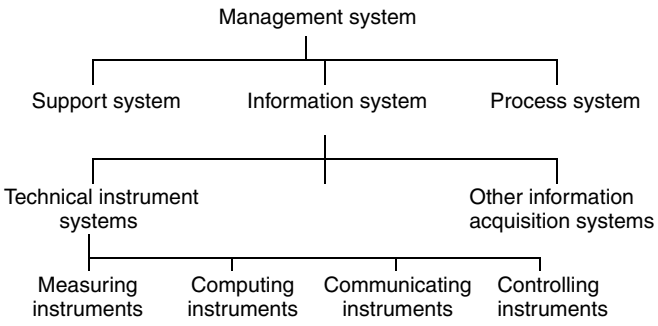

Figure 1. Instruments in a systems hierarchy.

the *subdivisions* of *deductive* or *inductive* types. Deductive types of machines perform mathematical calculations that inexorably lead to only one possible calculated result. On the other hand, inductive machines use rules for reasoning so that logical inference is used to form a conclusion, which is not generally numeric. Further distinctions lead to the four *classes* of information machines, which allow measuring, calculating, communicating, or controlling operations to be performed. A significant feature of these diagrams is the representation of the calculating function as providing an important primary support for the other three functions. This does not imply that calculation or processing cannot exist independently of the others. Indeed, the emphasis is meant to indicate the overall importance, which this data processing function possesses.

Further analysis indicates that lower levels of classification can be proposed in the same way as for biological systems. Thus, the lower level groups are called the *order*, *family*, *species*, and *subspecies* of the *machine kingdom*. The *order* and *family* groups will be considered below. Lower orders of this kingdom can be built up by considering specific kinds of sensors and other elements, that Solopchenko (1994) has called *formal data measurement components*, or FDMCs.

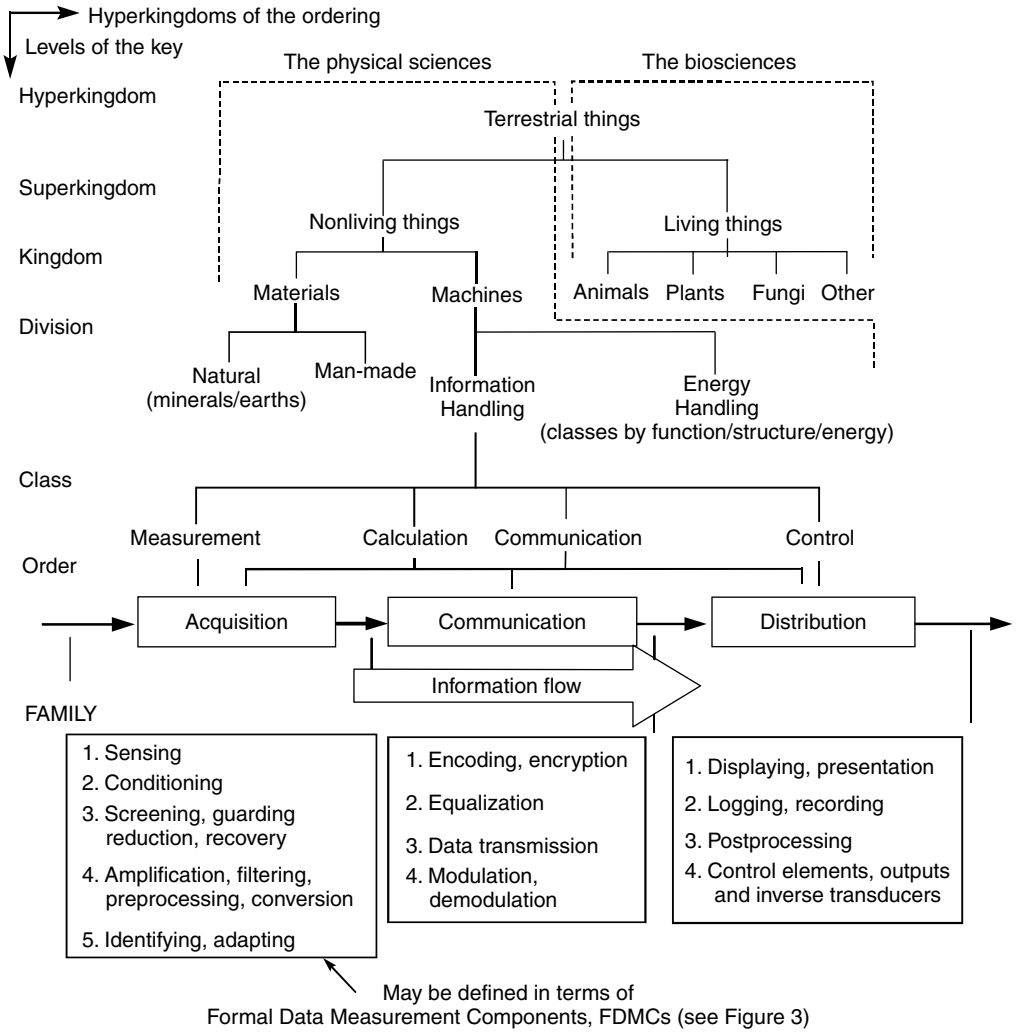

Figure 2. Instruments in a machines hierarchy. From the physical and biosciences to the ORDERS of technical instruments.

3 SECONDARY FUNCTIONS OR ORDERS OF MEASUREMENT SYSTEMS

Before any data can be processed, an ACQUISITION SUBSYSTEM acquires it. Within the context of measuring systems, further subdivision by function is possible as shown in Figure 2. Hence, a separation of the sensing and transduction functions, from those performed by any conditioning of the sensor output, is apparent. *Conditioning functions* may be galvanic isolation, screening, and guarding against electromagnetic penetration, circuit completion, and supply of energy to modulating types of sensors. Preamplification, which is also a subsidiary function appropriate to measurement, emphasizes the importance of electronic circuits and systems in modern instrumentation (Lang, 1987).

Information *Communication and Distribution* are important from the broader view of measurement in particular and information technology in general. Some subsidiary functions appropriate to communication systems are given in Figure 2. Aspects of distribution systems, such as data presentation and recording, and human–machine interfaces, are relevant for measuring systems. The dendrograph of Figure 2 also provides a clear illustration of the place occupied by materials science, which is important for sensors, in the ordering of the physical sciences.

4 FORMAL DATA MEASUREMENT COMPONENTS

Measurement systems are formed from the interconnection of FDMCs (McGhee *et al*., 2001; Solopchenko, 1994), which are their subsystems, elements, or building blocks. The term Data Measurement is used by Solopchenko (1994). A clear view of the place occupied by information machines, one of the two types of human-made machines in the physical universe, is given in Figure 2, which has been built upon the ideas of classification. The relationship between the various key levels of the division of information machines as far as the individual Formal Data Measurement Components, or FDMC, is shown in Figure 2. In the present context, they are referred to as *Data Measurement components*, or DMCs, to emphasize that analog and digital signals are used to carry information in the form of data from the sensor to the output of the instrument.

Extending Figure 2 allows the classification of FDMCs given in Figure 3. It can be seen from this figure that analog sensors are classified as Formal Analog DMCs, or FADMCs, while digital sensors are classified as Formal Analog-to-Digital DMCs, or FA-to-DDMCs. Each of the FDMCs shown in the tree diagram may be represented by a universal, coherent model (McGhee *et al*., 2001; Solopchenko, 1994), which allows the errors at each stage of a measurement chain to be taken into account. Since such an approach allows a single block diagram to be used to represent widely different DM components, the primary measurement aim of taking account of errors, their sources, and their quantification is achieved. The classification given in Figure 3 is supported by the definition of Data Measurement systems in Solopchenko (1994) and McGhee *et al*. (2001). It can be seen that measuring instruments perform a number of functions such as sensing, conditioning, screening, and guarding, amplification, and filtering as well as others. These functions may be described in terms of FDMCs as given in the tree diagram of Figure 3.

The physical world is dominantly analog in nature. Since interfacing with the real world is usually accomplished using analog means, it is clear that there is a group of FADMCs. This group of components is appropriately used

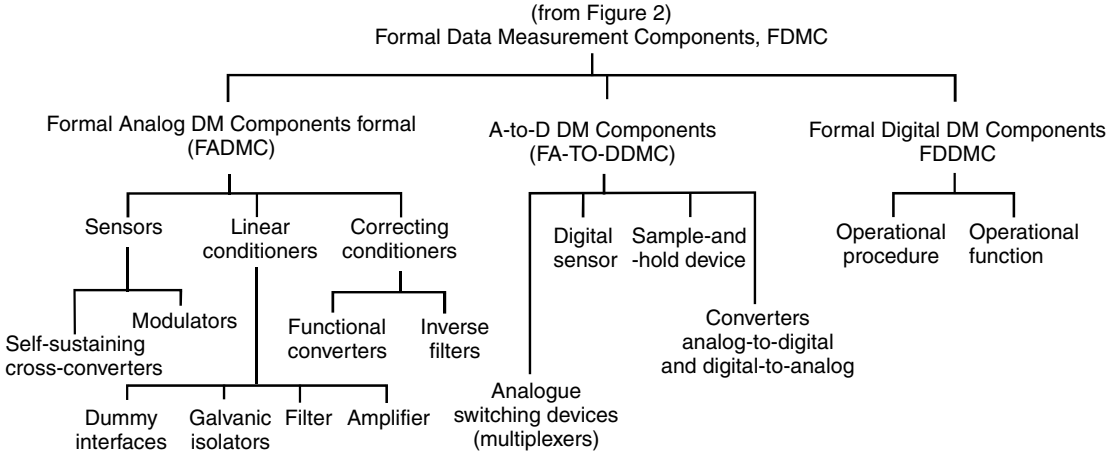

Figure 3. The classification of formal data measurement components, FDMCs.

when analog information handling operations are to be performed on the information bearing signals. In accordance with the predominance of digital instrumentation, most contemporary instrumentation uses a minimum of analog circuits. The group of formal components used in this case are named FA-to-DDMCs. Thus, all forms of analog-to-digital and digital-to-analog converters belong within this group. Other components are used for multiplexing purposes and for sample-and-hold operations.

It has been observed that software is the most important group of components in modern instrumentation systems. The two main groups of FDDMCs, may be either operational procedures or operational functions.

5 BOUNDARY PERSPECTIVE OF THE FOUR INFORMATION MACHINES

A combination of the tree diagrams of Figures 1 and 2 with the boundary view of human–machine systems leads to the boundary view of the four information machines given in Figure 4. This approach again illustrates the recursive aspect of the total, or holistic, view, which is a feature of the systems engineering method (McGhee *et al*., 1996; McGhee, Henderson and Sankowski, 1986). Only one output is shown in these diagrams. However, the totality of influencing impacts is evident.

A distinction is also seen between the control instrumentation system and the other three. Power flow is ultimately modulated or regulated by information feedback in control instrumentation systems, whereas power flow supports information flow in the other three. The information input or output at the system boundary may also be in any of the COMETMAN energy forms described in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. In the case of the measurement system, typical variables to be measured in different energy forms could be mechanical displacement, fluid flow rate, or thermodynamic temperature. As a complete visualization is complex, a simpler consideration is appropriate. The information and energy tetrahedron, described for systems in **Article 6, Substructure of Human–Machine Systems, Volume 1** and more fully for sensors in **Article 109, Structure and Energy in Sensor Systems, Volume 2**, is an illustration of such a simplification for the resource, contamination, and energy or signal forms of the input. Again it should be emphasized that, when this figure represents a measuring system with electrical information carrying output signals, the importance of the disturbance inputs is immediately seen. Contamination of the electrical output signal may be due to any of the energy forms shown, although only the temperature and chemical form are considered. Thus, the holistic aspect of the systems engineering approach, when applied to contamination using the information and energy tetrahedron, allows the introduction of the concepts relating to error sources and error characterization. Solopchenko (1994) has emphasized that taking errors and their sources into account is a primary aim in the analysis and design of measurement systems.

1 GENERALIZED ARCHITECTURE OF A MEASUREMENT SYSTEM

A measuring system has the general structure shown in Figure 1 (McGhee *et al*., 1996). There are three main divisions within the system. Input elements are primary sensing elements and transducers. This distinction is not trivial as there are many cases in which the sensing element is fashioned for one energy domain, while the transducer as its name implies converts the output of the sensing element into a signal in another energy form. The intermediate elements are usually electronic circuits and systems that make extensive use of *large scale integration* and possibly distributed *computing,* where *microprocessors* and *personal computers* are dispersed throughout the system. *Data transmission* and *telemetry* methods would be used if the measuring point is remote from the observation or display point. *Signal recovery/detection* may be necessary if the information is transmitted using a suitable form of modulation. Output elements could consist of some *postprocessing* before the output of the measuring system is used to provide a soft copy in a *display*, a hard copy in a *plotter*, or *printer*, or a stored record in a *data-logger*.

2 MICROPROCESSOR-BASED INSTRUMENTATION

The hierarchical subdivision of measurement systems reveals the existence of four classes of *Information Machines* (**Article 14, Hierarchical Aspects of Measurement Systems, Volume 1**; McGhee *et al*., 1996; McGhee, Henderson and Sankowski, 1986) that perform the primary functions of

1. measurement,
2. calculation,
3. communication,
4. control.

Essential support to the remaining three classes of information machines is provided by the calculating machine. They may also be used as central elements in microprocessor-based instrumentation (**Article 158, Microcontroller Systems, Volume 3**), as shown in Figure 2. Note the different structures at the input end of the system (Lang, 1987; McGhee *et al*., 1996, 2001; McGhee, Henderson and Sankowski, 1986). Among the many elements, it is important to note the **s**ample-and-hold, or S&H, units, the multiplexers and the data converters. The first p inputs are analog signal inputs, which are analog multiplexed before being **s**ampled and held, or S&H. This S&H operation is sequentially performed on each signal. By contrast, each of the analog inputs from $(p + 1)$ to q are synchronously sampled and held before conversion. A

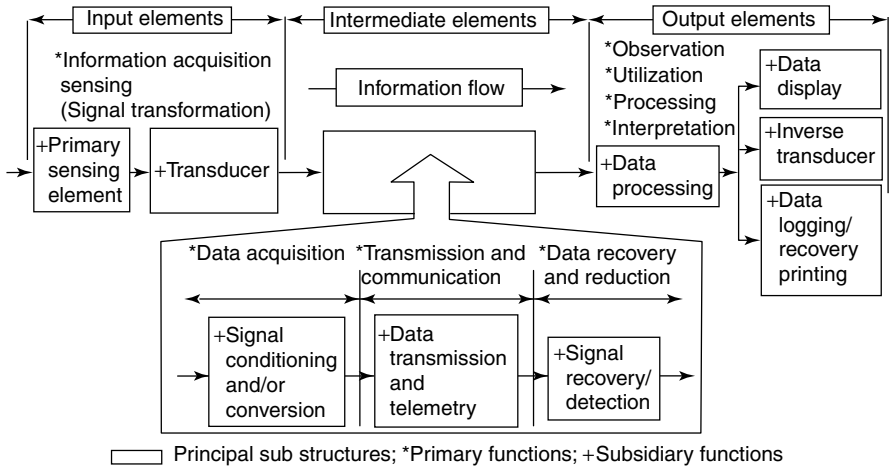

Figure 1. Generalized architecture for a measuring system. (Each system must be examined to allow consideration of particular features such as the absence of certain elements or the existence of more complex interconnection of structures).

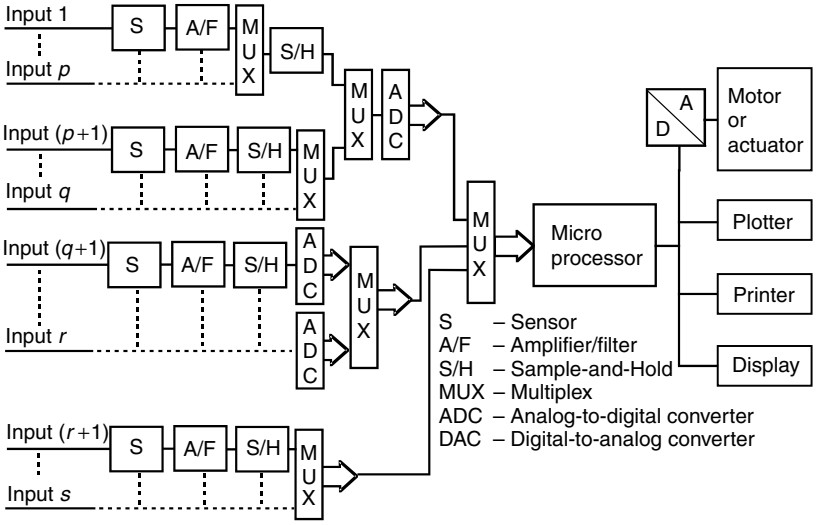

Figure 2. Architecture of microprocessor-based instrumentation.

possibility, which is shown for inputs $(q + 1)$ to r, is for individual channels to consist of a sensor, an amplifier/filter an S&H and a dedicated converter. All of the $(r + 1)$ to s inputs are assumed to be binary signals, which may be generated from switch contacts or other event detectors. In these lines, the amplifiers/filters may also include some kind of binary signal conditioner such as a Schmitt trigger.

Calculating machines, more commonly referred to as *computers, minicomputers* or *microprocessors*, which are considered in **Article 152, Fundamentals of the Stored Program Digital Computer, Volume 3**; **Article 153, Single Address Instruction Microcomputer, Volume 3**; **Article 154, Internal Operation of the Microprocessor, Volume 3**; **Article 155, External Operation of the Microprocessor, Volume 3**; **Article 156, Memory Management in the Microprocessor, Volume 3**; **Article 157, Data Acceleration in Computers, Volume 3**; and **Article 158, Microcontroller Systems, Volume 3**, process information using binary operations. These binary operations may belong to either the arithmetic group of operations or the Boolean group of operations. Arithmetic operations are addition, subtraction, multiplication, and division. Boolean operations consist of conjunction, or logical AND, disjunction, or logical NAND, and exclusive OR, or logical XOR. Microprocessors also allow the generation of diverse signal forms for use in system testing.

3 PROCESS CONTROL INSTRUMENTATION

A Process System is a complex combination of men, money, machines, and materials (**Article 5, Humans in**

the Real World, Volume 1, McGhee, Henderson and Sankowski, 1986) with the specific aim of producing some resource output having enhanced or surplus value. Instrumentation is required in process systems (Sydenham, 1983) to assist the humans involved in operating the process for assessing process behavior and so extending and refining their ability to monitor and control it.

In most cases, humans will be replaced by instruments for the following:

- *Measurement* – to provide more accurate, reliable data.
- *Calculation* – to process large quantities of data more quickly and efficiently.
- *Communication* – to transmit information for a wide range of uses, frequently between remotely separated transmitters and receivers.
- *Control* – to improve the quality of the process resource output with a minimal involvement of humans

A schematic of a typical process control measurement loop is shown in Figure 3. There are a number of identifiable stages of a process control system. The most commonly occurring structure is called a *loop*. In a loop, a sensor, also called a *gauge*, a primary transducer, or pickup, measures a physical variable whose value is to be controlled. As this signal is rarely in a form that is convenient for easy handling, it must be conditioned by using some appropriate technique. Such conditioning is most commonly performed using electronic circuitry consisting of amplifiers, filters, and data converters. All of this circuitry must be designed to be intrinsically safe if the instrument is to be used in a hazardous location.

Subsequently, this conditioned signal is transmitted or relayed to a *controller*. The controller compares the conditioned received signal with the process *set-point*. From this comparison, it generates a control signal, which is then amplified, if necessary, before being applied to an *actuator* and *final control element*. The actuator and final control element cause a manipulation that appropriately regulates the flow of energy in the form of say a fluid-flow rate, a pressure, a level, a temperature, or a chemical composition.

A loop will also consist of some means of monitoring its behavior by displaying the value of the set-point, the error, and any operational limits. Such facilities may also include a graphical mimic diagram of the process, as well as appropriate means for logging and recording of process data. Status, alarm, and warning indicators are also normally included.

Some severe problems, which must be dealt with using process instrumentation, are as follows:

- Generally, the instruments of whatever class must remain in operation for 24 h every day with attention only being provided during scheduled maintenance periods.
- The reliability of the instruments must be high to ensure that they perform their specified function. Failures cause lost production, which can be compounded if the failure endangers the safety of the plant or more seriously of the personnel or of the environment.
- Instrumentation may operate in a wide range of environments. They may operate in hazardous locations. They may also be subjected to extremely high or low temperatures, dry or humid. Under failure conditions, the instrumentation should always '*fail-to-safety*'. This means that hazardous processes should be rendered safe in a controlled manner, and in such a way as to present no dangerous occurrences or conditions, which could

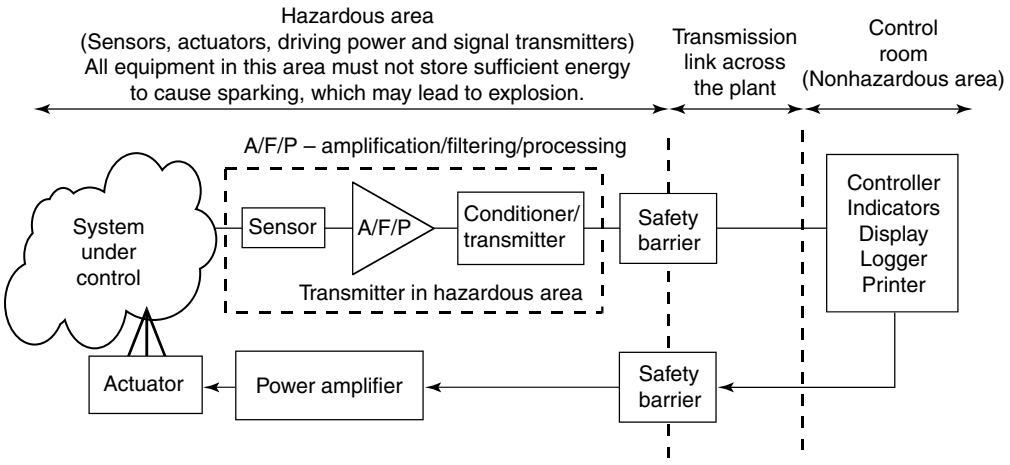

Figure 3. Architecture of a process control measurement loop.

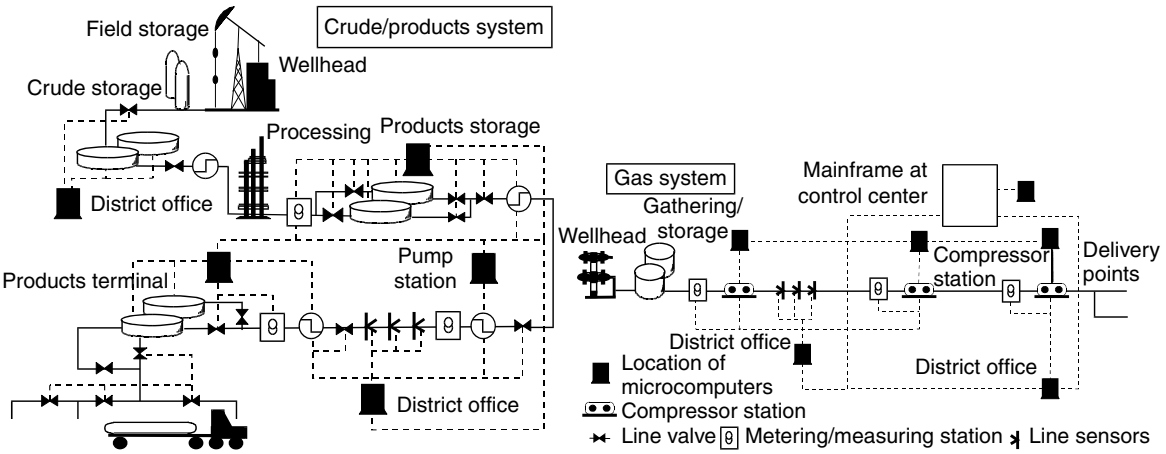

Figure 4. Schematic diagram of the instrumentation in a crude/petroleum products system and a gas process system.

lead to damage of equipment or, more seriously, to injury or death of personnel.

4 PETROLEUM AND GAS PROCESS INSTRUMENTATION

Computer-based instrumentation is now regarded as indispensable in these industries. Figure 4 shows the main parts of the instrumentation for both petroleum and gas process systems. Although petroleum and gas process systems handle different materials, they have the following common features:

- Both have wellheads, which are used to extract the raw resources.
- Secure storage facilities are required in both cases.
- Distribution is achieved through piping, which may be extensive.
- Security against dishonest fiscal accounting and custodial delivery is essential.

The figures emphasize the important role played by computers as well as the diversity of the systems and noteworthiness of their distributed nature. There are many remote measuring points. These may be in locations, such as at the wellhead storage, where large numbers of temperature, level, flow, and pressure variables need to be measured. It is necessary to integrate these measurements to provide effective control of such complex systems. Pipelines, which are an indispensable part of both petroleum and gas process systems, require supervision and control just as much as the process systems themselves. Indeed, the pipeline system could be considered a complex process in its own right.

5 SUPERVISORY CONTROL AND DATA ACQUISITION SYSTEM

To assist in the overall control of the process system and its distributing pipeline requires the incorporation of an important system known as a Supervisory Control And Data Acquisition, or SCADA, system. Figure 5 illustrates the block diagram of a typical SCADA system. The master station includes fully redundant computers that communicate over suitable links such as microwave or cable links to Remote Transmitter Units (RTUs).

The master station instrumentation also consists of what is called a Human–Machine Interface, or MMI. This interface consists of Visual Display Units, or VDUs, printers, and data loggers. Other graphic facilities will include a hard mimic hydraulic profile of the process and its associated pipeline. This MMI also includes a control panel for process/pipeline dispatchers. It is also usual to include redundant communication channels between the various pumping/compressor stages of the pipeline, and also between the various important elements of the process.

Master station computers process all-important data at regular intervals so that hourly or daily reports may be printed automatically. Data to be printed on these summary reports may be inventories of process/pipeline performance, volumes of various materials received and delivered. Volumes and leakage information may also be indicated. This data may be used for direct invoicing.

6 REMOTE TRANSMITTER UNITS

Remote Transmitter Units, which are microprocessor-based units for digitally multiplexing data before transmission to the master station, are connected in a SCADA system as

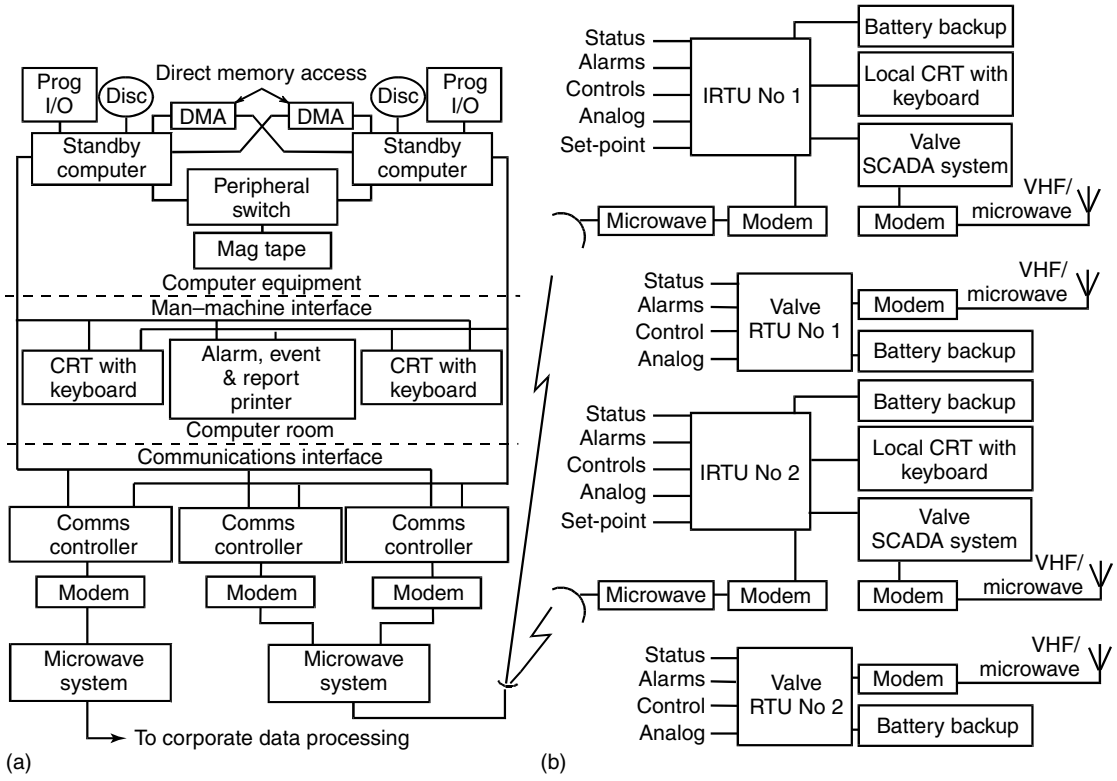

Figure 5. A Supervisory Control and Data Acquisition, or SCADA, system: (a) computer equipment, human–machine interface and communications interface, (b) field located Intelligent Remote Transmitter Units (IRTUs) in a SCADA system.

shown in Figure 5. It is also possible that these RTUs are independent, in so far as they implement local supervision, data acquisition, and control in their own right. RTUs may also have some *intelligence*, in which case they are referred to as IRTUs.

Typically, an RTU may acquire data from pumping or compressor stations on a pipeline or perhaps from a local process. Variables such as suction, pump case temperature, discharge and process temperatures and pressures are typical of the wide range, which are monitored. Flow rate is also important, especially if the discharge is an origin or destination location for custodial transfer of the product. As volume accumulation is also important, then tank levels and temperatures must be measured, so that temperature compensated tank volumes can be computed both locally and at the master station. Leaks may also be detected if flow rates are monitored at separate locations in the product flow system. Measurement of energy consumption in kilowatt-hours is also essential.

Status and alarm signals are required to ensure safe and reliable operation of the system. It is normal to indicate the open or closed status of valves, on or off status as well as high levels of vibration, shaft bearing temperature and so on, of pumps and motors, low suction pressures, power failures, relief valve open, leak detection, fire and smoke detection, high sump level, and many more. Of the many control actions, the most common are starting and stopping pumps and motors as well as opening and closing valves. Others are set-point control of many system variables such as valve throttling, turbine speed, vessel fluid level, pressure, temperature, flow rate, and discharge pressure regulation, not forgetting station reset or shutdown.

Technology convergence has meant that programmable controllers and/or IRTUs now almost exclusively perform many process operations involving logical sequence control. Continuous analog control uses direct digital control strategies, which provide fast control response while processing or in transit. Design changes are easily implemented using these programmable controllers, with downloading of program revision to the RTUs by the master station.

1 INFLUENCE EFFECTS

Any measurement system has imperfections and any act of measurement is liable to errors. Measurement errors either originate from system deficiencies (for instance system noise, quantization, and drift), or are due to environmental influences such as thermal, electromagnetic, and mechanical interference. Manufacturers of measuring instruments try to minimize such intrinsic errors by a proper design of the instrument structure; the remaining imperfections should be given in the data sheets of the system. The user of a measurement system should minimize additional errors that could arise from improper use and faulty interfacing.

Besides influence effects from outside the system, instruments may suffer from many other imperfections. They influence the magnitude of the instrument transfer (*multiplicative error*) or give rise to unwanted output signals (*additive errors*). Both error types may occur as a deterministic or a stochastic error. Figure 1 shows a simplified model of a measurement system, with an indication of these error sources. In this figure, x_m is the measurand and y_o the output signal. Additive error signals are modeled as additional input signals: x_d and x_s represent deterministic and stochastic signals respectively. They model all kinds of interference from the environment as well as the equivalent input error signals due to system offset and noise. Additive error signals are always expressed as (equivalent) input signals, which facilitates comparison with the actual input signal.

The error inputs ε_d and ε_s symbolize deterministic and stochastic multiplicative errors; they mainly originate from environmental influences: temperature changes, electric, magnetic, or electromagnetic fields, mechanical vibrations, shocks, and nuclear radiation. For this simplified model, the output signal of a sensor can be written according to:

$$y_o = S(1 + \varepsilon_d + \varepsilon_s)(x_m + x_d + x_s) \tag{1}$$

where S is the nominal sensitivity (transfer) of the measurement system. This model is useful for evaluating system errors, influence factors, and the various error-reduction methods. When all influence factors are eliminated, the output of the system satisfies:

$$y_o = S \times x_m \tag{2}$$

This situation is hypothetical and will never occur in practice. Therefore, it is important to know what is the deviation from this ideal situation and to quantify it. It is equally important to know the type of error: deterministic or stochastic; additive or multiplicative, in order to effectively suppress them when necessary. Error suppression can be obtained by a sophisticated design, or by just some additional signal processing. Some of these methods will reduce mainly additive sensors, others minimize multiplicative errors. We will discuss some basic error reduction methods in the next sections.

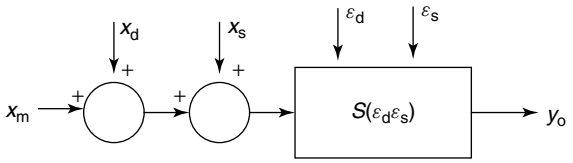

Figure 1. Simplified sensor model including error signals.

2 ISOLATION OF INFLUENCE EFFECTS

Error signals can be reduced or eliminated by isolating the measurement instrument from the interference source. The error signals may be kept outside the measurement system by several isolation techniques, depending on the type of signal. The isolation techniques are also referred to as *shielding*, *guarding*, or *(pre)filtering*, according to the implementation. We briefly review some causes and the associated isolation methods.

2.1 Capacitively induced errors

Capacitively induced errors arise by electric injection of spurious signals, through a capacitive connection between the error voltage source (for instance, wires of the mains) and the measurement system, notably the electrical parts at its input (Figure 2a).

Capacitive coupling (in the figure, the distributed capacitances are modeled with only lumped capacitors) results in an equivalent error signal:

$$V_{n,o} = \frac{C_s}{C_g} V_{n,i} \tag{3}$$

with the assumption $C_s < C_g$. Its effect can be reduced by a *grounded* shield around the sensor structure and the input leads (Figure 2b). The equivalent error signal is reduced to

$$V_{n,o} = \frac{C_{rest}}{C_{sh}} V_{n,i} \tag{4}$$

This approaches zero when the rest capacitance can be made very small (so an effective enclosure around the sensitive parts of the system is provided).

2.2 Magnetically induced errors

Magnetically induced signals arise by a time varying magnetic flux through the loop made up by the input circuit.

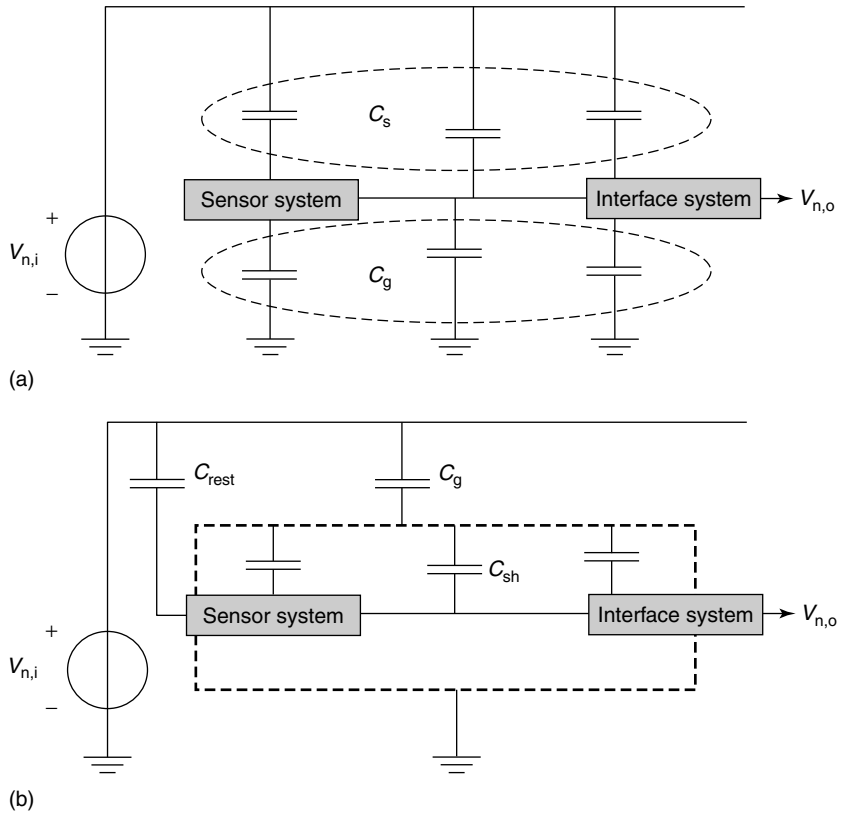

Figure 2. Capacitively induced errors: before and after shielding.

The induced error signal amounts to

$$V_{\mathrm{n,o}} = \frac{\mathrm{d}\Phi}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\oint_A B \times \mathrm{d}A\right) = A\frac{\mathrm{d}B}{\mathrm{d}t} \tag{5}$$

and is proportional to the surface area of the loop, the strength of the magnetic field, and the frequency of the field (for instance 50 or 60 Hz from the mains). The interference can be reduced by a shield made of a material with a high magnetic permeability (to reduce the induction B), and by minimizing the area of the loop A (for instance, by placing the input leads close to each other or by twisting).

2.3 Temperature induced errors

Changes in environmental temperature may introduce both additive errors (for instance, offset drift) and multiplicative errors (for instance, the temperature coefficient of the transfer). This interference can be reduced by thermal shielding (an encapsulation with high thermal resistance or a temperature controlled housing).

2.4 Optically induced errors

Unwanted optical input can be stopped by optical filters; many filter types are available on the market. Measurand and interferences should have a substantial difference in wavelength to make the filtering sufficiently effective. Optical interference originating from environmental light (daylight, lamplight) has a low frequency (DC, 50/60 Hz and harmonics). If the frequency of the optical measurand is in the same band, filtering is not a solution. In that case, modulation may help reduce interference. If the measurement system contains an auxiliary light source (as with many optical systems), that signal source can be modulated (using an LED or laser diode). If the source itself cannot be modulated, optical modulation can be performed by, for instance, a chopping wheel, as is applied in many pyroelectric measurement systems.

2.5 Mechanically induced errors

Mechanical disturbances (shocks, vibrations) are reduced by a proper mechanical construction with elastic mounting, performing suitable damping of the vibrations. The method requires knowledge about the most important resonance frequencies of the structure.

3 COMPENSATION FOR INFLUENCE EFFECTS

Compensation is a simple and effective method of minimizing additive errors due to interference signals. The basic idea is as illustrated in Figure 3, where the technique is applied on the sensor level.

In Figure 3(a), the output of the sensor is y_1, which contains unwanted signal components, for instance, due to interference x_i or offset. From this output, a compensation voltage y_c is subtracted. The condition for full compensation is $y_\mathrm{c} = S \times x_\mathrm{i}$, making $y_\mathrm{o} = S \times x_\mathrm{m}$, independent of x_i. For correct compensation, the interference signal as well as the sensor transfer should be known. One way of accomplishing compensation is by an adjustable compensation signal: at zero input, y_c is (manually) adjusted to a value at which the output is zero. A more elegant way of compensation is by applying a second sensor, as illustrated in Figure 3(b). The measurement signal, x_m, is supplied simultaneously to both sensors, which have equal but opposite sensitivity to the measurement input (for example, two strain gauges, one loaded on compressive stress, the other on tensile stress). A minus sign represents the opposite sensitivity of the sensors. The two output signals are subtracted by a proper electronic circuit. Because of the antisymmetric structure with respect to the measurement signal only, many interference signals appear as *common* output signals, and are thus eliminated by taking the difference of the two outputs.

The effectiveness of the method depends on the degree of symmetry of the double-sensor or differential sensor structure. From Figure 3 it follows:

$$y_1 = S_{m1}x_\mathrm{m} + S_{i1}x_\mathrm{i} \tag{6}$$

$$y_2 = -S_{m2}x_\mathrm{m} + S_{i2}x_\mathrm{i} \tag{7}$$

where S_{mk} and S_{ik} are the sensitivities for the measurement signal and the interference signal. So, the output of the total

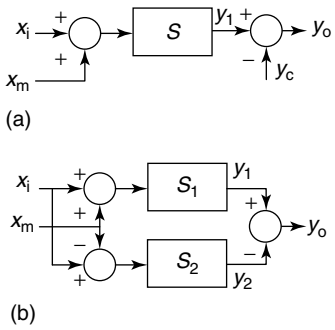

Figure 3. General layout of compensation; (a) compensation signal and (b) balanced configuration.

sensor system equals

$$y_o = (S_{m1} + S_{m2})x_m + (S_{i1} - S_{i2})x_i \tag{8}$$

The sensitivities S_{m1} and S_{m2} are about equal, so the output signal becomes

$$y_o = 2S_m x_m + \Delta S_i x_i = 2S_m \left(x_m + \frac{\Delta S_i}{2S_m} x_i \right) \tag{9}$$

Analogous to the definition of the rejection ratio for differential amplifiers, we can define a quality measure for the imbalance of the differential sensor:

$$H = \frac{2S_m}{\Delta S_i} \tag{10}$$

a parameter characterizing the system's ability to distinguish between measurand and interfering signals.

The method is illustrated with a two-active element Wheatstone bridge in Figure 4.

In this half-bridge mode, R_3 and R_4 are fixed resistances; R_1 and R_2 are resistive sensors: their resistance values change with a particular physical quantity as well as an interfering signal, according to

$$R_1 = R(1 + S_{m1}x_{m1} + S_{i1}x_{i1}) \tag{11}$$

$$R_2 = R(1 + S_{m2}x_{m2} + S_{i2}x_{i2}) \tag{12}$$

Here, S_{mk} is the sensitivity of sensor k ($k = 1, 2$) to the measurand (for instance, deformation), and S_{ik} is the sensitivity to the interference signal (for instance, temperature). Note that in this system, the sensor resistance is just R at a particular reference value of the measurand, and at zero interference. Assuming both sensor parts experience the same measurement signal, and have equal but opposite sensitivities to the measurand, the bridge output voltage approximately satisfies, the equation:

$$\frac{V_o}{V_i} = \frac{1}{2} S_m x_m + \frac{1}{4} \Delta(S_i x_i) \tag{13}$$

If both sensor parts have equal sensitivity to interference (by a symmetric sensor design), and both sensor parts experience the interference equally, the error term is zero, and the interference is completely eliminated. The equation is useful for making a quick assessment of the error due to asymmetry, relative to the measurement signal.

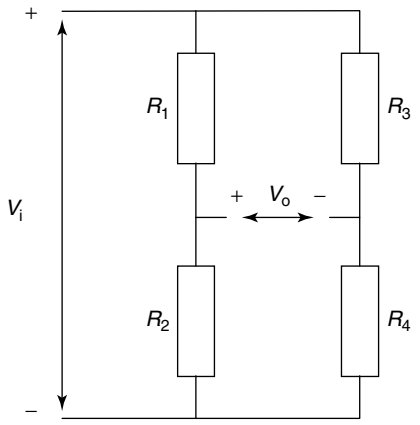

Figure 4. Measurement bridge with two active elements.

4 FEEDBACK METHODS FOR SUPPRESSING INFLUENCE EFFECTS

Feedback is an error reduction method originating from the early amplifiers with vacuum tubes. Their instable operation was a real problem until the systematic application of feedback, which reduces in particular multiplicative errors. Figure 5 shows the general idea.

The sensor has a nominal transfer S, but due to multiplicative interference, it has changed to $S(1 + \varepsilon_i)$. The feedback is accomplished by an actuator with an inverse transduction effect, and a transfer k. From classical control theory, the error reduction factor can easily be found. The transfer of the total system, S_f, is given by

$$S_f = \frac{S}{1 + S \times k} \tag{14}$$

A relative change dS in the sensor transfer S causes a relative change dS_f in S_f according to

$$\frac{dS_f}{S_f} = \frac{1}{1 + kS} \times \frac{dS}{S} \tag{15}$$

So, the relative error in the feed-forward part is reduced by a factor equal to the loop gain $1 + kS$ of the system. The penalty for this improvement is a reduction of the overall sensitivity with the same factor.

Feedback also reduces additive interference signals to a degree that depends on the point of injection in the system.

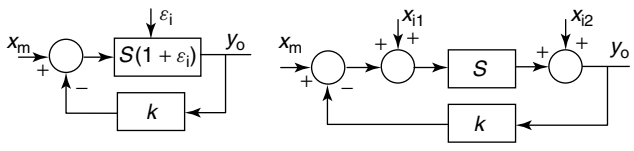

Figure 5. Interference signals in a feedback system.

Two cases are discussed (Figure 5). The output due to two interfering signals x_{i1} and x_{i2} equals:

$$y_o = \frac{S}{1+kS} \times x_{i1} + \frac{1}{1+kS} \times x_{i2} \tag{16}$$

Obviously, signals entering at the input of the system are reduced by feedback as much as the measurement signal (so the SNR is not better); interfering signals injected at the output of the sensing system are reduced by a factor S more than the measurement signal.

Feedback reduces errors in the forward signal path: the transfer is mainly determined by the feedback path. Prerequisites for an effective error reduction are

- high forward path transfer,
- stable feedback path transfer.

The application of this method to sensors requires a feedback element with a transfer that is the inverse of the sensor transfer. The imperfections of the sensor are reduced; however, the demands on the actuator are high. The method is illustrated with an example of a capacitive accelerometer system in which two error reduction methods are combined: compensation by a balanced sensor construction and feedback by an inverse transducer (Figure 6).

A displacement of the seismic mass m results in a capacitance difference ΔC; this value is converted to a voltage that is compared with a reference value (here this value is zero). The amplified voltage difference is supplied to an electromagnetic actuator that drives the mass back toward its neutral position. When properly designed, the system reaches a state of equilibrium where the applied inertial force is compensated by the electromagnetic force from the actuator. The current required to keep equilibrium is a measure of the applied force or acceleration.

A more detailed model of this system, for instance, for stability analysis, is depicted in Figure 7. All transduction steps are visualized in separate articles.

Obviously, the feedback is performed in the mechanical domain, by counteracting the inertial force F_i with the electromagnetic force F_a of the actuator. The transfer function of the whole system can easily be derived from this model,

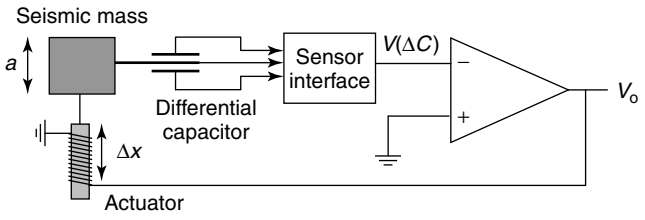

Figure 6. Illustration of a feedback system to reduce sensor errors: capacitive accelerometer.

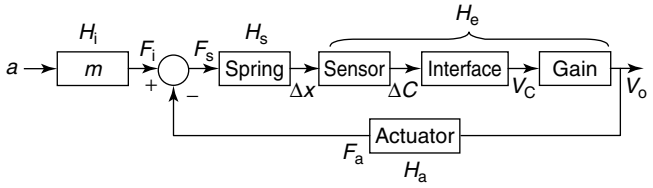

Figure 7. Model of the differential capacitive accelerometer with feedback.

and is given in the next equation:

$$V_o = \frac{H_s H_e}{1 + H_a H_s H_e} H_i a \tag{17}$$

In this equation, H_i is the transfer from applied acceleration a to inertial force F_i. H_s is the transfer of the mechanical spring: from force to displacement. The transfer of the electrical system: capacitive sensor, electronic interface, and amplifier together) is H_e. Finally, H_a is the transfer of the actuator. For $H_a H_s H_e \gg 1$ the transfer function of the total sensor system becomes:

$$V_o = \frac{H_i}{H_a} a \tag{18}$$

Indeed, this is independent of the spring stiffness, the sensor transfer, the interface, and the gain of the amplifier, according to the feedback principle. In equilibrium, the mass is at its center position. Hence, no particular demands have to be made on the spring, the sensor, and the interface circuit; the only requirement is a low zero error. Actually, the requirements with respect to the sensor quality have been transferred to those of the actuator. The system transfer only depends on the seismic mass m and the actuator transfer H_a.

There are various sensors on the market that are based on the feedback principle, which is discussed in more detail in **Article 113, Force-feedback Sensors, Volume 2**.

5 CORRECTION METHODS TO REDUCE INFLUENCE EFFECTS

An erroneous sensor signal can be corrected if knowledge about the causes of the errors or the value of the errors is available. Two different strategies can be distinguished:

- static correction
- dynamic correction.

In the first class of strategies, correction is performed while leaving the sensor as it is. Figure 8 shows the general configuration for two approaches. In the model-based

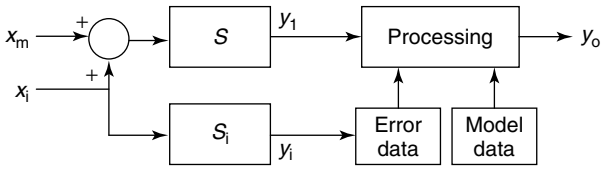

Figure 8. Model-based correction and measurement-based correction.

approach, the sensor signal is corrected on the basis of prior knowledge about the origin of the error, for instance, nonlinearity or a calibration curve, stored in a look-up table. If the errors are unknown (interference), the error signal could be measured separately by additional sensors. The output of these sensors is used to correct the original sensor signal. The method is straightforward, but requires additional sensors, at least one for each type of interference.

Dynamic correction involves a particular sensor design. Basically, the method involves a series of measurements of the same quantity in such a way as to eliminate the errors by postprocessing. This can be done in various ways, according to the type of quantity and error:

- multiple input signal measurements, eliminating scale, and offset errors;
- cyclic interchanging of components (dynamic matching);
- cyclic changing in the sensitivity direction of the sensor (flipping).

The first method is illustrated in Figure 9. Alternately, the input of the system is connected to the measurand (yielding an output y_{o1}), to 'ground' (giving output y_{o2}) and to a reference (resulting in the output y_{o3}). Multiplicative errors due to the interfering signal x_s are represented by the relative error ε_s.

The three output signals are:

$$y_{o1} = S(1 + \varepsilon_s)(x_m + x_{off}) \tag{19}$$

$$y_{o2} = S(1 + \varepsilon_s)(x_{off}) \tag{20}$$

$$y_{o3} = S(1 + \varepsilon_s)(x_{ref} + x_{off}) \tag{21}$$

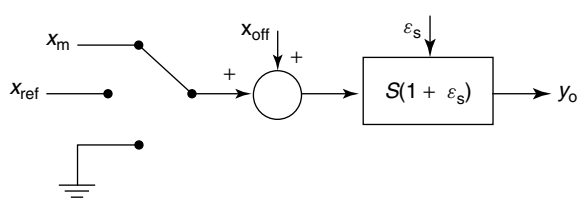

Figure 9. Three-point measurement to eliminate scale and offset errors.

From these equations, the measurand can be calculated:

$$x_m = \frac{y_{o1} - y_{o2}}{y_{o3} - y_{o2}} x_{ref} \tag{22}$$

Offset and scale errors are completely eliminated if the errors do not change during the sequence of the three measurements. The method requires a reference of the measurand type, as well as the possibility of completely isolating the input from the measurand to find the offset error contribution. For most electrical quantities, like voltage, capacitance, and resistance, this is quite an easy task. This is not the case for many other physical quantities: repetitively short circuiting the input of a magnetic field sensor or a force sensor, for instance, without removing the measurand itself requires complicated and therefore impractical shielding techniques.

Modulation, as discussed before, is a very effective way of eliminating offset and the effects of influence factors. The basic idea is to shift the (low frequency) information in the input signal to another, higher frequency band. After high-pass filtering, the offset and drift are effectively eliminated. However, modulation of the input signal is not always possible. An alternative way of reducing offset is flipping the directivity of the sensor, without changing the sign and value of the offset (Van Putten, Van Putten and Van Putten, 1994). Clearly, the method can only be applied to sensors that are sensitive to the direction of the input quantity (which should be a vector). Another technique, applicable to modulating sensors, is spinning. An example where this technique is applied is the spinning-current Hall sensor (Bellekom, 1998). Here, the auxiliary current is electronically rotated stepwise with respect to the geometry, yielding a number of outputs; each output contains an offset signal, originating from layout asymmetries of the chip. However, going around the average of the offset is zero, and by averaging the outputs over a full cycle, offset is almost completely eliminated.

1 DEFINITIONS AND EXAMPLES OF EMC AND EMI

Electromagnetic interference (EMI) occurs when one electrical circuit interferes with another. EMI may exist between components within an electronic circuit, between electronic, and electrical subsystems, or between separate instruments. Electromagnetic compatibility (EMC) is the art and science of reducing EMI to acceptable levels.

General and specific accounts that review EMI and EMC, provide practical solutions to EMI and EMC, and provide key references are Fowler (1996), Johnson and Graham (1993), and Ott (1988).

Typically, the electromagnetic interference is called *noise*, which is any undesired electrical activity coupled from one circuit into another. EMI has three necessary components: a noise source, a susceptible circuit, and an energy coupling mechanism. EMC is concerned with reducing or eliminating the interference or noise to acceptable levels.

Examples of noise sources include

- power lines or mains
- motors
- high-voltage equipment (e.g. spark plugs, igniters)
- discharges and sparks (e.g. lightning, static electricity)
- high-current equipment (e.g. arc welders).

Examples of susceptibility within receiver circuits include

- crosstalk on inputs in digital logic causing unintentional changes in logic states
- crackle in the reception of radio
- static discharge that destroys components, such as keyboard circuits.

2 BASIC PRINCIPLES OF ENERGY COUPLING

EMI has three necessary components: a noise source, a susceptible circuit, and an energy coupling mechanism. Typically, neither the noise source nor the susceptible circuit may be eliminated; this leaves you to reduce or remove the energy coupling mechanism between the two.

2.1 Reciprocity

Anything that reduces emissions usually makes the circuit less susceptible to disruption. This means that the same techniques to reduce noise or remove a noise source will probably work to reduce susceptibility within receiver circuits. Reciprocity is a useful guideline but not an absolute rule.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

ISBN: 0-470-02143-8.

2.2 Impedance versus resistance

One component of understanding energy coupling and interference in EMI and EMC is to understand how electrical current flows. Current always follows the path of lowest impedance Z (*see* (1)), not necessarily the path of lowest resistance R. Remember that impedance includes reactive terms for inductance L and capacitance C. Consequently, electrical charge follows the path that represents the minimum of resistance and inductive reactance and maximum capacitive reactance; generally, this is true for signal frequencies above the audio range (>3 kHz).

$$Z = \sqrt{R^2 + \left[\varpi L - \left(\frac{1}{\varpi C}\right)\right]^2} \tag{1}$$

2.3 Pseudo-impedance

A very useful diagnostic tool for signal frequencies above the audio range (>3 kHz) is Pseudo-impedance as explained by Van Doren (1991). Pseudo-impedance is the diagnostic ratio of the rates of change in voltage to current.

$$\text{Diagnostic ratio} = \frac{\left(\frac{dv}{dt}\right)}{\left(\frac{di}{dt}\right)} \tag{2}$$

3 MECHANISMS OF NOISE ENERGY COUPLING

Noise may couple between circuits through four primary mechanisms: conductive, inductive, capacitive, and electromagnetic.

3.1 Conductive coupling

Conductive coupling, see Figure 1, requires a connection between the source and the receiver that completes a continuous circuit. Often these connections are inadvertent; when they are, they are called *sneak circuits*.

A ground loop is a particular form of conductive coupling, which has two primary characteristics. It has multiple ground connections providing multiple return paths that cause significant current flow in the grounding structure. It unbalances the desired circuit. (*See* Figure 5 in **Article 177, Grounding and Shielding, Volume 3**.)

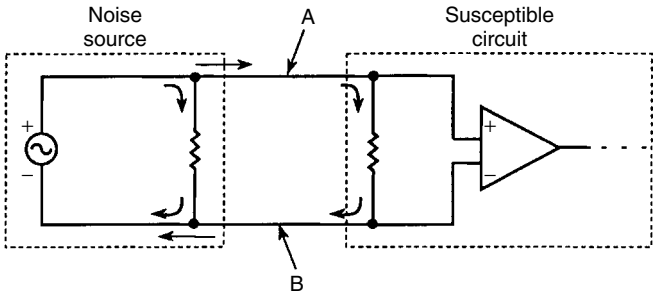

Figure 1. Conductive coupling. If either connection A or B is removed, the conductive noise is eliminated. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

3.2 Inductive coupling

Inductive coupling requires a receptive loop circuit and a changing magnetic flux through the loop. A current bearing a loop circuit may be the source of the changing magnetic flux. The coupled or induced noise voltage is proportional to the time rate of change in current in the source and the loop area of the circuit(s). The Pseudo-impedance or diagnostic ratio in (3) gives a value much less than free-space impedance.

$$\text{Inductive coupling} = \frac{\left(\frac{dv}{dt}\right)}{\left(\frac{di}{dt}\right)} \ll 377\,\Omega \tag{3}$$

Straight wires create small loops that can magnetically couple. Twisted wire eliminates the effective loop area of the cables and magnetic coupling, thus eliminating inductive coupling (see Figure 2).

Inductive coupling meets the principle of current flow through the path of least impedance in designing circuit boards. The return current mirrors the topology of the signal current; that is, it flows in the return plane immediately adjacent to the signal line. This means that the return plane of a circuit board should not have any slots in it that cut across the signal path. A slot, Figure 3, increases the loop area, hence, it increases the inductive reactance and the generation of a magnetic field.

3.3 Capacitive coupling

Capacitive coupling requires both proximity between circuits and a changing voltage. The coupled or induced noise voltage is proportional to the time rate of change in the voltage in the source and inversely related to separation distance

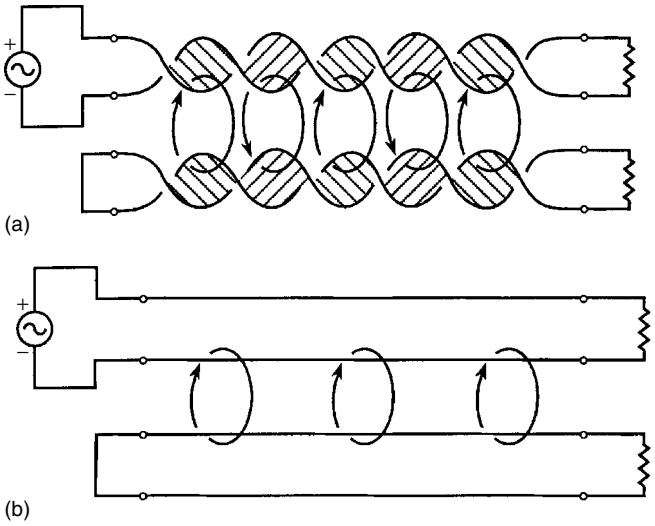

Figure 2. Effect of twisted wire. (a) Straight wires create small loops that can couple magnetically and (b) twisted wire eliminates the effective loop area of cables and magnetic coupling. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

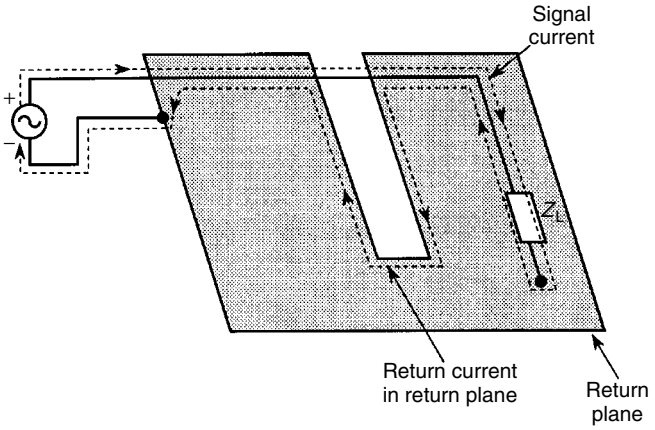

Figure 3. A slot in the return plane of a circuit board increases the current loop area and the self-inductance. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

between the circuits. The Pseudo-impedance or diagnostic ratio in (4) gives a value much larger than free-space impedance.

$$\text{Capacitive coupling} = \frac{\left(\frac{dv}{dt}\right)}{\left(\frac{di}{dt}\right)} \gg 377\,\Omega \qquad (4)$$

Generally, a properly connected shield will reduce capacitive coupling (see Figure 4).

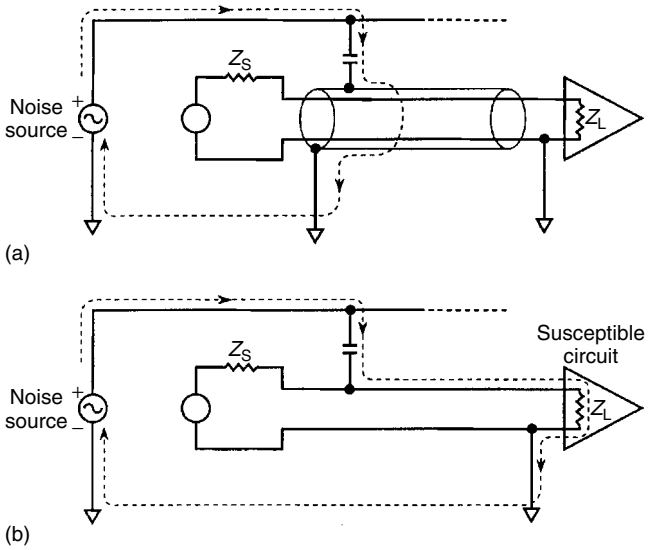

Figure 4. Effect of shielding. (a) Without the shield, stray currents can disrupt susceptible circuits and (b) a properly connected shield can divert capacitively coupled current from susceptible circuits. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

3.4 Electromagnetic coupling

Radiated electromagnetic energy requires an antenna in both the noise and susceptible circuits. The antenna must be an appreciable portion of the wavelength. Electromagnetic coupling usually occurs for frequencies greater than 20 MHz and for signal conductors that are longer than a small fraction of the fundamental wavelength ($>\lambda/20$). The Pseudo-impedance for electromagnetic coupling in (5) is around the value for free-space impedance or 377 Ω; practically, any value between 100 and 500 Ω is a reasonable value for electromagnetic coupling.

$$\text{Electromagnetic coupling} = \frac{\left(\frac{dv}{dt}\right)}{\left(\frac{di}{dt}\right)} \cong 377\,\Omega \qquad (5)$$

EMI through electromagnetic coupling always begins as conductive (i.e. current in wires), becomes radiative, and ends as conductive, that is, fields interact with circuitry. Cables can be primary sources and receivers for frequency of operation above 200 MHz.

4 ELECTROSTATIC DISCHARGE (ESD)

Electrostatic discharge (ESD) is a transfer of electrical charge at very high voltage, ranging from hundreds to thousands of volts (Table 1), and very low current. Generally,

Table 1. Some typical values for ESD.

Static generation	Static voltage (V)	
	10% relative humidity	65% relative humidity
Walking across carpet	35 000	1500
Walking over vinyl floor	12 000	250
Common plastic bag picked up from bench	20 000	1200
Work chair padded with polyurethane foam	18 000	1500

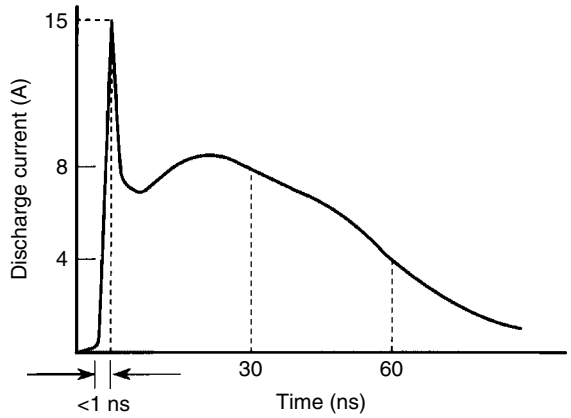

Figure 5. ESD discharge waveform at 4 KV; this is one of several different waveforms for testing circuits against ESD. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

ESD has very fast rise times (<1 ns) and short duration (~90 ns), as shown in Figure 5. ESD can easily damage sensitive electronic circuits. Any instrument containing integrated circuits is susceptible to ESD if not protected.

ESD transfers charge in three stages: pickup, storage, and discharge. Usually mechanical rubbing between dry, insulated materials picks up and transfers the charge from a source to storage. Sources include plastic work surfaces, carpeted floors, wool, cotton or synthetic garments, vinyl or fiberglass chairs, common plastic bags, trays and bubble wrap, spray cleaners, and electrostatic copiers. Humans often can be the storage means for the electrical charge until its discharge occurs.

Control methods for ESD eliminate activities and materials that create high static charge and provide transient protection to sensitive circuits. Eliminating high static charge includes appropriate grounding, using protective handling and materials, and maintaining humidity. A checklist in **Article 177, Grounding and Shielding, Volume 3** lists some of the activities that will reduce problems with ESD. Figure 13 in **Article 177, Grounding and Shielding, Volume 3** illustrates one way to protective sensitive circuits by shunting ESD to chassis ground.

5 GENERAL GUIDELINES FOR EMC AND EMI

Characterize your instrument or circuit for EMI and EMC in the following ways:

- Establish: grounding options, source and load impedances, and frequency bandwidth needed.
- Determine the predominant coupling mechanisms.
- Diagram the circuit paths and reduce loops, such as ground loops and inductive loops.

Use good design techniques to reduce EMI and improve EMC:

- reduce frequency bandwidth
- balance currents
- route signals for self-shielding: use return planes, short traces, and decoupling capacitors
- add metal enclosure shielding only when necessary.

Remember reciprocity, anything that reduces emissions usually makes the circuit less susceptible to disruption, as well. If you decrease the inductive loop of a circuit to reduce emission, then you will also reduce the mutual coupling that could receive noise.

Susceptibility often traces to incorrect return paths or long signal lines that are not properly shielded. Remember that current follows the path of lowest impedance. Understand mechanisms of noise energy transmission:

- conductive coupling
- inductive coupling
- capacitive coupling
- electromagnetic coupling.

When you do encounter EMI, begin the search for the coupling mechanisms using the diagnostic clues in Table 2.

6 STANDARDS FOR EMC

Many different regulations and standards exist around the world for designing instruments to meet EMC requirements. These standards provide levels that tests must pass for instruments to avoid interference. Commercial regulations cover the frequency band from 9 kHz to 1 GHz.

Typically, these standards specify conducted and radiated environments for interference and susceptibility. Clearly, conductive coupling falls into the conducted environment.

Table 2. Diagnostic clues for noise-coupling mechanisms.

Coupling mechanism	Diagnostic clues
Conductive	1. Complete conductive path (such as multiple ground connections) 2. Frequency < 10 MHz
Inductive	1. $(dv/dt)/(di/dt) \ll 377\,\Omega$ 2. Ringing on pulse edges 3. Low source impedance and high load impedance 4. Laying conductive foil over cable decreases noise level (acts as an eddy current shield) 5. Large circuit loops
Capacitive	1. $dv/dt)/(di/dt) \gg 377\,\Omega$ 2. Rounding of pulse edges 3. High source impedance and high load impedance 4. Laying conductive foil over cable increases noise level (acts as a coupling capacitor)
Electromagnetic	1. Distance between noise source and susceptible circuit $> \lambda$ 2. Frequency > 20 MHz

Source: Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.

Table 3. Diagnostic clues for noise-coupling mechanisms.

Type	Standard	Country
Commercial	CNELEC	Europe
	IEC 871, 801, 555	Europe
	FCC	United States
	VCCI	Japan
	VDE	Germany
Military	GAM-EG-13	France
	VG NORM	Germany
	DEF STAN 59-41	United Kingdom
	MIL STD-461E	United States

Source: Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.

Generally, the three remaining types of coupling, inductive coupling, capacitive coupling, and electromagnetic coupling, falls under the domain of the radiated environment. Table 3 lists examples of some of these standards.

1 HISTORY OF CLOSED-LOOP CONTROL SYSTEMS

This account of linear closed-loop control principles and theory is now a mature topic, wherein the control theory has greatly advanced to allow for sophistication of multivariable, stochastic, nonlinear, and digital applications.

The design of measuring systems does at times demand knowledge of such advanced ideas but the starting point, which often suffices, is the classical theory and its foundation. This set of articles is revised and edited from material first published in brief by Atkinson in Sydenham (1982). A detailed explanation is available in Atkinson (1972).

Modern closed-loop control systems can be traced back to James Watt, who invented the first rotating steam engine (patented in 1781). Initially, the speed of these engines was controlled manually using a throttle valve on the steam inlet.

In 1788, Boulton, Watt's coprincipal, in a company manufacturing the new steam engines, had visited the Albion Mill and described to Watt a form of centrifugal governor that was being used to regulate the grinding speed of the millstones driven by wind. Watt adapted this mechanical governor to measure and automatically control the speed of his steam engines (Atkinson, 1972).

Since those days, closed-loop control and measurement have been inexorably linked; indeed to control a physical quantity accurately and rapidly in the presence of changing demand, changing internal parameters, and changing load, measurement of the control quantity coupled with feedback control is essential. Such measurement can, of course, only be accomplished by means of instruments.

Another development down this path is that feedback itself is often used extensively within measuring instruments to improve the accuracy of the measurement.

In the nineteenth century, vast numbers of regulated steam engines were in operation in factories throughout Britain. These closed-loop systems were by no means perfect in that the precision of speed control was often rather poorly achieved with large and unpredictable fluctuations being the norm.

Engineers of that time had little real insight into the dynamics of systems. They attempted to improve the performance by making smaller, lighter, and better lubricated governors. Today, we can easily see from our understanding of the theory of closed-loop systems that this was not the way to go.

Much to their consternation these expected improvements normally led to an unforeseen associated difficulty in that the steam-engine speed then tended to oscillate or

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

hunt continuously about the demanded value. This particular form of *instability*, as it is now called, has plagued designers of feedback control systems of all kinds ever since. It is the main limitation on performance. Handled from an understanding of the physics involved, it can usually be limited to allow good dynamic performance – *see* **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1** and **Article 62, Second-order System Dynamics, Volume 1**.

The practical importance of this difficulty stimulated no less a person than Maxwell (1868) to investigate the problem in great depth. He brought mathematical insight to bear by relating the existence of instability to the presence of positive real parts in the complex roots of the characteristic equation of the system. His work did not, however, greatly influence matters at that time.

The First World War (1914–1918) caused military engineers to realize that to win wars it is necessary to position heavy masses (e.g. ships and guns) precisely and quickly. Classic work performed by Minorsky (1922) in the United States was on automatic ship steering and it was Hazen (1934) who defined a servomechanism for the first time.

The concepts of automatic control, as they developed, are covered in Bennett (1979). Sydenham (1979) gives an overview of the historical development of feedback control in its use in early instruments and the chart recorders, wherein it was first recognized intuitively that velocity feedback could aid loop response times.

2 ILLUSTRATION OF AN EXEMPLAR CLOSED-LOOP CONTROL SYSTEM

The operation of a mechanical position control provides a good example for illustrating the need for feedback in control. The following principles apply to all energy domains but the electromechanical one is more intuitively obvious than in others.

Suppose there is a need to control the angular position of a heavy rotating mass, such as a gun turret or a machine tool turntable. The power resource of mechanical or electrical power assistance, rather than total reliance on muscle power, allows the obvious advantage of rapid control.

To simplify the problem, suppose an ideal frictionless electric motor is available. To achieve maximum acceleration of the rotating load, the motor is coupled to the load through an ideal frictionless step-down gearbox. Friction is always present in real systems but for the moment it is ignored – see Section 5.

It is assumed that the motor produces a torque at the load, which is directly proportional to its supply voltage. In order to control the supply voltage to the motor, an ideal power amplifier is connected, which receives at its input a control voltage, v_i, that is directly proportional to an angular positional signal, θ_i.

This signal is applied manually through a light handwheel connected to a position-to-voltage transducer (such as a rotary potentiometer).

The notional arrangement is illustrated in Figure 1. This system will produce rapid acceleration of the rotating mass in response to small and effortless motion applied manually to the handwheel. When the handwheel is at a nominal zero position, the mass will cease accelerating; a change in the handwheel position in one direction will produce acceleration in one direction, and a change in position in the opposite direction will produce acceleration in the other direction.

This, the open-loop system will, however, be found to be quite unsatisfactory as a controller. To show why, the next section discusses its mathematical model.

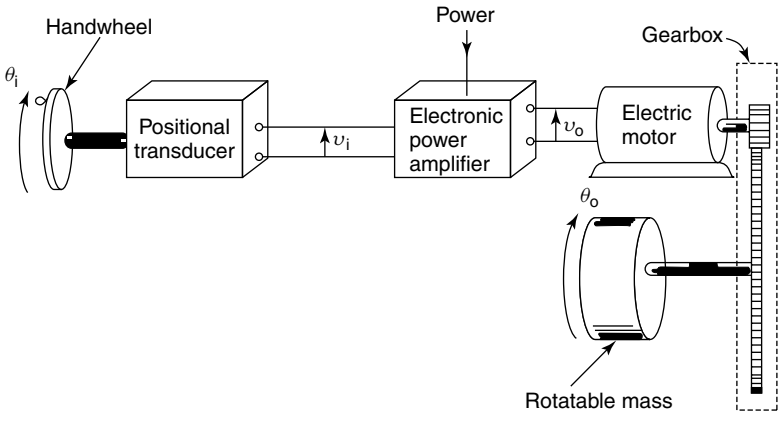

Figure 1. Position control system without feedback.

3 SETTING UP THE MATHEMATICAL MODEL FOR AN OPEN-LOOP SYSTEM

A simple mathematical analysis for the open-loop system is as follows.

Let the effective moment of inertia of the moving parts, referred to the position of the rotating mass, be J. Also, let

$$\upsilon_i = k_t \theta_i$$
$$\upsilon_a = k_a \upsilon_i \tag{1}$$

and the effective torque acting on the mass T be given by

$$T = k_m \upsilon_a \tag{2}$$

where k_t, k_a, and k_m are constants.

Thus,

$$T = k_m k_a k_t \theta_i = K \theta_i \tag{3}$$

where K is a composite system constant.

Expressed in calculus notation, according to Newton's second law of motion it is given by

$$J \frac{d^2 \theta_o}{dt^2} = T = K \theta_i \tag{4}$$

The response to a small change in θ_i from zero to a fixed positive angle is shown in Figure 2. This can be seen to be a first-order system – *see* **Article 61, First-order System Dynamics, Volume 1**.

In order to change the position of the mass from one fixed position to another in the shortest time, it is necessary to first accelerate the mass with all the torque available but then quickly retard it with a reversed torque such that at the instant the required position has been reached, both the velocity and acceleration are simultaneously reduced to zero. With this simple approach, the manual control problem is extraordinarily difficult to apply to advantage.

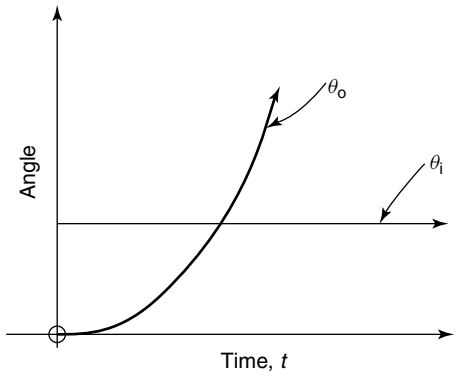

Figure 2. Response of position control system without feedback.

Worse still, in many circumstances (e.g. control of the position of a gun turret) there will be load disturbances present, for example, wind gusts which will cause the mass to deviate from the desired position in a random manner.

The result is that to get workable control of the position using open-loop control, only small torques can be applied and the result is a sluggish motion that is prone to system disturbances and sloppy following action.

4 MATHEMATICAL MODEL OF THE CLOSED-LOOP SYSTEM

This position control problem is provided with a much better solution similar to the one in which Watt solved his speed control problem, that is, by adding feedback of a measured value of the controlled variable to the power amplifier so that the system power can be applied with as much power as is needed and in the right direction at the appropriate time.

The mathematical model for such a feedback or closed-loop system is now developed using Figure 3 as the feedback system arrangement.

The controlled output variable θ_o can be measured by means of a transducer identical to that monitoring the input command θ_i, so that a signal υ_o (given by $\upsilon_o = k_t \upsilon_o$) is available for comparison with υ_i. The notion is now that if θ_i is made equal to the required position of the rotating mass, the amplifier can be fed by a difference signal $(\upsilon_i - \upsilon_o)$, which is given by

$$\upsilon_i - \upsilon_o = k_t \theta_i - k_t \theta_o = k_t \varepsilon \tag{5}$$

where ε is defined as the positional error between the required position θ_i (termed the *command* or *input*) and the actual output position θ_o.

This error signal is now amplified as before and applied to the motor. Thus, a driving torque will always be present as long as θ_o is different from θ_i. When they are of the same value there will be no driving torque and the mass will hopefully stop moving at the point where it needs to be. An analysis of this system is very revealing.

The effective torque, T, acting on the mass is no longer $K\theta_i$, but is now equal to $K\varepsilon$. Thus, again applying Newton's second law, gives

$$J \frac{d^2 \theta_o}{dt^2} = K \varepsilon \tag{6}$$

But $\varepsilon = \theta_i - \theta_o$, hence

$$J \frac{d^2 \theta_o}{dt^2} = K (\theta_i - \theta_o) \tag{7}$$

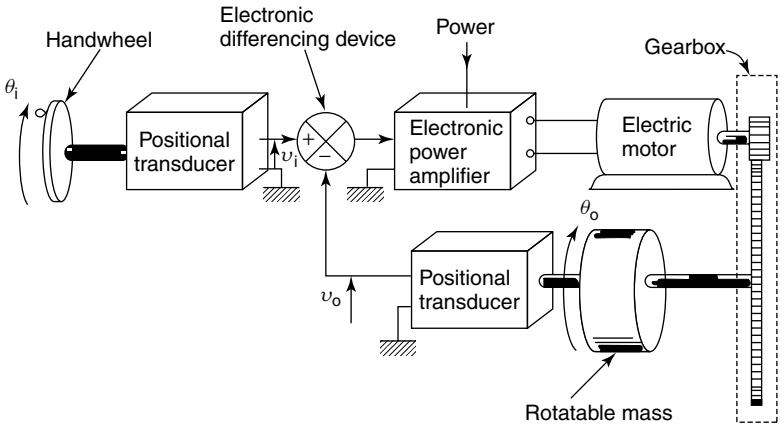

Figure 3. Position control system with feedback.

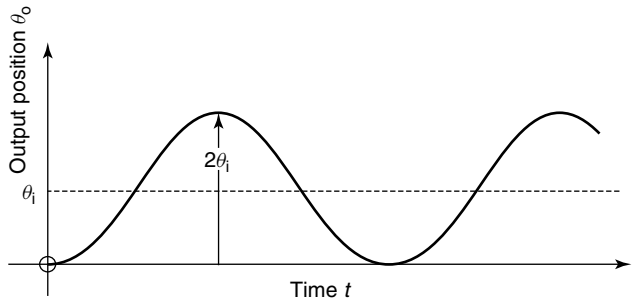

Figure 4. Response of position control system with feedback.

and so

$$J\frac{d^2\theta_o}{dt^2} + K\theta_o = K\theta_i \tag{8}$$

This will be recognized as the equation for simple harmonic motion – *see* **Article 62, Second-order System Dynamics, Volume 1**.

Hence, a sudden displacement in the handwheel position will lead to continuous oscillations as illustrated in Figure 4. Mathematicians define this system situation as *critically stable* because its oscillations will neither increase in magnitude nor decay; control engineers tend to regard such a system as unstable for this is not the desired state of control due to the continuous oscillation. This system is exhibiting exactly the same type of behavior as Watt's regulated steam engines did and it is entirely unsatisfactory for practical position control systems when compared with what can be achieved.

5 EFFECTS OF FRICTION IN REAL FEEDBACK SYSTEMS

To show how a more stable feedback system can be made, let us now look at the apparently nonideal practical system that has some friction present in the bearings, gearing contacts, and seals.

Friction almost always acts against motion regardless of direction and this will cause the oscillation to decay eventually. There are, however, various forms of friction including:

- Stiction (the torque necessary to just cause motion to begin)
- Coulomb friction (a constant torque independent of velocity) and
- Viscous friction (a torque which is directly proportional to velocity).

Stiction and Coulomb friction both cause undesirable side effects (stiction producing stick–slip motion when the system is commanded to follow a constant velocity input and Coulomb friction producing a constant offset in response to a constant input). It is thus essential to minimize stiction and Coulomb friction by good mechanical design before any form of electronic compensation is applied.

As will now be shown, it is useful to ensure that the viscous component dominates or that a similar kind of dominating effect is reproduced by other means.

The effect of viscous friction on the form of differential equation of motion for the system is to add an extra term proportional to output angular velocity, thus

$$J\frac{d^2\theta_o}{dt^2} + F\frac{d\theta_o}{dt} + K\theta_o = K\theta_i \tag{9}$$

where F is the viscous frictional torque per unit of angular velocity.

Practically, the required viscous damping can be achieved by either attaching a physical viscous damper to the rotating mass or more readily done by feeding back an extra signal that is derived from another transducer – this time

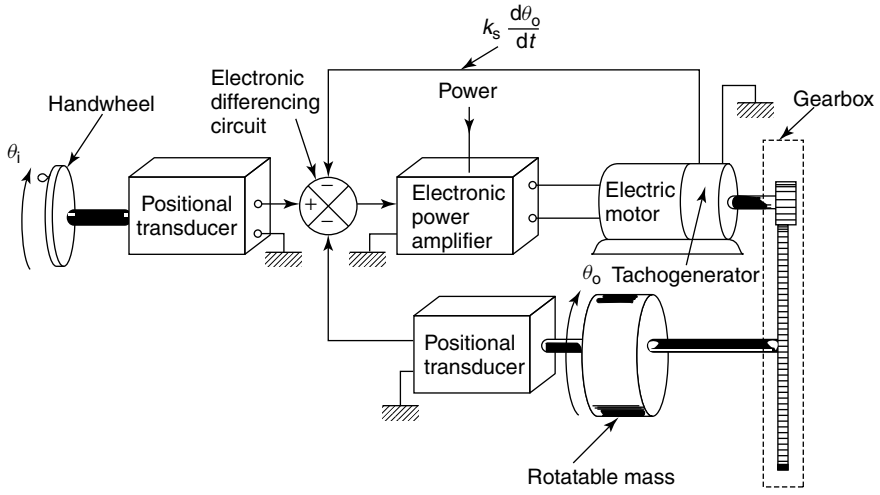

Figure 5. Position control system stabilized with velocity feedback.

a tachogenerator, which is directly proportional to angular velocity.

The second of these arrangements is shown in Figure 5. Electric motor-tachogenerators built as a combined unit are commercially available for this purpose, or a precision tachogenerator can be added to the gear train, or other output shaft.

The electronic differencing circuit will now produce a signal

$$k_t\varepsilon - k_s\frac{d\theta_o}{dt} \tag{10}$$

where k_s is the tachogenerator constant.

Hence, the drive torque T produced by the motor is given by

$$T = k_m k_a\left(k_t\varepsilon - k_s\frac{d\theta_o}{dt}\right) \tag{11}$$

Again assuming that all forms of unwanted friction are negligible, and using Newton's second law

$$\begin{aligned} J\frac{d^2\theta_o}{dt^2} &= k_m k_a\left(k_t\varepsilon - k_s\frac{d\theta_o}{dt}\right) \\ &= K\varepsilon - k_m k_a k_s\frac{d\theta_o}{dt} \end{aligned} \tag{12}$$

Hence,

$$J\frac{d^2\theta_o}{dt^2} + k_m k_a k_s\frac{d\theta_o}{dt} + K\theta_o = K\theta_i \tag{13}$$

The term $k_m k_a k_s$ can be regarded as the equivalent viscous frictional constant, F.

This can be recognized as a second-order harmonic system, but this time with damping – *see* **Article 62, Second-order System Dynamics, Volume 1**.

6 NATURE OF CLOSED-LOOP SYSTEMS USED IN MEASUREMENT SYSTEMS

The analysis of the response of this system to various inputs – *see* **Article 60, Zero-order System Dynamics, Volume 1**; **Article 61, First-order System Dynamics, Volume 1**; and **Article 62, Second-order System Dynamics, Volume 1** – is important for two dominant reasons; firstly, the arrangement forms the basis of most chart recording instruments, printers, plotters, cruise control in automobiles, and numerous other industrial applications involving measuring systems used in practice; and secondly, it represents the embodiment of the second-order system which is used as an important reference in the design of higher-order systems.

Feedback systems are more likely to be associated with the larger power systems but they also find extensive application in fine mechanisms. For example, the miniature laser reading head in a CD-ROM head has three positional servos acting to follow the disk. It is also used in feedback type sensors – *see* **Article 113, Force-feedback Sensors, Volume 2** and Jones (1979).

While the implementation of servos is usually done with digital signals today, the underlying thinking is as given above. The difference in digital systems is that the analog linear theory given above has to be transposed into the discrete mathematical domain due to the sampling carried out by the digitizer.

When designing instrument feedback arrangements, it is wise to make them linear systems if at all possible, for then

their behavior can be well modeled and predicted. If not, then modeling is considerably harder, but still feasible.

Texts on classical linear control theory matured by the 1960's; today, the topic does not attract much attention by publishers in new titles. However, most titles on process control engineering will cover the topic. A time-honored source is Levine (1996). Some titles appearing under control theory are best left for those who need and can handle the complex mathematics other than simple linear systems.

Instrument designers will usually make use of modeling tools to set up a system – *see* **Article 105, Modeling with LabVIEW™, Volume 2**.

1 USE OF THE LAPLACE TRANSFORM IN CONTROL SYSTEMS INVESTIGATIONS

This article continues the discussion on instrument feedback systems and is based on original material in Atkinson (1982). As shown in **Article 18, Nature and Scope of Closed-loop Systems, Volume 1**, the differential equation of a simple linear feedback control system can be derived by the application of physical laws (Newton's second law of motion in the example given).

However, in order to determine the behavior of the system in response to certain inputs, that is, as it responds to a change in input and has not settled down to the steady state, we need to have available a method of analysis for such systems when they are disturbed with a range of inputs; the method of Laplace transforms now used is also covered in **Article 36, Systems in the Frequency Domain, Volume 1** and **Article 143, DFT and FFTs, Volume 3**.

The Laplace transform of a signal $\theta_i(t)$ is formally defined as $\Theta_i(s)$, in which s (p is also often used) is the complex variable $\sigma + j\omega$ and

$$\Theta_i(s) = \int_{0-}^{\infty} \theta_i(t) e^{-st}\, dt \tag{1}$$

and

$$\theta_i(t) = \frac{1}{2\pi j} \int_{c-j\omega}^{c+j\omega} \Theta_i(s) e^{st}\, ds \tag{2}$$

Here, c is chosen to be larger than the real parts of all the singularities of $\Theta_i(s)$.

Fortunately, there is rarely any need to evaluate these integrals in practice because they have been tabulated in transform pairs to aid the rapid solution of differential equations – see Table 1 for the commonly seen transforms. Modeling tools will usually have them embedded in their data libraries.

In the presence of zero initial conditions, we may transform derivatives by the rule

$$\mathcal{L}\frac{d^n f(t)}{dt^n} = s^n F(s) \tag{3}$$

and integrals by the rule

$$\mathcal{L}\int_0^t f(t)dt = \frac{F(s)}{s} \tag{4}$$

in which $\mathcal{L}$ represents the operation of taking Laplace transforms and $F(s)$ is the Laplace transform of $f(t)$.

In situations in which the initial conditions are nonzero, then

$$\mathcal{L}\frac{d^n}{dt^n}[f(t)] = s^n F(s) - s^{n-1} f(0-) - s^{n-2} f^1(0-) \cdots - f^{n-1}(0-) \tag{5}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Table 1. Some functions and their Laplace transforms.

$f(t)$	$F(s) = \mathcal{L}[f(t)]$
Unit impulse function $\delta(t)$	1
Unit step function $u(t)$	$\frac{1}{s}$
Ramp function $u(t)t$	$\frac{1}{s^2}$
Exponential delay $u(t)\mathrm{e}^{-\alpha t}$	$\frac{1}{s+\alpha}$
Exponential rise $u(t)\ (1-\mathrm{e}^{-\alpha t})$	$\frac{\alpha}{s(s+\alpha)}$
$u(t)t\ \mathrm{e}^{-\alpha t}$	$\frac{1}{(s+\alpha)^2}$
$u(t)\sin(\omega_{\mathrm{rt}}t)$	$\frac{\omega_{\mathrm{rt}}}{s^2+\omega_{\mathrm{rt}}^2}$
$u(t)\mathrm{e}^{-\alpha t}\ \sin(\omega_{\mathrm{rt}}t)$	$\frac{\omega_{\mathrm{rt}}}{(s+\alpha)^2+\omega_{\mathrm{rt}}^2}$
$u(t)\mathrm{e}^{-\alpha t}\ \cos(\omega_{\mathrm{rt}}t)$	$\frac{s+\alpha}{(s+\alpha)+\omega_{\mathrm{rt}}^2}$
$f(t-\tau)$	$\mathrm{e}^{-s\tau}F(s)$

and

$$\mathcal{L}\int_0^t f(t)\mathrm{d}t = \frac{1}{s}F(s) + \frac{f^{-1}(0-)}{s} \tag{6}$$

where $f(0-),\ f^1(0-), \ldots, f^{n-1}(0-)$ are the values of the function, and its $n-1$ derivatives and $f^{-1}(0-)$ is the value of the time integral of $f(t)$ just prior to the application of the signal at $t = 0$.

It should be noted that the limit $t = 0-$ is used here, whereas in rigorous mathematical texts, in which the derivatives of discontinuous functions are not legitimate functions, the lower limit is quoted as $t = 0+$. However, in practical engineering analysis in which the unit impulse function ($\delta(t)$) is used, a more consistent methodology results by using a lower limit $t = 0-$.

Notice that when control engineers use the single-sided Laplace transform, all the driving signals are considered to operate after $t = 0$; they are defined as zero prior to this instant and this may be conveniently represented as multiplying all the time functions by the unit step $u(t)$.

2 ANALYSIS OF SIMPLE POSITION CONTROLLER WITH DAMPING AND VELOCITY FEEDBACK

Laplace transforms that have now been introduced allow analysis of a typical closed loop controller having damping and velocity feedback.

Returning to the simple position system described in **Article 18, Nature and Scope of Closed-loop Systems, Volume 1**, it is necessary to define the form of the input signal and the all-important initial conditions.

Assuming zero initial conditions, both sides of the differential equation can be transformed, thus

$$Js^2\Theta_{\mathrm{o}}(s) + Fs\Theta_{\mathrm{o}}(s) + K\Theta_{\mathrm{o}}(s) = K\Theta_{\mathrm{i}}(s) \tag{7}$$

Hence,

$$\Theta_{\mathrm{o}}(s) = \frac{K\Theta_{\mathrm{i}}(s)}{Js^2 + Fs + K} = \frac{(K/J)\Theta_{\mathrm{i}}(s)}{s^2 + (F/J)s + K/J} \tag{8}$$

Consider the response of this characteristic equation to various input signals.

2.1 Response to the unit impulse as an input demand

If $\theta_{\mathrm{i}}(t) = \delta(t)$, then $\Theta_{\mathrm{i}}(S) = 1$, and so

$$\Theta_{\mathrm{o}}(s) = \frac{K/J}{s^2 + (F/J)s + K/J} \tag{9}$$

If we take the case in which $F < 2\sqrt{(JK)}$ and complete the square in the denominator; then

$$\Theta_{\mathrm{o}}(s) = \frac{K/J}{(s+\alpha)^2 + \omega_{\mathrm{rt}}^2} \tag{10}$$

where

$$\alpha = \frac{F}{2J} \text{ and } \omega_{\mathrm{rt}} = \left(\frac{K}{J} - \frac{F^2}{4J^2}\right)^{1/2}$$

This does not quite agree with the form of any of the tabulated Laplace transforms, but with slight manipulation it becomes

$$\Theta_{\mathrm{o}}(s) = \frac{K/J}{\omega_{\mathrm{rt}}}\frac{\omega_{\mathrm{rt}}}{(s+\alpha)^2 + \omega_{\mathrm{rt}}^2} \tag{11}$$

which may be inverse transformed to yield

$$\theta_{\mathrm{o}}(t) = u(t)\frac{K/J}{\omega_{\mathrm{rt}}}\mathrm{e}^{-\alpha t}\sin(\omega_{\mathrm{rt}}t) \tag{12}$$

This is the unit impulse response of the system.

2.2 Response to the unit step as an input demand

If $\theta_{\mathrm{i}}(t) = u(t)$, then $\Theta_{\mathrm{i}}(s) = 1/s$, thus

$$\Theta_{\mathrm{o}}(s) = \frac{K/J}{s[s^2 + (F/J)s + K/J]} \tag{13}$$

This must be broken into partial fractions (done using special mathematical techniques not covered here) to find matching transforms, thus

$$\Theta_o(s) = \frac{1}{s} - \frac{\alpha}{\omega_{rt}} \frac{\omega_{rt}}{(s+\alpha)^2 + \omega_{rt}^2} - \frac{s+\alpha}{(s+\alpha)^2 + \omega_{rt}^2} \quad (14)$$

Each term has a recognizable inverse Laplace transform leading to the solution in the time domain of

$$\begin{aligned}\theta_o(t) &= u(t) - \frac{\alpha}{\omega_{rt}} u(t)\, e^{-\alpha t} \sin(\omega_{rt} t) - u(t)\, e^{-\alpha t} \cos(\omega_{rt} t) \\ &= u(t)\{1 - e^{-\alpha t} \sqrt{[1 + (\alpha/\omega_{rt})^2]} \\ &\quad \times \sin[\omega_{rt} t + \tan^{-1}(\omega_{rt}/\alpha)]\} \end{aligned} \quad (15)$$

This is the unit step response.

2.3 Response to the unit ramp as an input demand

If $\theta_i(t) = u(t)$, then $\Theta_i(s) = 1/s^2$, and so

$$\Theta_o(s) = \frac{K/J}{s^2[s^2 + (F/J)s + K/J]} \quad (16)$$

This must be broken into partial fractions to yield the response

$$\theta_o(t) = u(t) \left(t - \frac{F}{K} + \frac{K e^{-\alpha t}}{F \omega_{rt}} \sin(\omega_{rt} t + \phi) \right) \quad (17)$$

where

$$\phi = \tan^{-1} \left(\frac{2\alpha\omega_{rt}}{2\alpha^2 - K/J} \right)$$

This is the unit ramp response.
These responses are plotted in Figure 1.

The quantities M_{pt}, T_p, ε_{ss}, and ε_p form some of the basic means of performance specification.

A similar set of responses are analyzed in **Article 62, Second-order System Dynamics, Volume 1**, where systems in general are covered. The different terminologies, differing parameter, and process of analyses given will perhaps be found useful depending upon the discipline to which they are being applied.

3 CONCEPT OF DAMPING RATIO AND UNDAMPED NATURAL ANGULAR FREQUENCY

The value of the damping term F relative to the terms J and K governs the dynamic behavior of the system. There are four possibilities:

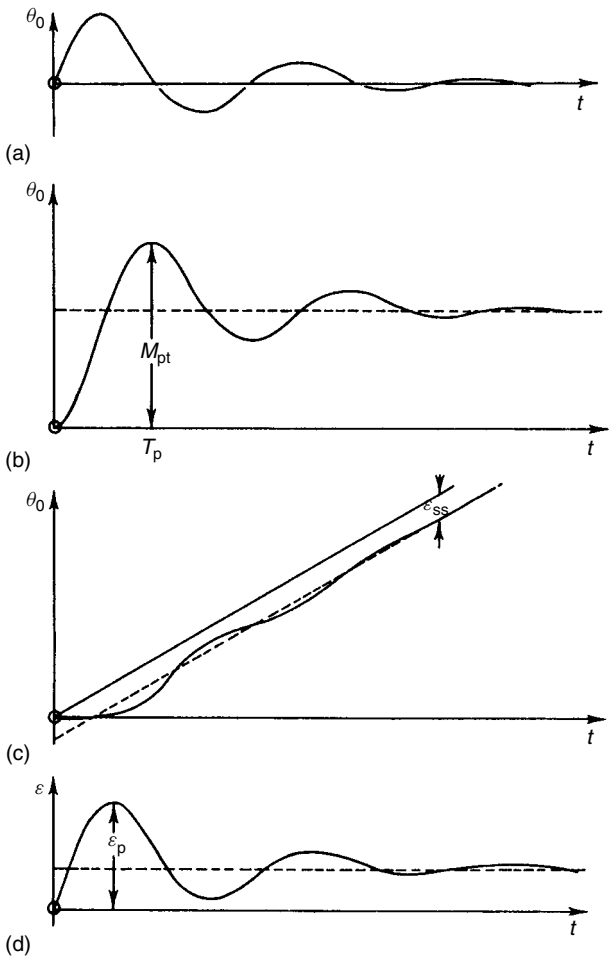

Figure 1. Time domain responses of a stabilized position control system: (a) impulse, (b) step, (c) ramp output, (d) ramp error.

1. $F = 0$, in which case the system will oscillate continuously with sinusoidal oscillations of angular frequency $\sqrt{(K/J)}$. This quantity is termed the *natural undamped angular frequency*. This response is termed *critically stable*.
2. $F < 2\sqrt{(JK)}$, in which case the response contains an exponentially damped sinusoidal mode and will exhibit overshoot in response to a step input. This is called the *underdamped response*.
3. $F = 2\sqrt{(JK)}$, for which the response is *critically damped*, that is, it does not quite overshoot in response to a step input.
4. $F > 2\sqrt{(JK)}$, for which the response is a double exponential rise in response to a step input. This is called the *overdamped response*.

The simple example given in article **Article 18, Nature and Scope of Closed-loop Systems, Volume 1** concentrates on condition 2 because this is in practice the most important case as it allows the system to settle within

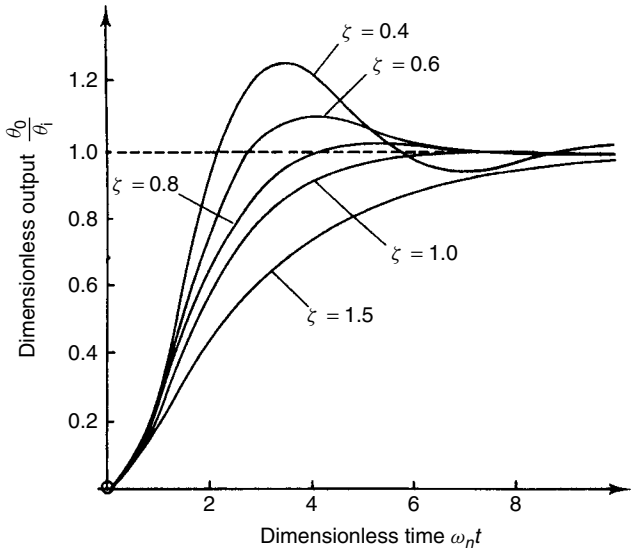

Figure 2. Dimensionless unit step response.

a given tolerance band around the desired value faster than any other.

It is convenient to normalize the effect of the damping term F by relating it to the value F_c required to achieve critical damping where $F_c = 2\sqrt{(JK)}$.

The damping ratio ζ is defined as

$$\zeta = \frac{F}{F_c} = \frac{F}{2\sqrt{(JK)}} \tag{18}$$

so that

$\zeta < 1$ is an underdamped system
$\zeta = 1$ is a critically damped system
$\zeta > 1$ is an overdamped system

The differential equation may be rewritten in terms of ω_n and ζ thus

$$\frac{d^2\theta_o}{dt^2} + 2\zeta\omega_n\frac{d\theta_o}{dt} + \omega_n^2\theta_o = \omega_n^2\theta_i \tag{19}$$

The response to a unit step input for various values of ζ is illustrated in Figure 2.

4 FREQUENCY RESPONSE OF CLOSED LOOP SYSTEMS

The steady state behavior of the system in response to a sinusoidal input is of considerable practical importance. When we refer to the frequency response of a system, we mean the variation of the phase and magnitude of the steady state output of the system, as the frequency of the input sinusoid is varied over the range of interest.

The Laplace transform of the output of the system is related to the Laplace transform of the input by the equation

$$s^2\Theta_o(s) + 2\zeta\omega_n s\Theta_o(s) + \omega_n^2\Theta_o(s) = \omega_n^2\Theta_i(s) \tag{20}$$

For steady state sinusoids, it is permissible to substitute $j\omega = s$, where ω is the angular frequency of the input, and produce the following operational relationship between $\Theta_i(j\omega)$ and $\Theta_o(j\omega)$:

$$\begin{aligned}\frac{\Theta_o(j\omega)}{\Theta_i(j\omega)} &= \frac{\omega_n^2}{(j\omega)^2 + 2\zeta\omega_n(j\omega) + \omega_n^2} \\ &= \frac{\omega_n^2}{\omega_n^2 - \omega^2 + j2\zeta\omega_n\omega} \\ &= \frac{1}{1 - (\omega/\omega_n)^2 + j2\zeta\omega/\omega_n}\end{aligned} \tag{21}$$

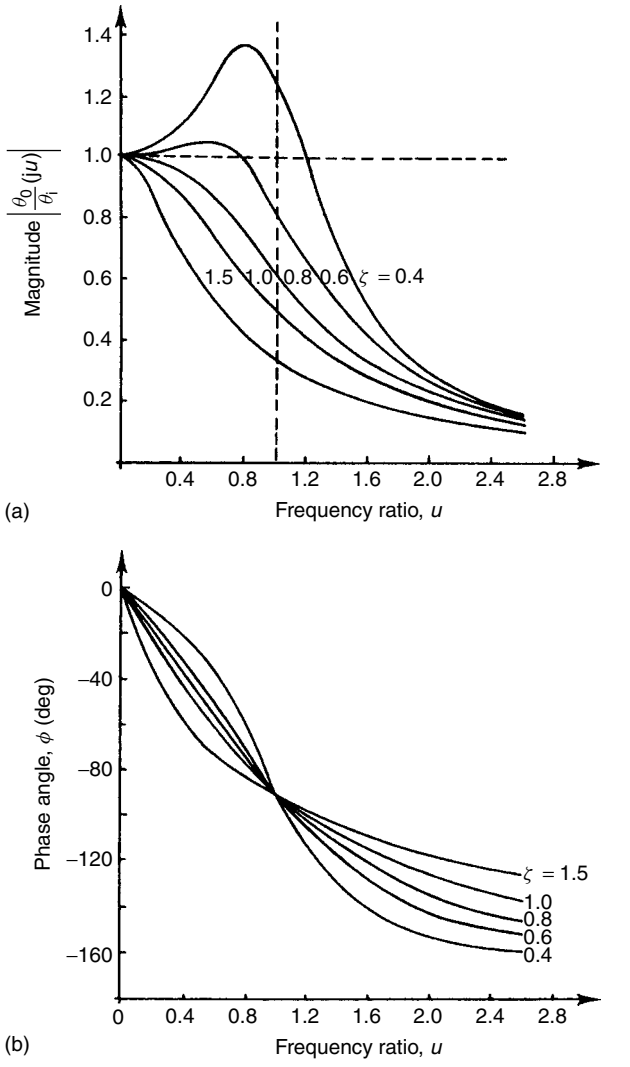

Figure 3. Frequency response characteristics: (a) magnitude, (b) phase.

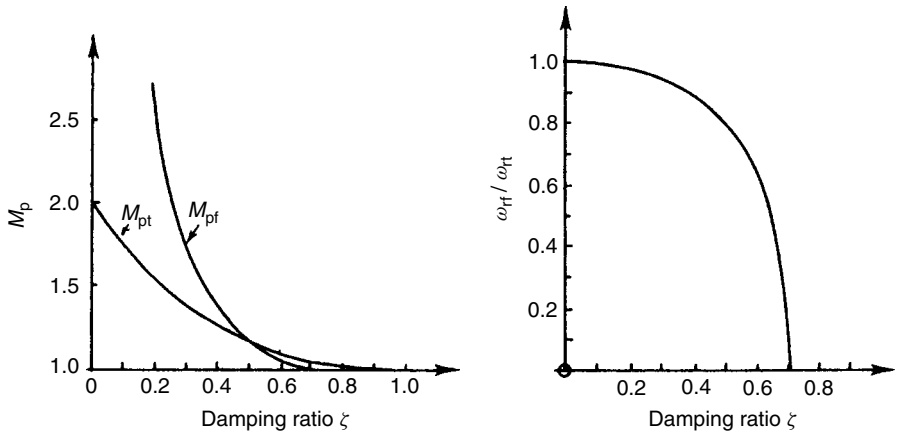

Figure 4. Time and frequency domain characteristics of the second-order system.

It is simpler to work in terms of a nondimensional frequency ratio $u = \omega/\omega_n$ for which

$$\frac{\Theta_o(ju)}{\Theta_i(ju)} = \frac{1}{(1-u^2) + j2\zeta u} \tag{22}$$

From this expression, we can determine the modulus, M, its peak value, M_{pf} (if any), and the phase, ϕ, which is given by

$$M = \frac{1}{\sqrt{[(1-u)^2 + (2\zeta u)^2]}} \tag{23}$$

$$M_{pf} = \frac{1}{2\zeta\sqrt{(1-\zeta^2)}} \tag{24}$$

and

$$\phi = -\tan^{-1}\left(\frac{2\zeta u}{1-u^2}\right) \tag{25}$$

The magnitude and phase characteristics are illustrated in Figure 3. The angular frequency at which the frequency response has its peak value is designated by the symbol ω_{rf}. It may be shown that

$$\omega_{rf} = \omega_n\sqrt{(1-2\zeta^2)} \tag{26}$$

5 SECOND-ORDER CORRELATIONS

The time domain (step response) and frequency response of the second-order system are connected through correlating equations; these may be combined as graphs, which are useful in the approximate design of higher-order systems (Atkinson, 1968). These graphs are given in Figure 4.

Levine (1996) provides a general background to control systems analysis.

1 INTRODUCTION TO CLOSED-LOOP SAMPLED DATA SYSTEMS

This article continues the discussion of instrument feedback systems and is based on original material in Atkinson (1982). Today many practical control systems use discrete digital signals. Their operation is an extension of analog principles usually by addition of sampling of the signal stream. The prior discussion of closed-loop systems in **Article 18, Nature and Scope of Closed-loop Systems, Volume 1** and **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1** have assumed operation using analog continuous signals by an A/D converter – *see* **Article 138, Sampling Theory Relevant to DAS, Volume 3** and **Article 139, Analog-to-Digital (A/D) Converters, Volume 3**.

To understand the complications that can arise and how the digital controller system can be analyzed in depth, it is necessary to understand the sampling process. It is not usually expected that a measuring systems designer be familiar with carrying out this level of analysis but its principles do need to be generally appreciated.

Sampling is defined in general as the generation of a sequence of impulses at the sampling instants, with the area or magnitude of each impulse being equal to the original signal value at that time (Figure 1).

The notation $x^*(t)$ represents the ideal impulse sampled version of the original signal $x(t)$ entering the sampler.

Feedback systems can be effectively represented by the block diagram shown in Figure 2, in which the continuous elements have a transfer function $H(s)$. The precise analysis of this type of system can be very involved; however, in many practical situations, the sampling interval T_s is short compared with the time for a transient oscillation of the whole system. Under these circumstances, it is possible to replace the impulse sampler theoretically by a pure gain of value $1/T_s$ and analyze the circuit by normal continuous theory or simulation.

2 USE OF SAMPLE AND HOLD CIRCUITS

In the arrangement illustrated in Figure 2, the impulse sampler is placed in the error channel of the feedback system. This is a fairly normal situation in control systems; in a properly designed system, the main elements then act as a low-pass filter, which smoothes the sampled error so that the output $\theta_o(t)$ follows the input $\theta_i(t)$ over the required profile of inputs.

Even in a system that has been designed correctly and that has a reasonably high sampling rate, the response will not be exactly the same as that of the equivalent linear

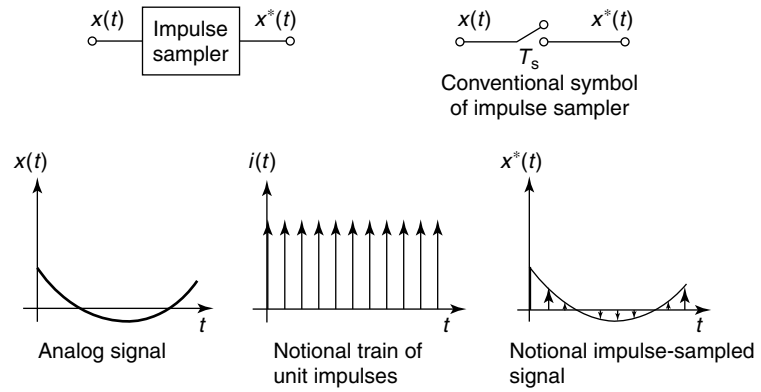

Figure 1. Action of a theoretical impulse sampler.

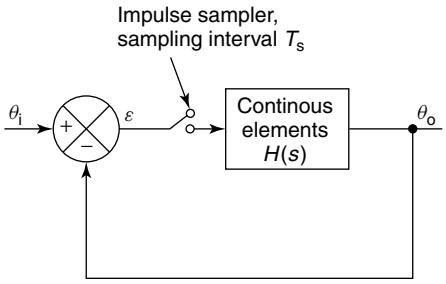

Figure 2. Closed-loop sampled data system.

system. It is often most economical to use low sampling rates, in which case the intersample ripple on the output may be very severe. In order to make the behavior of the sampled data system more like that of the continuous system and particularly to reduce intersampling ripple on the output, various forms of filter are used between the sampler and the continuous elements.

The simplest type of filter is the zero-order hold or clamp. The actions of an impulse sampler with a zero-order hold are shown in Figure 3.

The output is held at the previous sampled value until the next sampling instant. The transfer function of the zero-order hold takes the form:

$$\frac{1-\exp(-sT_s)}{s}$$

The total response of a sample and hold circuit approximates on average (ignoring harmonics) to a pure time delay of $T_s/2$. This approximation is valid down to quite low sampling rates and allows design to be performed by classical feedback control methods in the frequency domain. The approximation can also be used for approximate transient analysis even at quite low sampling rates.

Further improvements in signal smoothing can be achieved by using predictive hold circuits, which use the past two values to predict (or estimate) the slope of the curve to the next sampling instant.

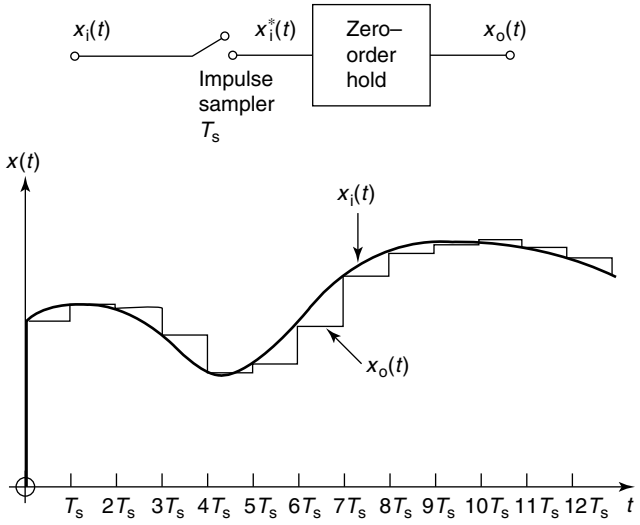

Figure 3. Action of the zero-order hold.

3 FREQUENCY RESPONSE METHODS APPLIED TO SAMPLED CLOSED-LOOP SYSTEMS

Although for many purposes frequency domain analysis may be employed for sampled data systems using the approximate continuous equivalents described in Sections 1 and 2 above, at very low sampling rates, or in cases where more accurate analysis is required, it is necessary to use a more accurate technique. Linvill (1951) developed a formula for computing the frequency response of a sampled data system by making a vector addition of all the harmonics produced by sampling.

Given a continuous signal of Laplace transform $E(s)$, then the Laplace transform $E^*(s)$ of the sampled signal is given by

$$E^*(s) = \frac{1}{T_s} \sum_{n=-\infty}^{+\infty} E(s + jn\omega_s) \tag{1}$$

where n is an integer and ω_s is the angular sampling frequency. The frequency response is then written in the usual way by substituting $s = j\omega$, that is,

$$E^*(j\omega) = \frac{1}{T_s} \sum_{n=-\infty}^{+\infty} E(j\omega + jn\omega_s) \tag{2}$$

Frequency response loci (i.e. Nyquist diagrams) can be constructed using this series to investigate stability of the loop.

4 TIME DOMAIN ANALYSIS OF SAMPLED DATA CLOSED-LOOP SYSTEMS

The method of z-transforms provides a basis for time-domain analysis and stability analysis of a closed-loop sampled data system. Its main limitation is that it provides information about signal amplitudes at the sampling instants only. It, therefore, provides no information regarding the intersample ripple.

An impulse-sampled signal $\varepsilon^*(t)$ has a Laplace transform $\varepsilon^*(s)$, which contains s in the form $\exp(sT_s)$; the z-transform is obtained by making the substitution $z = \exp(sT_s)$. The z-transform can be represented as a series

$$\varepsilon(z) = \sum_{n=0}^{\infty} \varepsilon(nT_s) z^{-n} \tag{3}$$

where n is an integer.

We can interpret z^{-1} as a delay operator of T_s seconds, z^{-2} as a delay operator of $2T_s$ seconds, and so on. The summation will take a general form

$$\varepsilon(z) = k_0 + k_1 z^{-1} + k_2 z^{-2} + k_3 z^{-3} + \cdots + k_n z^{-n} \tag{4}$$

Each term in the series contains the amplitude k_n at the sampling instant nT_s in the form $k_n z^{-n}$ (See Figure 4). The z-transforms for various functions of time are given in Table 1 for reference.

Although the z-transform can be inverted in a number of ways, it is generally best to expand the expression into a power series in powers of z^{-1} by algebraic long division. The coefficient of z^{-n} corresponds to the value of the time function at the nth sampling instant.

Classic control theory texts, such as Truxall (1955), show how to calculate the response of a closed-loop sampled data control system containing an impulse sampler in the error channel (Figure 5).

The z-transfer (or pulse transfer function) of the system is given by

$$\frac{\Theta_o(z)}{\Theta_i(z)} = \frac{G(z)}{1 + HG(z)} \tag{5}$$

It should be noted that $HG(z) \neq H(z)G(z)$.

The application of the closed-loop z-transform is illustrated by an example (Figure 6) in which the input is a unit

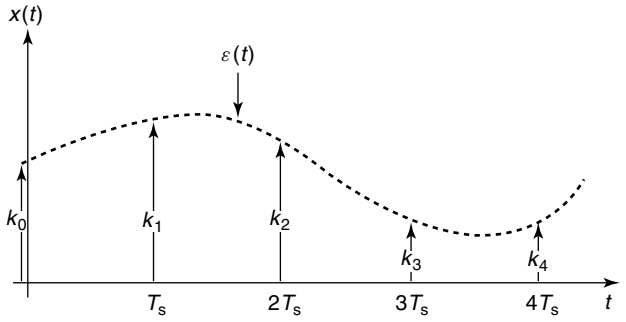

Figure 4. Illustrating z-transform series representation of a sampled signal.

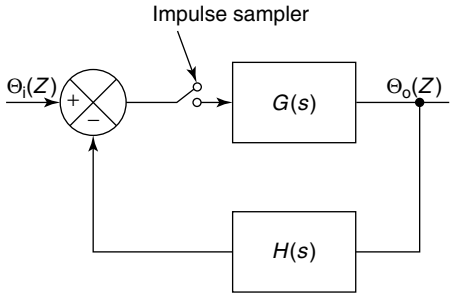

Figure 5. Sampled-data control system.

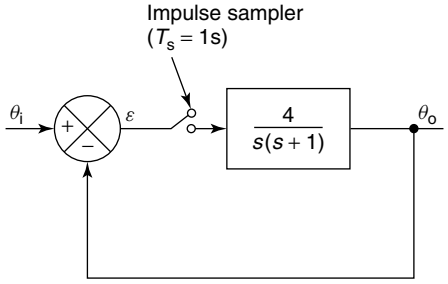

Figure 6. Sampled-data system for worked example.

Table 1. Laplace and z transforms of commonly met time functions.

Time function $f(t)$	Laplace transform	Z-transform
Unit step $u(t)$	$\frac{1}{s}$	$\frac{z}{z-1}$
Unit ramp $u(t)t$	$\frac{1}{s^2}$	$\frac{T_S z}{(z-1)^2}$
Acceleration function $u(t)t^2/2$	$\frac{1}{s^3}$	$\frac{T_s^2 z(z+1)}{2(z-1)^3}$
$u(t)\frac{t^n}{n!}$	$\frac{1}{s^{n+1}}$	$\lim_{\alpha\to 0}\frac{(-1)^n}{n!}\frac{\partial^n}{\partial\alpha^n}\left(\frac{z}{z-\exp(-\alpha T_s)}\right)$
$u(t)\mathrm{e}^{-\alpha t}$	$\frac{1}{s+\alpha}$	$\frac{z}{z-\exp(-\alpha T_s)}$
$u(t)t\ \mathrm{e}^{-\alpha t}$	$\frac{1}{(s+a)^2}$	$\frac{T_s z\exp(-\alpha T_s)}{[z-\exp(-\alpha T_s)]^2}$
$u(t)\ (1-\mathrm{e}^{-\alpha t})$	$\frac{\alpha}{s(s+\alpha)}$	$\frac{[1-\exp(-\alpha T_s)]z}{(z-1)[z-\exp(-\alpha T_s)]}$
$u(t)\sin(\omega_{rt}t)$	$\frac{\omega_{rt}}{s^2+\omega_{rt}^2}$	$\frac{z\sin(\omega_{rt}T_s)}{z^2-2z\cos(\omega_{rt}T_s)+1}$
$u(t)\mathrm{e}^{-\alpha t}\ \sin(\omega_{rt}t)$	$\frac{\omega_{rt}}{(s+\alpha)^2+\omega_{rt}^2}$	$\frac{z\exp(\alpha T_s)\sin(\omega_{rt}T_s)}{z^2\exp(2\alpha T_s)-2z\exp(\alpha T_s)\cos(\omega_{rt}T_s)+1}$
$u(t)\cos(\omega_{rt}t)$	$\frac{s}{s^2+\omega_{rt}^2}$	$\frac{z[z-\cos(\omega_{rt}T_s)]}{z^2-2z\cos(\omega_{rt}T_s)+1}$
$u(t)\mathrm{e}^{-\alpha t}\ \cos(\omega_{rt}t)$	$\frac{s+\alpha}{(s+\alpha)^2+\omega_{rt}^2}$	$\frac{z^2-z\exp(-\alpha T_s)\cos(\omega_{rt}T_s)}{z^2-2z\exp(-\alpha T_s)\cos(\omega_{rt}T_s)+\exp(-2\alpha T_s)}$

step function and it is required to calculate the output.

$$H(s)=\frac{4}{s(s+1)}=\frac{4}{s}-\frac{4}{s+1} \tag{6}$$

From the table of z-transforms (Table 1)

$$H(z)=\frac{4z}{z-1}-\frac{4z}{z-\exp(-\alpha T_s)} \tag{7}$$

where $\alpha T_s=1$. Thus,

$$H(z)=\frac{2.53z}{z^2-1.37z+0.368} \tag{8}$$

and so

$$\frac{\Theta_o(z)}{\Theta_i(z)}=\frac{H(z)}{1+H(z)}=\frac{2.53z}{z^2+1.16z+0.368} \tag{9}$$

Now $\theta_i(t)=u(t)$. Hence, again using the table of transforms:

$$\begin{aligned}\Theta_i(z)&=\frac{z}{z-1}\\ \Theta_o(z)&=\frac{2.53z}{z^2+1.16z+0.368}\ \frac{z}{z-1}\\ &=\frac{2.53z^2}{z^3+0.16z^2-0.793z-0.368}\end{aligned} \tag{10}$$

By algebraic long division this expression yields:

$$\begin{aligned}\Theta_o(z)=2.53z^{-1}&-0.406z^{-2}+2.03z^{-3}+0.339z^{-4}\\ &+1.37z^{-5}+0.827z^{-6}+1.06z^{-7}+1.00z^{-8}+\cdots\end{aligned} \tag{11}$$

As can be seen from this response, although the system is highly undamped, its output eventually converges towards the input.

5 STABILITY OF CLOSED-LOOP SAMPLED DATA SYSTEMS USING THE Z-TRANSFORM

For a sampled data control system, the z-transfer function is given by

$$\frac{\Theta_o(z)}{\Theta_i(z)} = \frac{G(z)}{1 + HG(z)} \tag{12}$$

The stability of the system depends on the positions of the zeros of $[1 + HG(z)]$ in the s-plane. However, the transformation of $\exp sT_s = z$ has been made and the positions of the zeros can be mapped in the z-plane. The mapping, $z = \exp sT_s$, maps the imaginary axis of the s-plane into the unit circle about the origin of the z-plane and the left half of the s-plane into the interior of the unit circle.

A sampled data control system will only be absolutely stable if all the zeros of $1 + HG(z)$ lie inside the unit circle.

Direct application of this criterion can be tedious; use of the bilinear transform $z = (1 + w)/(1 - w)$ maps the inside of the circle in the z-plane onto the left-hand side of the w-plane. It is then possible to use the Routh–Hurwitz or the Nyquist stability criterion directly.

6 COMPENSATION OF SAMPLED DATA CLOSED-LOOP SYSTEMS

Sampled data (i.e. digital) systems offer a wider range of possibilities for compensation than do continuous signal systems. Series and parallel or series/parallel compensation using continuous transfer functions can be designed in a similar way using a Nyquist or inverse Nyquist diagram based on the Linvill approximation (Section 3 above).

Alternative strategies involve series digital compensators alone (Figure 7a) or in combination with a parallel continuous compensator (Figure 7b).

Digital compensators can be arranged to produce a phase-lead for which $H_c(z) = (z - a)/(z + b)$, with the zero lying to the right of the pole in the z-plane, or a phase lag for which $H_c(z) = (z + a)/(z - b)$, with the zero lying to the left of the pole.

Many other forms of a digital compensator could be realized by construction from hard-wired logical circuitry or, more usually today, by means of software implemented on a digital microprocessor almost always associated with a closed-loop controller; software implementation is clearly very advantageous.

The arrangement illustrating control and digital compensation of a continuous process is shown in Figure 8; the error signal is generated by the computer and is

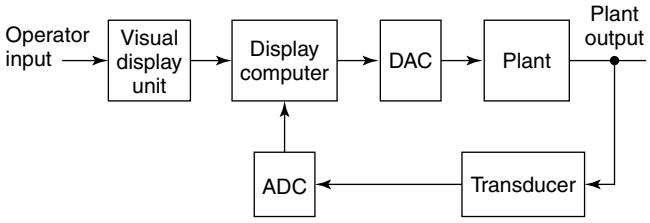

Figure 8. Control and compensation using a digital computer.

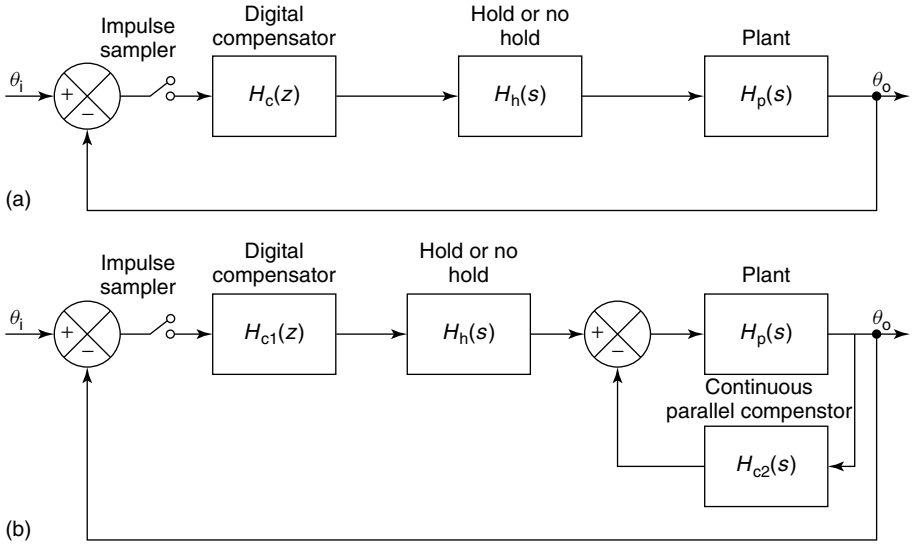

Figure 7. Forms of digital compensation: (a) series digital compensation; (b) series digital with parallel continuous compensation.

then operated on by a suitable algorithm before it is outputted to the plant via a digital-to-analog converter (DAC).

This article has only introduced the foundational approach to understanding the operation and tuning of digital closed loops. More detail can be found in Franklin *et al*. (1997), Nekoogar and Moriarty (1998), Ogata (2001), Stubberud, Williams and DiStefano (1994), and Wittenmark (1990). Application is now assisted using the current, widely available circuit system simulation tools, Bishop (1997).

1 INTRODUCTION TO NONLINEAR SYSTEMS

This article continues the discussion of instrument feedback systems and is based on original material in Atkinson (1982).

Although certain nonlinearities (Coulomb friction and stiction) were mentioned in connection with the positional servomechanism in **Article 18, Nature and Scope of Closed-loop Systems, Volume 1**, the theory covered there and in **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1** and **Article 20, Closed-loop Sampled Data Systems, Volume 1** describes the class of closed loop that are called *linear systems*.

Linear systems are those which obey the principle of superposition. Although linear theory is an indispensable design aid, it must be realized that all practical systems do inevitably contain nonlinearities to some degree.

For example, an amplifier can exhibit saturation if overdriven; when the error signal in a control system becomes large the control signal driving the equipment under control will be limited in amplitude. The result of this will normally be that the response time of the system will be longer than predicted by means of linear theory, which is based on the assumption that saturation is not present.

There are many types of nonlinearity. They were first distinguished in Gelb and Vander Velde (1968) as explicit or implicit nonlinearities.

Explicit implies that the output of the nonlinearity is explicitly determined in terms of the required input variables, whereas implicit implies a more complicated relationship between input and output through, for example, an algebraic or differential equation.

With explicit nonlinearities, we have to distinguish between static and dynamic forms, in which dynamic implies that the output is related not only through the input but also through the derivatives of the input. Among the explicit, static nonlinearities, we must again divide between single-value (memoryless) nonlinearities such as saturation and dead-space, and multiple-value (memory) nonlinearities such as hysteresis.

The analysis and design of nonlinear systems is vastly more complex than that of linear systems, every nonlinear system being a miniature universe. Fortunately, simulation tools are available for such work that make design easier than by long hand formal methods.

Although some nonlinearities are intentionally inserted by the designer to obtain improved system performance, for the most part, they are a nuisance causing undesirable side effects when the error signal is large (e.g. the effect of saturation) or when it is small (such as, backlash in gears that may cause tick to occur). System errors of this kind are discussed in **Article 57, Static Considerations of General Instrumentation, Volume 1**.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

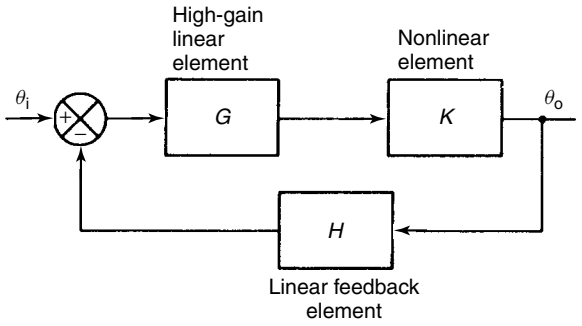

Figure 1. Nonlinear element in high-gain feedback loop.

In some circumstances (as with hysteresis), it may be possible to effectively eliminate the effects of the nonlinearity by means of a high-gain stable local feedback loop. This procedure is strongly recommended where it is possible. The procedure is based on the idea that the nonlinear element has a variable static gain, K. It is driven from a high-gain linear amplifier of gain, G, and feedback is applied through an element of gain, H, as shown in Figure 1.

Analysis shows that the transfer function in such cases is given by

$$\frac{\theta_o}{\theta_i} = \frac{GK}{1 + HGK} \tag{1}$$

The method relies on making $HGK > 1$ for all possible values of K, so that

$$\frac{\theta_o}{\theta_i} > \frac{1}{H} \tag{2}$$

The effects of the nonlinearity are thus made quite negligible so long as none of the elements saturate, this point often being overlooked.

This arrangement is only of use so long as the loop is relatively stable, so careful design of the loop is essential. This is probably best performed in the frequency domain using the describing function method given in Section 4.

Stiction can cause stick–slip motion in feedback mechanisms following constant velocity (ramp) inputs. This problem can again be overcome by means of a high-gain local feedback loop. In this case, velocity feedback is used around a motor–amplifier series combination; the gain of the amplifier is made very high so that the arrangement behaves like a perfect integrator of transfer function $1/k_s s$ where, k_s, is the velocity feedback constant. The arrangement is again identical to that shown in Figure 1; K represents the nonlinear motor characteristic $H = k_s s$, and G is the high gain of the amplifier. There is usually very little problem in designing this loop to have adequate relative stability.

2 METHODS FOR STUDYING NONLINEAR SYSTEMS

There are no completely satisfactory methods of studying nonlinear systems. Computer simulations are of great importance; to perform a simulation it is, however, necessary to choose a model to represent the important characteristics of a system.

A computer tool study of any nonlinear system is an essential final step before the real system is built.

Trial and error design based entirely on computer simulation is not advisable as it may not give a complete insight into the system behavior and the strategies which are available.

In instrumentation systems design, it is often possible to avoid nonlinearities by choice of components and their working regimes. For efficient lowest cost design it is, however, often better to make use of nonlinear effects meaning that more investigation into the behavior will be needed.

The first step in designing a nonlinear system is usually to attempt to linearize the essential nonlinearities for small signals about a working point.

For example, if we have a nonlinear device with an input signal $x(t)$ and an output $y(t)$ such that $y(t) = kx^2(t)$ then $\partial y/\partial x = 2kx$

If we are working at some particular working point x_p, then for small departures from the working point, the effective gain of the device is $2kx_p$.

For working points at values of x greater than x_p, the gain will be greater than $2kx_p$ and for working points at values of x less than x_p, the gain will be less.

Linear systems design application, combined with a sensitivity analysis and a computer simulation should again prove adequate.

Phase-plane analysis is a useful tool in the analysis of nonlinear second-order systems – *see* **Article 62, Second-order System Dynamics, Volume 1** – subjected to step (and ramp) inputs.

The technique involves the determination of the response in terms of its derivative of output (or error) plotted as a function of its output (or error). This plot is called a *phase-plane diagram*. In formulating the relevant equations, time is removed explicitly. For many practical nonlinearities, where the nonlinearities can be represented by linear segmented characteristics, the phase plane can be divided into various regions each of which corresponds to motion on a particular linear segment of the nonlinearity (see Section 3).

For higher-order systems, on occasions where it is necessary only to determine whether the designed system will remain absolutely stable for the entire envelope of input

signals, the methods of Lyapunov or Popov will provide exact answers without solving the differential equations.

The method of describing functions based on the concept of quasi-linearization for a given class of input signals provides a sound basis for the analysis and design of nonlinear feedback-control systems (see Section 4).

3 PHASE-PLANE ANALYSIS

Phase-plane analysis considers any second-order differential equation of form:

$$\ddot{x} + A\dot{x} + Bx = F \tag{3}$$

where A, B, and F are not necessarily constant. A phase portrait consists of a number of phase trajectories in the $\dot{x}$-versus x-plane.

If we define $y = \dot{x}$, then

$$\frac{dy}{dx} = \frac{dy/dt}{dx/dt} = \frac{F - Bx - Ay}{y} \tag{4}$$

This equation represents the slope of the phase trajectory in terms of functions of x and y. In general B, A, and F may be functions of x and y. To find the phase trajectory itself, this equation must be integrated; sometimes this can be performed analytically, but usually it is better done numerically using a digital computer or, the original long hand way, graphically using the method of isoclines.

By way of example, consider the simple viscously damped second-order servomechanism described in **Article 18, Nature and Scope of Closed-loop Systems, Volume 1** but now with the additional Coulomb friction.

Consider the response of the system with a step input and let C be the magnitude of the Coulomb frictional torque, which always opposes motion.

The instantaneous accelerating torque in $K\varepsilon$ and the retarding torque is $F\dot{\theta}_o + C\sin\dot{\theta}_o$, where $\sin\dot{\theta}_o$ is positive for $\dot{\theta}_o > 0$ and negative for $\dot{\theta}_o < 0$. Thus, applying Newton's second law, we have

$$J\ddot{\theta}_o = K\varepsilon - F\dot{\theta}_o - C\sin\dot{\theta}_o \tag{5}$$

Now $\varepsilon = \theta_i - \theta_o$, thus $\theta_o = \theta_i - \varepsilon$; also for a step input $d\theta_i/dt = 0$ and $d^2\theta_i/dt^2 = 0$ under steady state conditions.

It is possible to translate the above equation into the error form

$$J\ddot{\varepsilon} + F\dot{\varepsilon} + K\varepsilon + C\sin\dot{\varepsilon} = 0 \tag{6}$$

From this equation we can deduce

$$\dot{\varepsilon} = -\frac{K\varepsilon}{NJ + F} - \frac{C\sin\dot{\varepsilon}}{NJ + F} \tag{7}$$

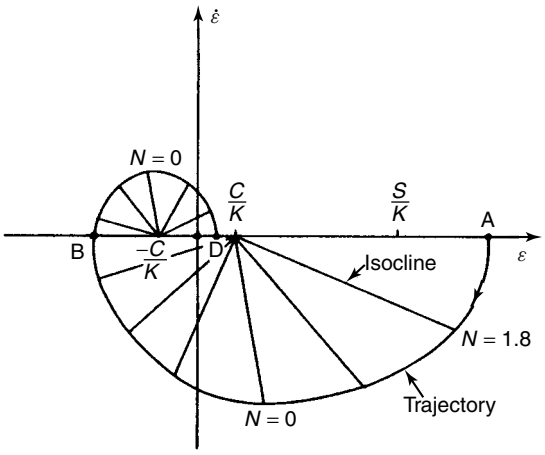

Figure 2. Phase trajectory for simple positional servomechanism with Coulomb friction.

in which N is the slope of the phase trajectory where it crosses the isocline.

The first term defines the family of isoclines for the linear system, whereas the second term introduces the effect of the nonlinearity.

The focal point is changed from $\varepsilon = +C/K$ to $\varepsilon = -C/K$ as $\dot{\varepsilon}$ changes from a negative value to a positive value.

If a trajectory begins at $\varepsilon = A$ (where A is equivalent to the value of the input step), it transverses through the phase plane as shown in Figure 2. The slope of the phase trajectory is given by the value of N as each isocline is crossed. The determination of the passage of the trajectory through the isoclines to point B when $\dot{\varepsilon}$ becomes negative, thence to point D when it again becomes positive is a simple matter. Motion ceases at D because the generated torque is less than C.

The phase-plane technique can be used to analyze the behavior of the second-order system for a variety of commonly encountered nonlinearities.

The main disadvantage of the phase-plane method is that it cannot be extended to higher-order systems in a satisfactory manner.

4 DESCRIBING FUNCTION METHOD FOR INVESTIGATING NONLINEAR CLOSED-LOOP SYSTEMS

In its most simple form, the describing function method is an extension of ordinary transfer function analysis to take into account the effect of single nonlinearities in systems excited by sinusoidal input.

It is particularly useful as a method for predicting the amplitude and frequency of limit cycles, but it can also be

used to assess relative stability by conventional frequency response methods.

In essence, the describing function of a nonlinear element is the gain of the element in terms of the ratio of its fundamental component output to a sinusoidal input of given magnitude and frequency.

Whereas the gain of a linear element is only ever frequency dependent the gain of a nonlinear element is always amplitude dependent and, additionally, can also be frequency dependent.

Here we will confine our study to amplitude dependent describing functions. In order to illustrate this point, consider a very common form of nonlinearity, namely, *saturation*.

The output is linearly related to the input for small positive or negative excursions of the input, but the output reaches a limiting value for large excursions (see Figure 3). The response of this nonlinearity to a sinusoid will be sinusoid for small signals, a clipped sinusoid for medium size signals, and tending to a square wave of magnitude KE_s for very large signals.

The gain of the element, based on the ratio of fundamental output to input thus is constant at a value K for small inputs; beginning to decrease as the input goes beyond E_s and eventually trailing off towards zero as the fundamental output tends towards its limiting value of $4KE_s/\pi$ as the input tends towards infinity (see Figure 4).

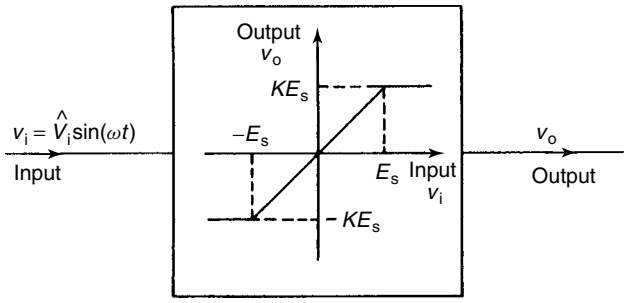

Figure 3. Illustrating a saturation nonlinearity.

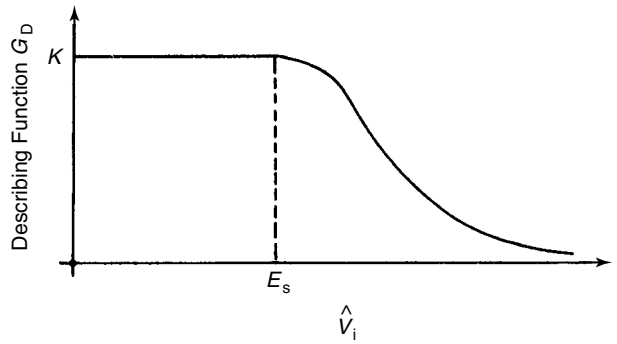

Figure 4. Describing function G_D for a saturation nonlinearity.

For memoryless nonlinearities the describing function is purely real, while memory-type nonlinearities introduce a phase shift, causing the describing function to be complex.

In general, if the fundamental output is expressed as a complex operator

$$V_o(j\omega) = \hat{V}_o \cos\theta + j\hat{V}_o \sin\theta \tag{8}$$

where $\hat{V}_o$ is the peak fundamental output and θ is the phase shift, then the describing function G_D is given by

$$G_D = \frac{\hat{V}_o \cos\theta}{\hat{V}_i} + j\frac{\hat{V}_o \sin\theta}{\hat{V}_i} \tag{9}$$

where $\hat{V}_i$ is the peak input.

To derive a describing function from this, we must use the Fourier series representation for the output

$$\begin{aligned} v_o(t) = {} & \tfrac{1}{2}A_o + A_1\cos(\omega t) + A_2\cos(2\omega t) \\ & + A_3\cos(3\,\omega t) + \cdots + B_1\sin(\omega t) + B_2\sin(2\,\omega t) \\ & + B_3\sin(3\,\omega t) + \cdots \end{aligned} \tag{10}$$

where

$$A_N = \frac{2}{\pi}\int_0^{\pi} v_o(t)\cos(N\omega t)\,\mathrm{d}(\omega t)$$

and

$$B_N = \frac{2}{\pi}\int_0^{\pi} v_o(t)\sin(N\omega t)\,\mathrm{d}(\omega t)$$

The definition of the describing function requires $A_o = 0$ and A_N and B_N for $N > 1$ to be negligible.

The fact that most control systems contain low-pass filtering elements, which filter out the harmonics to a substantial degree usually justifies these assumptions.

The describing function is then given by

$$\frac{B_1}{\hat{V}_i} + j\frac{A_1}{\hat{V}_i} \quad \text{in coordinate form}$$

or

$$\frac{\sqrt{B_1^2 + A_1^2}}{\hat{V}_i} \Big/ \tan^{-1}\frac{A_1}{B_1} \quad \text{in polar form}$$

Evaluation of the Fourier integrals may be quite simple, as in the case of the saturation nonlinearity but, sometimes, extremely difficult.

Fortunately, the describing functions of some commonly encountered nonlinearities have long been tabulated in the past, Thaler and Pastel (1962) and Gelb and Vander Velde (1968).

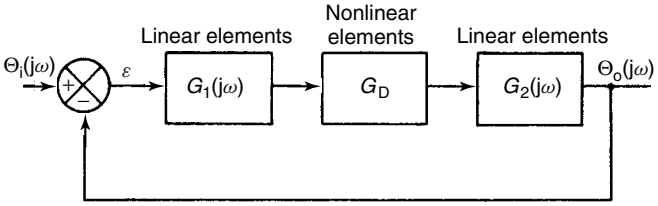

Figure 5. Nonlinear feedback system schematic.

The describing function for the saturation element is given by

$$G_D = \frac{2K}{\pi}[(\sin^{-1} R) + R\sqrt{(1 - R^2)}]\angle 0^\circ \qquad (11)$$

The Nyquist stability criterion – *see* **Article 38, Stability Issues, Volume 1** – may be involved for the determination of the stability of systems containing a nonlinear element as shown in Figure 5.

The closed-loop transfer function of this system is given by

$$\frac{\Theta_o}{\Theta_i} = \frac{G_1(j\omega)G_D G_2(j\omega)}{1 + G_1(j\omega)G_D G_2(j\omega)} \qquad (12)$$

The Nyquist criterion is based on the characteristic equation

$$1 + G_1(j\omega)G_D G_2(j\omega) = 0 \qquad (13)$$

To avoid the need to plot numerous Nyquist diagrams for every value of G_D, we may reform the characteristic equation as

$$G_1(j\omega)G_2(j\omega) = -\frac{1}{G_D} \qquad (14)$$

The encirclement of the locus $-1/G_D$ by the function $G_1(j\omega)G_2(j\omega)$ plotted as a polar diagram now indicates absolute instability.

Relative stability can be assessed by treating the locus $-1/G_D$ as the equivalent of the critical point $(-1, j0)$ used in linear systems design.

The amplitude and frequency of a limit cycle can readily be assessed by the point at which the frequency locus

$$G_1(j\omega)G_2(j\omega)$$

intersects the locus of $-1/G_D$. This is illustrated in Figure 6, which shows the Nyquist diagram of an unstable system that must limit cycle at angular frequency ω_c, where

$$\angle G_1(j\omega_c)G_2(j\omega_c) = -180^\circ \qquad (15)$$

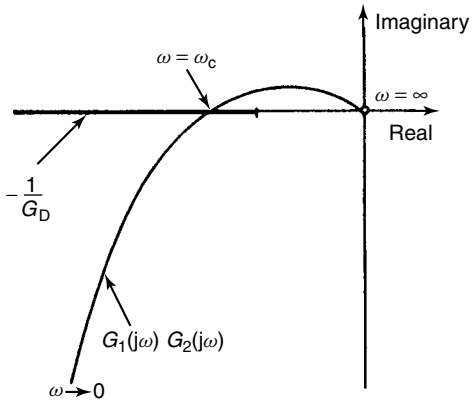

Figure 6. Nyquist diagram for a typical nonlinear system showing $-1/G_D$ (unstable situation).

from which ω_c may be calculated (generally by iterative trial and error).

The amplitude of the limit cycle can now be determined from

$$|G_1(j\omega)||G_D||G_2(j\omega)| = 1 \qquad (16)$$

which is the Nyquist amplitude condition for continuous oscillation.

The value of G_D can now be determined and the value of $\hat{V}_i$, the signal input to the nonlinear element, can be estimated by trial and error.

The error signal entering the first linear element can hence be computed from $\hat{V}_i/|G_1(j\omega_c)|$.

In the absence of any input to the system itself, the error and the output are identical in magnitude so that $\theta_o = \hat{V}_i/|G_1(j\omega_c)|$. This is the magnitude of the resultant limit cycle.

In general, it is necessary to determine the conditions graphically rather than analytically or by iterative trial and error.

Atherton (1975) has shown how the method of describing functions can be used to design compensating elements for nonlinear systems and be extended to treat multiple nonlinearities, to handle transient oscillations, dual sinusoidal inputs, and random inputs. Systems modeling tools often include means for investigating nonlinear systems.

5 HOW TO APPROACH THE DESIGN OF CLOSED LOOPS IN MEASUREMENT SYSTEMS

Many lengthy textbooks have been written on closed-loop systems so that it is hardly surprising that the information presented here merely touches the surface of a vast subject.

Material described here is based on the transfer function approach because this certainly offers the designer the most comprehensive set of techniques.

It should be understood, however, that many authors prefer to integrate the classical transfer function approach with the more recent state-variable approach.

In the state-variable approach the system model is described in terms of n first-order differential equations, each equation being a separate description of the behavior of a particular state and its connection with the other states and the driving inputs.

This form of description allows the equations for the system states to be condensed into the form of a single vector, $\mathbf{x}(t)$, and related to the driving input vector, $\mathbf{u}(t)$, by the equation

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) \tag{17}$$

where $\mathbf{A}$ and $\mathbf{B}$ are coefficient matrices.

The system outputs can then usually be related to the internal states by the vector equation

$$\mathbf{y}(t) = \mathbf{C}\mathbf{x}(t) \tag{18}$$

where, $\mathbf{C}$, is another coefficient matrix and, $\mathbf{y}(t)$, is the output vector.

The solution to the first of these matrix equations can be determined by various powerful computerized matrix methods and hence the response $\mathbf{y}(t)$ for a given $\mathbf{u}(t)$ can be determined quickly and accurately.

Apart from their application in time-domain analysis, state-variable techniques form the basis of the Lyapunov stability analysis and of optimal control theory. It can also be used in other design techniques, such as pole assignment, and pole assignment and decoupling methods, using state vector feedback.

In order to obtain greater sensitivity and better accuracy of measurement, it is likely that more and more instruments will incorporate feedback. The designers of instruments of all kinds will, therefore, have to become more familiar with the analysis and design of feedback systems.

In essence, the design of measuring systems loops is best kept manageable by avoiding nonlinear effects in any elements under the designer's control.

Those nonlinear effects that cannot be eliminated or lessened at source should be reduced by the use of local feedback solutions.

Manufacturing them in hardware form, even with a control prototyping kit, is not recommended until they have been investigated thoroughly with an appropriate modeling tool, of which many are available including Matlab® and Simulink – see Bishop (1997).

1 THE PROBLEM OF KNOWLEDGE

Human beings know but do not definitely know what knowledge is: traditions, prejudices, expectations, and projections are more or less always part of knowledge and make it a combination of objectivity and subjectivity. Rationality allows some critical control on knowledge, and the recognition of the limitations to which human knowledge is subject is precisely a result of rationality.

The interest in theorizing about knowledge arises from the observation that different persons have different beliefs, and ultimately that beliefs and facts are distinct: 'theory of knowledge is a product of doubt', as Bertrand Russell wrote. In the history of both western and eastern culture, such a doubt has stimulated an impressive amount of research, ideas, and philosophical systems, and nevertheless very different positions have been maintained and still remain on the nature of knowledge and its object (it is reasonable to hypothesize that, more than from the plethora of such positions, the complexity of the topic derives from its inherent reflexivity, due to the fact that the object of the analysis coincides with the tool by means of which the analysis is performed: to know knowledge, only knowledge can be employed). A basic dichotomy can be identified, whose elements play the role of competing attractors for an ideal continuum of positions: *objectivism* assumes that a world external to the subject exists independently of him and has predefined properties, existing as such before they are acquired by the perceptive-cognitive system of the subject, whose aim is to reconstruct them; on the other hand, *solipsism* asserts that the cognitive system of the subject projects his own world out of him, and the reality of such a world is just an image of the laws internal to the system.

The position currently supported by the majority of scientists and engineers can be plausibly characterized as a kind of 'pragmatic realism', close to but not coincident with objectivism, according to which the conjoint efforts of science and technology are aimed at reaching, and actually guarantee, better and better, that is, more and more objective knowledge of the world whose properties are therefore progressively discovered.

Measurement plays a crucial role in supporting this realism.

2 THE STATUS OF REALISM

In acquiring and processing information from the world, human beings constantly *produce models* (and sometimes theories: we will not emphasize here the distinction between models and theories, grounded on formal logic) of the world they observe, thus generating knowledge on it (see Figure 1).

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Figure 1. Human beings produce models of the world they observe.

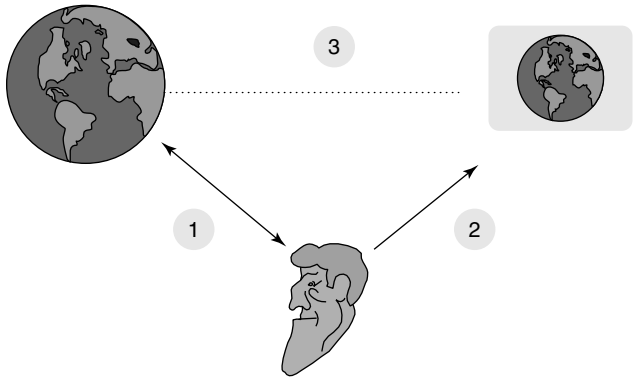

Figure 2. The relations among subjects, world, and models.

Such knowledge results from the relations among the three interacting entities, the subject, the world, and the model, so that the relation between the world and its model is not direct, but always mediated by the subject who produced the models themselves as shown in Figure 2.

Whenever it remains individual, knowledge is just tacit and usually implicit and as such it reduces to personal experience that can be communicated only by person-to-person means, as imitation.

Critical is therefore the *objectivity*, that is, the independence from the subject, of the relation between the world and its models. Realism assumes two operative reasons for justifying the possibility of some objective knowledge:

- *Intersubjectivity*: were knowledge only subjective, mutual understanding would be an exception more than a rule (Figure 3).

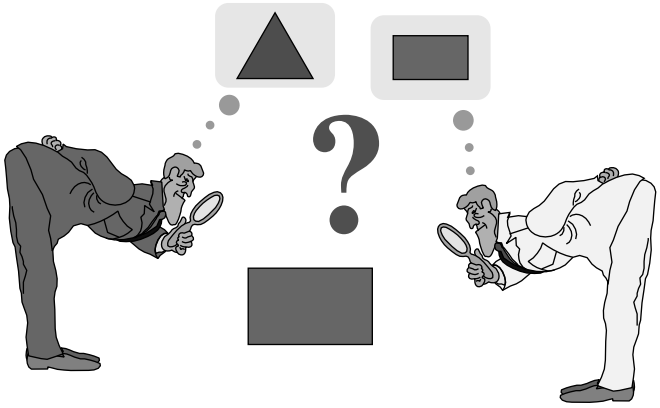

Figure 3. A justification for realism: mutual understanding.

- *Pragmatics*: were knowledge only subjective, our ability to effectively operate on the world would be an exception more than a rule (Figure 4).

Realism can be then interpreted as a weak form of objectivism: the world exists independently of us and both intersubjective and pragmatic experiences lead us to assume that it cannot be too different from our models of it.

On the other hand, to generate knowledge that can be shared, subjective models must be expressed in some socially understandable and usable form, such as statements in a natural language or mathematical laws. This points out a further basic issue on knowledge: 'how can it be

Figure 4. A justification for realism: effectiveness.

that mathematics, a product of human thought independent of experience, is so admirably adapted to the objects of reality'? in the words of Albert Einstein.

Philosophers and scientists have formulated different opinions in this regard, more or less explicitly in reference to a basic dichotomy: either 'scientific laws faithfully describe how the world is' or 'scientific laws are just synthetic means to express information about events in an aggregate way'. The former position implies a *metaphysical* hypothesis on the nature of the world, classically stated as 'numbers are in the world' (Kepler) or by assuming that 'the great book of nature' cannot be understood 'but by learning its language and knowing the characters in which it is written: it is written in mathematical terms' (Galileo); in contrast, the latter position suggests the *economic* nature of science: since 'in Nature the law of refraction does not exist at all, but only different cases of refraction', by means of such a law 'we do not have to keep in mind the countless phenomena of refraction in the various compositions of matter and under the various incidence angles, but only the rule that we call 'law of refraction', a much easier thing' (Mach).

Measurement has been often adopted to justify the former position.

3 SEMIOTICS OF KNOWLEDGE

Knowledge can be *about* the physical world but it is not *part of* it. Given the realistic assumption of the independence of the physical world from the subject, both subjective and objective knowledge can be interpreted in an evolutionary context as the results of mankind to adapt to his (firstly only physical and then also social) environment. In this regard, Karl Popper has suggestively proposed to identify 'some stages of the cosmic evolution' as organized in three 'worlds', as follows:

World 1

0. hydrogen and helium
1. heavier elements; liquids and crystals
2. living organisms

World 2

3. sensitivity (animal conscience)
4. conscience of self and death

World 3

5. human language; theories of self and death
6. products of art, technology, and science.

In this framework, knowledge (whose object can belong to either Worlds, and finally could even become knowledge itself...) is a rather advanced entity, appearing initially within World 2, in the form of subjective experiences, and then fully evolving in the context of World 3. The transition from World 2 to World 3 corresponds to the social ability to communicate, and therefore to share, experience: that is why the availability of a (textual or nontextual) language is considered the first step within World 3. Furthermore, the usage of a language gives knowledge a syntax and makes it a semiotic entity (*see also* **Article 23, Principles of Semiotics as Related to Measurement, Volume 1**).

Given the complexity of the concept of knowledge and its fuzzy characterization, rather than trying a definition of it we suggest that the (possible) presence and the relative importance of the semiotic components, syntax, semantics, and pragmatics, can be adopted as a criterion to distinguish among the different entities that are commonly deemed to be (related to) knowledge. In particular,

- the exclusive availability of *pragmatic* information ('to know how to do'), such as the competence shown by many craftsmen, appears to be a limited kind of knowledge, if knowledge at all;
- the exclusive availability of *syntactical* information and the ability of purely symbolic (i.e. only syntactical) processing, as performed by most automatic devices, appears to be a limited kind of knowledge, if knowledge at all.

The designation of 'knowledge-based' for the systems operating on the basis of an explicit semantics is a further argument to support the hypothesis that meanings are critical for the emergence of 'proper' knowledge, and therefore that socially communicable knowledge ('World 3 knowledge') is an entity spanning all the semiotic components.

4 PRAGMATIC CLASSIFICATION OF MODELS

If the pragmatic component is taken into account, different purposes for knowledge can be recognized: models can be adopted for description, explanation, prevision, prescription.

It is usual that the first stages of the development of a new field of knowledge are devoted to the production of models aimed at the *description* of the system under analysis. Typical outcomes of this work are the identification of properties relevant to describe the system and their evaluation to classify the system itself into more or less rough categories.

To overcome the conventionality of taxonomies and whenever the available knowledge allows it, some relations among properties are identified, so that each property is

embedded in a network of dependencies. In such cases, the relational information that is (explicitly or implicitly) conveyed by properties can be referred to in order to obtain an *explanation* of the system state/behavior: the value of the property x_1 is v_1 because x_1 is connected to the properties $x_2, \ldots, x_n$ by the relation R, and the properties $x_2, \ldots, x_n$ have values $v_2, \ldots, v_n$ respectively, and $R(x_1, \ldots, x_n)$.

Sometimes, models can be further enhanced to include relations connecting properties with an explicit functional time dependence, $\forall i = 1, \ldots, n, x_i = x_i(t)$, for example, in the form (known as *canonic representation*, or *local state transition* in System Theory):

$$\frac{\mathrm{d}x_i(t)}{\mathrm{d}t} = f_i(x_1(t), \ldots, x_n(t)) \tag{1}$$

for time-continuous models, and

$$x_i(t + \Delta t) = x_i(t) + f_i(x_1(t), \ldots, x_n(t))\Delta t \tag{2}$$

for time-discrete models. Models can then be used also for *prevision*, in particular if the integral/time-global versions of the canonic representations is taken into account:

$$x_i(t) = x_i(t_0) + \int_{t_0}^{t} f_i(x_1(\tau), \ldots, x_n(\tau))\,\mathrm{d}\tau \tag{3}$$

$$x_i(t_n) = x_i(t_0) + \sum_{j=0}^{n-1} f_i(x_1(t_j), \ldots, x_n(t_j))\Delta t \tag{4}$$

allowing to compute the system state $\langle x_1(t), \ldots, x_n(t)\rangle$ at a generic (future or past) time t from a reference, initial state $\langle x_1(t_0), \ldots, x_n(t_0)\rangle$ and by means of the state transitions $\langle f_1, \ldots, f_n\rangle$.

Finally, if an external intervention is possible on the system, its spontaneous dynamics can be controlled to let the system evolve toward a required target. In this case, models are then aimed at *prescription*: given a generalized version of the local state transition function including in its domain both the current state and the user input, models specify how to provide such an input, and therefore become decision-making tools (see Figure 5).

According to the traditional paradigm of science and its relations with technology, by repeatedly following this

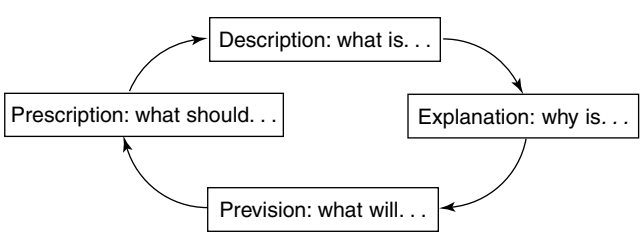

Figure 5. The knowledge loop among the four kinds of models.

knowledge loop, the quality of knowledge itself and the effectiveness of system control can always be enhanced.

On the other hand, in many situations prescriptions are required even when predictive, explanatory, and sometimes even socially agreed descriptive models are not available (let us quote the crucial examples of medicine and business administration). In these cases, experiences and expectations (i.e. World 2 knowledge) still play a critical role.

5 THE EVALUATION OF QUALITY OF KNOWLEDGE

Given the combination of subjectivity and objectivity so usually present in knowledge, it is not amazing that the evaluation of the quality of knowledge represents a basic issue in the process of acquisition of candidate items for their integration in an existing body of knowledge.

The quality of a model can only be evaluated in reference to the goals for which the model itself has been produced: the general criterion for this quality evaluation is therefore the *adequacy to goals*. Truth, traditionally thought of as 'correspondence to facts', is regarded as a specific case of adequacy, applicable whenever correspondence to facts is indeed considered an important issue (note how this position radically differs from the pragmatist definition of truth, according to which 'a sentence may be taken as a law of behavior in any environment containing certain characteristics; it will be "true" if the behavior leads to results that are satisfactory to the person concerned, and otherwise it will be "false"' (Russell)).

While adequacy is hardly the object of general treatment, the possibility of evaluating the truth of a model has been widely debated and is surely one of the most critical topics of the Philosophy of Science. Following Karl Popper, it can be suggested that the controversy is specifically related to two basic Problems:

1. how to compare (the statements of) competing models?
2. how to evaluate (the truth of) a model?

in reference to which three standpoints can be identified:

- *Verificationism*: typical of classical science and brought to its extreme consequences by the Neo-Positivistic school: Problem 2 admits a solution (and therefore the truth of a model can be determined), from which a solution to Problem 1 is derived: the reference to truth is the foundation allowing the advancement of science.
- *Falsificationism*: also called 'critical rationalism', as advocated by Popper himself: Problem 1 admits a solution (in the presence of competing models, the one that is chosen is the one that is not falsified and has the

greater empirical content), but a solution to Problem 2 cannot be derived from it: by means of conjectures and confutations, truth is approximated; the preference of a model over a competing one can be rationally motivated, but a model cannot be justified in itself.

- *Epistemic relativism*, also called 'irrationalism', supported by philosophers such as Thomas Kuhn and, in its extreme consequences, Paul Feyerabend: Problem 2 does not admit a solution ('the only principle that does not inhibit progress is anything goes. For example, we may use hypotheses that contradict well-confirmed theories and/or well-established experimental results. We may advance science by proceeding counter-inductively' (Feyerabend)), and therefore also Problem 1 cannot be solved: no criterion/method that is absolutely valid holds in scientific research.

6 DATA AND INFERENCE IN KNOWLEDGE

We get an insight into knowledge by considering its operational side of being a *faculty to solve problems*, and, in particular, to modify the state of systems according to given goals. As human beings, we constitutively have the ability to operate state transitions on the systems with which we interact by means of a 'World 2 strategy': we acquire data on the current state through our sensorial apparatus; by means of the brain, we perform inference on such data, and finally we use the data resulting from this process to drive our motor apparatus whose activity actually carries out the required state transition (these three steps correspond to the tripartite structure of the neural system: *sensorium*, brain, and *motorium*; note that more than 99% of the about 10^{10} neurons of human beings are part of the brain). In many cases, this strategy is manifestly both more efficient and more effective than a blind 'try-and-error' approach, although far more complex than it.

The same conditions, the availability of data and the ability to deal with them by means of inference, are also characteristic of the 'World 3 strategy' to problem solving, as shown in Figure 6.

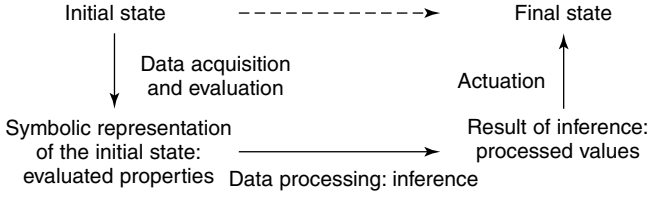

Figure 6. The 'World 3 strategy' to problem solving.

This scheme highlights the complementary role of data and inference in knowledge (*see also* **Article 10, Extensions of the Representational Theory of Measurement, Volume 1**).

Data, that is, evaluated properties, are aimed at being a *faithful representative* of the observed state, as obtained by either subjective or intersubjective and objective procedures, and can be expressed by means of either an informal or a formal language. The fundamental operation to empirically get formal data by means of an intersubjective and objective procedure is measurement: according to the representational point of view to measurement theory (*see also* **Article 8, Formal Theory of Measurement, Volume 1**), such a faithfulness is formalized by requiring that the mapping from empirical states to symbols be a homomorphism for the scale type in which states are measured; the existence of monomorphisms for the measurement scale type (i.e. admissible scale transformations) manifests the residual presence of conventionality in the selection of symbols. It is in this regard that one could wonder about *the truth* of symbols and the related sentences.

Inference is an operation aimed at obtaining new data 'conclusions' from the processing of the given inputs 'premises'. To understand the structure of inferential processes, the fundamental distinction between *singular* and *universal assertions* (sometimes called *facts* and *laws* respectively) must be taken into account. In set-theoretical terms, $a \in P$ (the element a belongs to the set P; the property P holds the element a) is singular, whereas $P \subset Q$ (P is a subset of Q; for all elements x, if the property P holds for x then also the property Q holds for it) is universal (it should be clear therefore that data obtained by means of measurement are singular).

Two kinds of inference are then traditionally considered, that in their simplest forms are as follows:

- From the singular $a \in P$ and the universal $P \subset Q$ by *deduction*, the singular $a \in Q$ is obtained; deduction is a truth-preserving inference that, strictly speaking, *does not lead to new knowledge*.
- From a collection of singular $a \in P$ and $a \in Q$ by *induction*, the universal $P \subset Q$ can be obtained; induction is a hypothetical inference that *does not lead to conclusive knowledge*.

The problem of foundation of empirical knowledge is traditionally ascribed to this circularity: deduction leads to true conclusions, but only if the truth of its (both singular and universal) premises can be assumed; induction is the only means to obtain new universal knowledge, but the truth of such knowledge cannot be definitely assumed.

7 INEXACTNESS OF KNOWLEDGE AND MEASUREMENT

We have already noted the relevance of language for World 3 knowledge: truth is a property of sentences (actually: of declarative ones), and 'science, though it seeks traits of reality independent of language, can neither get on without language nor aspire to linguistic neutrality. To some degree, nevertheless, the scientist can enhance objectivity and diminish the interference of language, by the very choice of language' (Quine). That is why formalization (i.e. the expression of knowledge in a form such that inferential processes can be entirely performed on the basis of the syntactical component of data) is often regarded as a critical requirement for scientific knowledge. On the other hand, formalized languages can be (and in many cases actually are) far too precise for expressing empirical knowledge: 'there are certain human activities which apparently have perfect sharpness. The realm of mathematics and of logic is such a realm, par excellence. Here we have yes-no sharpness. But (...) this yes-no sharpness is found only in the realm of things *we say*, as distinguished from the realm of things *we do*. (...) Nothing that happens in the laboratory corresponds to the statement that a given point is either on a given line or it is not' (Bridgman).

Hence, the same empirical knowledge can be expressed in sentences by balancing two basic components: *certainty* (a term for some aspects more general than truth) and *precision* (also called *specificity* or, at the opposite, vagueness). Therefore, 'all knowledge is more or less uncertain and more or less vague. These are, in a sense, opposing characters: vague knowledge has more likelihood of truth than precise knowledge, but is less useful. One of the aims of science is to increase precision without diminishing certainty' (Russell).

The fact that the length of the diagonal of a physical 1 m side square *cannot* be $\sqrt{2}$ m is an important consequence of metrological thinking: the information conveyed by real numbers (and the related concepts of continuity/differentiability) is too specific to be applicable, as is, to physical systems. By progressively enhancing the resolution of the measuring systems, and therefore by increasing the specificity of the measurement results, their uncertainty consequently grows, until the object of measurement itself becomes uncertain (in the previous example, at the atomic scale the concept of 'physical square' is meaningless), and an 'intrinsic uncertainty' (also called 'model uncertainty') is reached.

This reflects a basic feature of the relation that by means of knowledge it is established between World 1 (to which the object of knowledge belongs) and World 3 (to which the sentence that expresses knowledge belongs): if symbols are not generally so specific to univocally denote (properties of) things ($2 + 2 = 4$ holds for both apples and aircraft carriers), at the same time, things are too complex to be fully described by means of symbols.

8 (NON)FOUNDATIONS OF KNOWLEDGE

Philosophy of Knowledge (and Philosophy of Science, in particular) has always quested for a *foundation* of knowledge, that is, the elements on which the 'building of knowledge' can be firmly erected. In the course of history, such a foundation has been found in natural elements (for example, Thales of Miletus affirmed that the principle that causes all the things is water, while Heraclitus of Ephesus found it in fire), in physical or conceptual structures (atoms according to Democritus of Abdera, numbers in the conception of Pythagoric school), in metaphysical principles (such as the hypothesis that Nature is simple), in methodological assumptions (in particular, the postulation that any empirical knowledge cannot be derived but from sense data). The usage of the metaphor of foundations is not conceptually neutral: the architectural image of 'foundations' reveals the hypothesis that scientific research can make knowledge incrementally grow from its bases, where measurement has been traditionally recognized as the operation that is able to produce the objective data playing the role of such bases.

In the last decades, this confidence in the progressive development of scientific knowledge has been questioned by concentric objections, all emphasizing that definitive foundations are beyond the reach of the means human beings adopt to know. Complementary to the abovementioned philosophical positions of epistemic relativism (according to which raw sense data do not exist because data are always theory laden), an important area of scientific research is currently devoted to the systems that exhibit relevant *structural complexity*, a characteristic that makes such systems irreducible from the classical paradigm of reduction to simplicity through the hypotheses of linearity, principle of superposition of effects, and so on. Knowledge is recognized to be an always evolving process, where 'there is never an absolute beginning. We can never get back to the point where we can say, 'Here is the very beginning of logical structures' (Piaget). More than the actual availability of data, knowledge is recognized to be a potentiality (what is 'stored' in our brain is how to compute multiplications, not the results of operations such as 1234×5678), information is always under reconfiguration.

The role assigned to measurement is paradigmatic of the shift toward what could be called *reticular* (and therefore without foundations) knowledge. Indeed, according to the current standpoints of philosophy of measurement:

- Since measurement results depend on standards through a traceability chain, standards themselves could be thought of as 'realizations of true values,' than playing the role of actual foundations for measurement; on the other hand, standards must be indeed 'realized' by primary laboratories, who maintain their quality by means of interlaboratory comparisons: therefore, this claimed 'path towards foundations' cannot but include a component of conventionality.
- Any measurement result depends for its evaluation on the previous measurement of a set of influence quantities, in their turn being new measurands so that in principle such a dependence should be recursively applied, with the consequence that a 'well-founded measurement' would be impossible to be completed; the usual operative choice to assume that the quantities influencing the initial measurand are not influenced by other quantities, and therefore, that they can be 'directly measured', highlights the conceptual approximation inherent in any measurement.
- While the adequacy of empirical models is controlled by means of measurement, the quality of measurement results depends on the quality of mathematical models used for designing measuring systems.

This complexity makes knowledge the most versatile tool available to human beings and a fascinating object for knowledge itself.

1 SIGNS AS ENTITIES THAT 'STAND FOR' SOMETHING

Semiotics is commonly defined as the *doctrine of signs*, a sign being 'something which stands to somebody for something in some respect or capacity' according to Charles S. Peirce, one of the seminal thinkers about semiotics itself. The emphasis is here on the relation of 'standing for', which, in its simplest form, can be modeled as follows.

When a purpose is assigned to, or recognized proper of, things, they can be evaluated in their ability to satisfy it. Any given purpose induces a relation of *functional substitutability* S on the set of considered things T such that $\forall x, y \in T$, $S(x, y)$ if and only if x is a substitute of y with respect to the purpose, that is, x is as able as y to satisfy the purpose itself.

Instead of investigating here the general properties of the relation S (but at least the observation should be made that in many cases functional substitutability is not a matter of a yes–no alternative, and therefore that S could be usually formalized as a fuzzy relation: *see also* **Article 12, Fuzzy Approaches for Measurement, Volume 1**), let us devote our attention to the specific relation of *identification*. The functional substitution implied in the identification is such that x identifies a given y if and only if x operates as the selector of y in a set of candidate things $y_1, y_2, \ldots$ the exhibition of x being considered functionally equivalent to the selection of y and the nonselection of any other $y_i \neq y$ in the candidate set. In such a relation $S_{id}(x, y)$ let us call x and y the *identifier* and the *identified entity* respectively: x *stands for* y. For example, the sound c-h-a-i-r (a physical thing as a space-time event produced by the utterance of a speaker), could be the identifier chosen to select a chair instead of any other nonchair object (note that no restrictions have been imposed on the set of the entities that are the object of identification: y can be a physical object but also an informational entity).

It is a common observation that different $x_1, x_2, \ldots$ can be adopted as identifiers for the same entity y, $S_{id}(x_1, y)$, $S_{id}(x_2, y), \ldots$ (a chair can be identified by different sounds, possibly pronounced by different persons in different languages in different times, but also by writings, drawings, gestures, ...). In this case, the $x_1, x_2, \ldots$ are functionally substitutable with each other in their role of identifiers for y, and therefore a derived relation S_{id-y} holds among them. Formally (we will continue to forget the fact that also S_{id-y} could be fuzzy) $S_{id-y}(x_1, x_2)$ if and only if $S_{id}(x_1, y) \wedge S_{id}(x_2, y)$.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

A fundamental step is taken when the *class* $\hat{x}$ of all the identifiers x for which the relation S_{id-y} holds is abstractly considered as the identifying entity for y, thus recognizing that signs, although instantiated in physical things, are *information entities* (*see also* **Article 22, Characteristics and Theory of Knowledge, Volume 1**).

2 CODING AND DECODING

Signs generally result from the relation between two elements: identifiers and identified entities. Such a relation is operatively realized and performed in two phases:

- for a given entity y to be identified, an identifier is obtained by means of an operation of *coding*: an information entity $\hat{x}$ is at first associated with y, and then an identifier x is selected such that $x \in \hat{x}$; for example, see Figure 1,
- for a given identifier x, the identified entity is obtained by means of an operation of *decoding*: an information entity $\hat{x}$ is at first identified, by means of a pattern recognition, as the class to which x belongs, and then an entity y is selected as associated with $\hat{x}$; for example, see Figure 2, (*see also* **Article 33, Coding Theory and its Application to Measurement, Volume 1**).

Figures 1 and 2 are instances of a more general 'semiotic triangle', in which the 'standing for' relation is represented as in Figure 3: where the dotted line expresses that the relation is indirect and a 'mediator' is usually required to connect identifiers and identified entities.

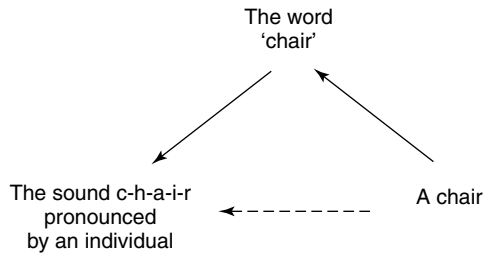

Figure 1. An exemplification of the structure of a coding operation.

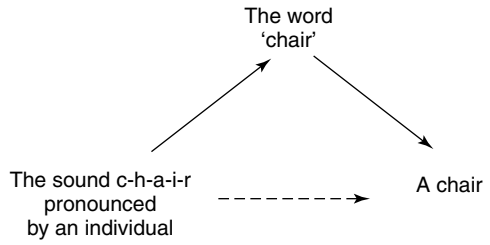

Figure 2. An exemplification of the structure of a decoding operation.

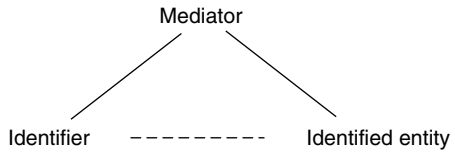

Figure 3. The 'semiotic triangle'.

In the history of Semiotics, diagrams of this kind have been widely adopted to present and generalize the relation that we have introduced as between identifiers and identified entities. For example, de Saussure defined it in terms of 'signifiers' and 'signifieds' (and called 'signification' the relation itself), while Hjelmslev used the terms 'expression' and 'content' respectively.

These diversities witness the different interpretations and emphasis put on the elements of the relation. For example, the mediator has been thought of as either the *sense* of the identifier (chairs are identified by means of the term 'chair' because of the meaning associated with such a term, that is, the set of features that are shared by everything to which the term applies, the so-called *intension* of the term), or the *set of the entities*, the entities to what the identifier stands for (the so-called *extension* of the term), or the *subject* with the competence to maintain the relation, or the *social context* of the individuals who agreed to associate the identifier with the identified entity.

In the case in which the entity to be identified belongs to the physical world (let us mention again that it could be a purely informational entity, as in the case when one is talking about words or numbers), a common, although surely not necessary, situation is such that the relation between the physical thing chosen as identifier and the identified entity is mediated by *two* informational entities, for example, (see Figure 4) so that each arrow in Figure 5 represents a partial realization of the 'standing for' relation.

Semiotics has been in particular working on the *informational component* of the 'standing for' relation, thereby often minimizing, or even neglecting, the analysis of the relation between the symbols and the physical things adopted as support for them. From now on we will accept

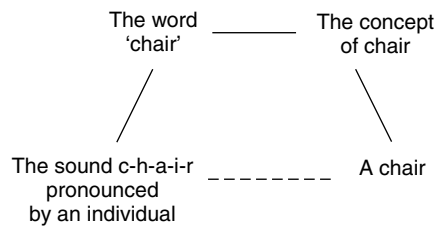

Figure 4. The structure of the semiotic relations.

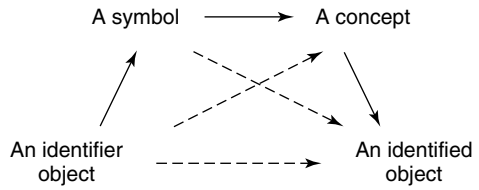

Figure 5. The 'standing for' relations.

this general standpoint, and follow the terminology proposed by Ogden and Richards who describe the 'standing for' relation in terms of *symbols* that stand for *referents* (*see also* **Article 8, Formal Theory of Measurement, Volume 1**).

3 CONVENTIONALITY OF SIGNS

The 'standing for' relation is a complex one: the same symbol could stand for different referents, and different symbols could stand for the same referent (e.g. in the case of the linguistic phenomena of *polysemy* and *synonymy* respectively). This suggests that such a relation is not inherent to the entities involved in it: an entity becomes a symbol only as the result of a choice.

The issue of the (degree of) arbitrariness of signs has been thoroughly inquired by many philosophers, who noticed its fundamental implications in terms of autonomy of symbols in relation to referents and therefore, generally speaking, of language in relation to reality. For example, in Plato's Cratylus, the problem of 'right names' for things is discussed, and it is concluded that 'whatever name you give to a thing is its right name; and if you give up that name and change it for another, the later name is no less correct than the earlier, just as we change the name of our servants; for I think no name belongs to a particular thing by nature'.

Following Peirce, signs are usually distinguished in three broad categories, characterized by their increasing degree in conventionality:

- *Indexes*, such as 'natural signs' (smoke standing for a yet unseen fire) and 'signals' (a phone ringing standing for a waiting call), for which the symbol is causally connected to the referent, so that every subject informed on the connection is able to infer the existence of the relation.
- *Icons*, such as images or onomatopoeic words, for which the relation symbol-referent is based on some mutual resemblance or imitation of the related entities; in this case, the relation can be intensively learned (e.g. the higher the sound the angrier the speaker) and is easily, while often implicitly, shared among cultural communities.
- *Symbols* (in specific sense), such as those constituting many elements of textual languages, for which the relation symbol-referent is purely conventional (obtained sometimes by an explicit ruling convention, sometimes by usage), so that it must be learned according to an extensive strategy, that is, by explicitly listing the symbol-referent pairs.

4 THE OPPOSITION ANALOG/DIGITAL IN A SEMIOTIC PERSPECTIVE

The latter two categories, icons and symbols, can be meaningfully expressed in terms of the *opposition between analog and digital*, as traced back to the concept of *structure* modeled and formalized in Measurement Theory (*see also* **Article 8, Formal Theory of Measurement, Volume 1**). The opposition A/D concerns the strategy adopted for *coding and decoding the metainformation* that complements the information that symbols convey on referents. Indeed, together with the information enabling the selection of referents, in many cases, some structural information must be maintained in coding and recognized in decoding. For example, if the referent is a grade in $\{A, \ldots, E\}$ the observation of a physical support coding the symbol 'B' should bring both the information 'is B' (and 'is not A, and not C, ...') and the (ordinal) metainformation 'is less than A but more than C, ...'. Therefore:

- *analog* is the strategy by which the metainformation is coded in the support configuration, so that both coding and decoding correspond to the application of a homomorphic (i.e. structure preserving) mapping;
- *digital* is the strategy by which the metainformation is maintained in the coding rule, so that the physical support is only required to be able to assume at least two distinguishable configurations (those usually symbolized as '0' and '1'), as specified in Shannon's Theory of Information.

This characterization accounts for the nature of *opposition* of the strategies of analog and digital coding:

- The definition of the code rule can be intensive in analog cases, whereas it must be extensive in digital cases: while analog codes can be analytically defined, the lack of structure forces digital codes to be defined by explicitly and completely listing the occurrences symbol-referent.
- The set of information entities to code can be incompletely preidentified in analog cases, whereas it must be

preidentified in digital cases: for example, to increase the cardinality of the set of the possible symbols to code on a physical support, an analog code can be adopted as is, whereas a digital code must be redefined.

On the other hand;

- analog coding can be adopted only if some metainformation is available, whereas digital coding is always available for finite sets of symbols;
- supports adopted in coding must be able to maintain the metainformation in physically distinguishable configurations in analog cases, whereas it can be very simple since only two distinguishable configurations are in principle required in digital cases.

It should be noted that mixed (partly analog, partly digital) coding rules are common, as in the case of the usual numerical notation, in which the single digits are digitally coded while the positional rule is analog.

5 THE SYSTEMIC NATURE OF SIGNS

The 'standing for' relations are seldom defined as single and independent coding rules. Rather, their conventionality is considerably restricted by the effects derived by their *systematic definition* (as an example, consider the possibility of reconstructing the meaning of a linguistic term, that is, 'decoding' it, by means of its etymological analysis).

Natural languages, such as English or Italian, are far more complex than artificial languages, such as the formalism of mathematical logic or computer programming languages, also because they include a huge amount of exceptions, that is, irregularities, in their coding and decoding rules. Nevertheless, the fact that some systematic effects progressively emerge from historical usage instead of explicit decision, as indeed in the case of natural languages, does not reduce their relevance but only the uniformity of the system of rules.

This systemic component was called *language* (*langue*, in French) by Saussure, who contrasted it with *speech* (*parole*, in French), regarded as the individual act of selection and actualization of symbols that stand for intended referents by means of some coding rules of the language. Any specific film would be therefore the 'speech' of the 'language' of cinema, an example highlighting that *langue*/*parole* is actually the dichotomy code/instance or schema/usage, as Hjelmslev termed it. 'Each of these two terms achieves its full definition only in the dialectical process which unites one to the other: there is no language without speech, and no speech outside language: it is in this exchange that the real linguistic praxis is situated' (Barthes).

Dialectical is also the process by which the decoding of composite structures of symbols, for example, sentences, is performed: paradigmatically, whenever coding rules are *context-sensitive* (a typical characteristic of natural languages), not only can the meaning of a sentence be derived from the meaning of its constituting parts, but the meaning of such parts could also depend on their role in the sentence, so that it can be determined only after some hypothesis of the meaning of the whole sentence itself. This generally makes the recognition of the 'standing for' relations a complex, recursive process, and again this explains why the constructs of artificial languages are defined as context-free whenever recognized as adequate (as an example of the role of context in rule evaluation, consider two possible definitions of the disjunction operator OR: if $v(x)$ is the truth value of the sentence x, in classical logic, such an operator is context-free, since $v(x \vee y) = f(v(x), v(y)) = \max(v(x), v(y))$; on the other hand, in the case of probabilistic logic $v(x \vee y) = v(x) + v(y) - v(x \wedge y)$ and therefore the operator is context-sensitive, because $v(x \vee y) \neq f(v(x), v(y))$, with the term $v(x \wedge y)$ playing the role of context).

6 SYNTAX, SEMANTICS, AND PRAGMATICS

A fundamental classification to isolate the different contributions to the complexity of the 'standing for' relation was proposed by Charles W. Morris, who suggested three basic subdisciplines as the constituting components of Semiotics: *syntactics* (also, and more commonly, called *syntax*), *semantics*, and *pragmatics*. Despite their large reciprocal autonomy, such disciplines can be presented in terms of progressive extension of scope:

- *Syntactic* is the information dealt with as *data*, taking into account the collection of available signs and its structure; a basic issue of syntax is *parsing*, that is, the check that a sentence is well formed according to a given set of syntactical rules.
- *Semantic* is the information dealt with as data provided *with meaning*, taking into account (also) the entities to what the signs stand for; a basic issue of semantics is *truth evaluation*, that is, the check of the correspondence between the content of a sentence and the actual state of the reality (it should be noted that the evaluation of the truth of a sentence does not always require the interpretation, that is, the 'semantization' of the sentence itself; for example, tautologies in propositional logic (e.g. $A \vee \neg A$) are true for any interpretation of A; this establishes a distinction between *linguistic* and *empirical truth*).

- *Pragmatic* is the information dealt with as data provided with meaning *and value*, taking into account (also) the relation of signs to interpreters and therefore issues related to behaviors, subjective interests, utilities, . . .; a basic issue of pragmatics is *relevance assessment*, that is, the check that a sentence is actually useful for its deemed receivers.

The distinction among these disciplines and their goals can be exemplified by means of that particular system of signs that is mathematics:

- The formula '$2)\sqrt{(+ \leq)x}$' is not well formed, so that a fortiori neither its meaning and truth nor its utility for a given subject can be evaluated.
- The formula '$2 + 3 = 4$' is well formed, its meaning can be evaluated, and it is actually false in the usual interpretation of its constituting signs.
- The formula '$1 = 1$' is well formed and it is true, but plausibly useless for most subjects.

Given the centrality of the 'standing for' relation, semantics can be considered the core component of semiotics. Nevertheless, the threshold between syntax and semantics is not always well defined, and often actually a matter of 'point of view'. For example, in the case of Morse code, the physical support is an electric current, whose patterns are interpreted as sequences of 'dots' and 'dashes', whose patterns are in their turn interpreted as sequences of alphanumeric characters; the sequence 'dot-dash' is then a semantic entity with respect to an electric signal but it is a syntactical entity with respect to its deemed interpretation, that is, the character 'a'.

7 SEMIOTICS AND COMMUNICATION

An important area of application of Semiotics is *communication*, that is, the transfer of messages conveying some sort of information from a sender to a receiver through a channel, (see Figure 6). The standard model for a basic communication system has been defined by Shannon: the message generated by the sender is coded into a pattern of signs, here called a *signal*, that is transmitted by the channel and finally decoded again into a message for making it accessible to the receiver.

As formalized by Shannon, the communication problem – how to maximize the probability that the received message is the same as the one generated by the sender even in the presence of a noisy channel – specifically relates to syntax. The general semiotic nature of the problem has been shown by Roman Jakobson, who suggested that each of the six components of a communication system shown in Figure 7: is associated with a specific *function*, more or less present and emphasized in each communication act. Indeed, if the prominence is usually given to the referent (i.e. the 'content' of the message, corresponding to the so-called *referential*, or *cognitive*, *function*), in many messages, the role of the other functions must also be taken into account to fully understand the communication act itself. According to Jakobson, a communication can differently stress:

- the position of the sender (*emotive function*) on the communication subject (e.g. in terms of rage or irony);
- the orientation toward the receiver (*conative function*), as typically in the case of imperative sentences, whose aim is indeed to convey commands to receivers;
- the role of the channel (*phatic function*), whenever a support to the management of the communication itself is required, for example, to check whether the channel is still operative between the sender and the receiver (e.g. 'are you still there'?);
- the formal structure of the message itself (*poetic function*), for example, when homophonies, rhymes, . . . are adopted;
- the requirements on the code (*metalinguistic function*), typically whenever the sender and the receiver want to check whether they are using the same coding rules (e.g. 'what do you mean'?).

The semantic component is critical in communications with a prevailing referential function, and the problem of the truth evaluation of their contents can be generally posed. The other functions are instead oriented to the pragmatics of the communication: messages such as 'fantastic', or 'excuse me', or 'repeat please', or . . . are conveyed to obtain some communicational aim more than to state a meaning.

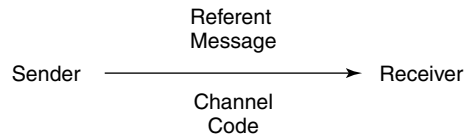

Figure 7. The components of a communication system.

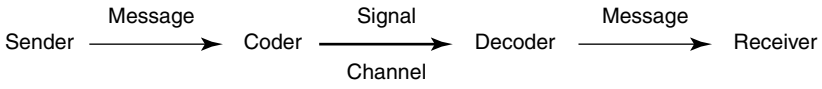

Figure 6. The structure of a communication system.

8 APPLYING SEMIOTIC PRINCIPLES TO MEASUREMENT SYSTEMS

As an operation aimed at expressing in symbols the information empirically obtained on a system about a quantity, measurement can be meaningfully analyzed in its semiotic character. In comparison with other forms of judgment, there are two general grounds of peculiarity for measurement:

- the mediator between the referent (i.e. the measurand) and the symbol (i.e. the measurement result) is an empirical entity, external to both the measured thing and the measurer subject: the measurement system;
- the symbols adopted as identifiers for the measurands are chosen in a formal language, whose composition and structure are explicitly known.

While for a general semiotic system only the syntactical component can be usually formalized (the attempt was made by logics and philosophers of science such as Bar-Hillel, Carnap, and Hintikka to quantify the semantic information conveyed by propositions as their 'quantity of content': with such a broad connotation, the problem remained largely unsolved and was substantially left aside), these characteristics of measurement allow to consider it in some more specific terms:

- *From the syntactical point of view*: measurement can be thought of as an operation of selection of a symbol from a set, the actual granularity of such a set (as usually formalized in terms of either number of significant digits or expanded uncertainty) depending on the resolution of the sensing device; the usual Shannon's concept of quantity of information can be adopted in this case, such that the quantity of information conveyed by a measurement result increases as its uncertainty decreases.
- *From the semantic point of view*: measurands are always evaluated relative to a reference, that is, explicitly reported in measurement results in terms of a measurement scale (and specifically measurement unit whenever applicable) and that expresses the actual meaning for the (usually) numerical symbols by which the measurand is quantified. Each measurement scale is characterized by a type, the most common scale types (nominal, ordinal, interval, ratio, absolute) being linearly ordered according to the algebraic structure they imply on the symbol set. The degree of semantic information conveyed by a measurement result depends thus on the degree of richness in algebraic structure of its scale type (formally, the semantic information increases as the class of admissible transformations for the scale type becomes more specific).
- *From the pragmatic point of view*: because of the existence of functional relations connecting them (the typical case of physical laws), measurands are embedded in a network of pragmatic information allowing new measurement results to be obtained by computation, that is, by derived measurement. While a completely disconnected measurand can be defined in a totally arbitrary way, and therefore its evaluation is pragmatically useless, the more the measurand is connected (e.g. the greater the number of functional relations in which it is present), the higher is the degree of pragmatic information conveyed by its values.

Even this summary presentation shows how the semiotic perspective can be useful to understand some fundamental characteristics of measurement (uncertainty, scale types, and derived measurement) in a general conceptual framework.

1 DEFINITION OF EPISTEMOLOGY

Epistemology is the branch of philosophy that is concerned with the study of how knowledge is possible. The basic problem of epistemology is that, in common language, people make claims to know certain things, and some basis for determination of whether the claims are reasonable or appropriate is necessary in order to ensure that any action taken consequent upon the belief that one knows the matter is appropriately founded.

The analysis of knowledge requires distinction between that which is known and the knowledge of it. That which is known is either a tangible thing or phenomenon that is observable in nature, or an idea that belongs as part of an intellectual construction. The knowledge of the matter is distinct from the matter in that it is a representation of that which is known without actually being that which is known. In the case of the matter being an idea, there is still a distinction between the idea and knowledge of the idea in that the idea is an existential part of the person and experience of the person who has the idea, whereas knowledge of the idea has the self-consciousness of enabling the knower to be aware of what the idea is, and of the fact that they know the idea. Thus, knowledge is always a representation of what is known and is never what is known in and of itself.

The relation of things and their representation in knowledge leads us to the central problem of epistemology, expressed by the question: 'How do I know that reality is what I conceive and assert it to be in cognitive experience?' (Russell, 1898). Epistemology aims at identifying the relation between matters in reality and the subject's consciousness of these matters (Perry, 1931), and so it explores the problem of how judgments joining various pieces of information may be made. Epistemology, in relation to measurement, is particularly concerned with the issue of how empirical information can be used to form knowledge, that is, how it is possible to make synthetic, as distinct from analytic, judgments (Rescher, 1980). Kant distinguished analytic judgments, judgments relying only on pure reason and *a priori* information with synthetic judgments, which rely on *a posteriori*, empirical information.

Epistemology develops theories of truth, evidence (Hall, 1943), meaning, and verification (Carnap, 1936) in order to clarify each of these concepts and to make clear when it is reasonable to trust information that one has received, and when not to trust information.

2 EXPLANATION OF EPISTEMOLOGY

The classical account of knowledge states that S knows that p if and only if

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

1. p is true;
2. S believes that p; and
3. S is justified in believing that p (Gettier, 1963).

The classical account of knowledge has three fundamental elements: truth, belief, and justification, and the only serious challenge to this understanding has been that which is raised in Gettier (1963). The classical account of knowledge is always satisfied in the case of matters known analytically. The classical account was developed to determine when matters known synthetically could be asserted as known.

A theory of truth develops an understanding of what it means to assert 'p is true'. The assertion that p is true must be explained so that it is clear. In brief, 'true' means that something is as it is represented to be in the statement that is described as 'true'. The assertion that p is true is thus an assertion of correspondence between what is the case of the matter and how the matter is represented in the information that is the subject of the assertion of truth.

Knowledge 'that p' requires that the subject, S, believes that the matter corresponds to the representation embodied in p. 'Believe' is a verb with several distinct uses, including 'believe that p', which pertains to the mental assent that p is true. Mental assent does not require commitment to the truth of that which is believed, but it does require that the believer intellectually accepts that the assertion believed is in fact true and that there is no confusion or error introduced by any factor such as may introduce any distortion of perception of the observed.

The requirement for justification in the classical account of knowledge demands a theory of evidence as the basis for determining those signs that are something other than the signs themselves and that are necessary to determine that which is signified as true. Evidence may be directly related to the matter and explicit evidence of something, or it may only indicate what is claimed, or it may be circumstantial, resulting in the matter being concluded as probable.

The physical sciences assume that there is a physical world, which is fundamentally and substantially as it appears to be. On some occasions, what is seen is not real, but the cause of this difference is distorting circumstances that result in seeing something different than what is present. The physical sciences assume that such distorting observational circumstances can be explained through the physical phenomena of the world, and that such illusions can be overcome.

3 RELEVANCE OF EPISTEMOLOGY TO MEASUREMENT

There are many definitions of measurement in the literature:

1. 'Measurement is the process of assigning numbers to represent qualities: the object of measurement is to enable the powerful weapon of mathematical analysis to be applied to the subject matter of science' (Campbell, 1920).
2. 'Measuring in a narrow sense (measurement) is the experimental comparison of a measured quantity with a metrological standard. Measuring in a wide sense (classification) is the experimental comparison of a measured object with a particular standard (pattern)' (Hofmann, 1983).
3. Measurement is 'the quantitative determination of a physical magnitude by comparison with a fixed magnitude adopted as the standard, or by means of a calibrated instrument' (Sydenham, 1976).
4. 'Measurement is the assignment of numbers or other symbols by an objective, empirical process to attributes of objects or events of the real world in such a way as to describe them' (Finkelstein, 1990).

Each of these definitions of measurement emphasizes that measurement is a process of observation of the real world that results in representation of the observed in the structured framework of the scale used for the investigation. The intention of measurement is to convert observation of the world into a form amenable to the application of the analytical processes of mathematics. The intention of conversion from synthetic knowledge to information that can be operated upon in an analytic manner is a major leap that demands the analysis of epistemology. The reason is that the results obtained from the analytic processes obtain a status, in ordinary thought, linked to their derivation by an analytic process, rather than the uncertainty associated with immediate recognition of the empirical nature of the observation process.

Epistemology emphasizes the limitations that are placed on claims to knowledge by the method and circumstances of the gathering of the information concerning the matter. Thus, epistemology encourages skepticism concerning whether what appears to be the case is actually the case. In the measurement situation, this subject matter of epistemology concerns the development of understanding of the possible sources and kinds of erroneous measures that may be obtained. This interest is at the level of verification of the data in the measurement system.

Epistemology is also of relevance in the theory of measurement in developing awareness that the ultimate purpose of measurement is to obtain understanding of the things that are observed. This awareness prompts the understanding that measurement concerns the development of knowledge about the observed and forms the basis for wise action based, in part, on knowledge of the observed, and on other knowledge.

4 APPLYING EPISTEMOLOGICAL PRINCIPLES TO MEASUREMENT SYSTEMS

Measurement systems apply instruments to systems that are considered interesting. This situation produces an interface between the observed and the instrument, which is an information boundary across which the measurement information must flow. The development of measurement processes has respected the skepticism concerning the quality of information as a basis for knowledge presented in epistemology. Traditional concerns in the development of measurement process theory have included the issues of accuracy and calibration. The ideas of both accuracy and calibration address different issues associated with the perspective on measurement provided through epistemology.

Accuracy: The definitions of measurement of Sydenham (1976) and Hofmann (1983), Section 3, above, involve comparison of the observed manifestation with some kind of scale or standard. If a measurement were entirely accurate, there would be an exact correlation between the real manifestation and the measure of it obtained. The discussion of accuracy is premised on the idea that there is a 'correct value' of the manifestation in the observed, and that that correct value is present to be obtained, should one have sufficiently good means to measure it. It is not possible to prove that there is such a thing as one true value of things.

Inaccuracy: The assumption that there is a true value arises from a variety of effects including influence effects, noise effects, instrument imperfections such as hysteresis or wear, error in implementation of the physical effect of the sensor system, and loading of the observed by the sensor system. Influence effects result from the sensitivity of the sensor to effects other than the target effect. Noise relates to the presence of random events in the observed and sensor system affecting the output. Instrument imperfections result in the instrument systematically producing erroneous results, either in a simple relationship to true value or in a relationship dependent on the history of the instrument. Error in the implementation of the system results in all output being misleading because it is a measure of something other than what was intended. Loading of the observed by the sensor is a particular class of poor design, in which the combined system of the sensor and the observed results in a different manifestation being present than would be present if the instrument were removed.

Calibration is the simplest approach to the accuracy problem. A set of measurements of known values of the manifestation is performed with the instrument, and results are recorded, and used to provide a conversion between instrument output and true value. Calibration can remove inaccuracy related to the instrument characteristics, but cannot remove inaccuracy arising from noise or influence factors or loading effects different than those at the time of calibration.

Awareness of epistemology has led to investigation of the issue of accuracy, and the development of the concept of calibration, to address the epistemological problems of illusion and hallucination. Nicholas (1994) has a discussion of several specific examples of these effects.

5 EXAMPLES OF THE USE OF EPISTEMOLOGY IN MEASUREMENT SYSTEMS

Section 4 discussed the application of epistemology to measurement systems at the data level. In this section, the application of epistemology to measurement systems at the levels of knowledge and wisdom is discussed.

Sacerdoti, Paggi and Sacerdoti (1991) describe measurement processes as 'the means by which man dialogues with the external world in order to enrich his knowledge. The processes pass through dialectic counterreacted phases, that is, 'historical phase', during which the 'receiver' learns to recognize forms and situations; organization of the experimental situations on the basis of results; representation of the results'. This description of measurement expresses the idea that measurement concerns the gaining of knowledge about the observed.

Sacerdoti, Paggi and Sacerdoti (1991) provides a frame leading to the Object Oriented Model of Measurement (OOMM) of Ferris (1997). The OOMM provides a structure for the analysis of measurement involving a class of entity, which is characterized as having relations into which it enters, attributes that it manifests, an attribute observation process, and the belief that repeatable and verifiable measurements are possible. The model of the class then controls the kind of measurements that are applied to the observed and the interpretation of the results, leading to the creation of knowledge. The major problem is that nothing in the structure enables one to determine that the observed is not a member of the class to which it is assumed to belong.

An example of the application of epistemology to measurement at the level of knowledge and wisdom is found in the testing and evaluation of complex products and systems. The design and development of product requires measurement of the prototypes of the product by which it is determined whether the product can perform its function.

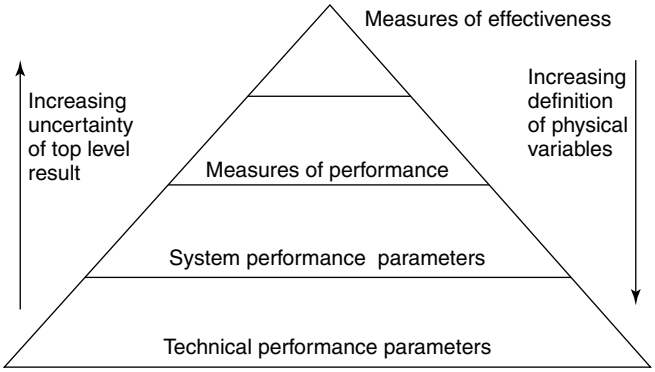

Figure 1. The pyramid of measures involved in the measurement of a product or system intended to perform some function. (Adapted from Crouch, V. and Sydenham, P. (1994) Relationship between T&E and M&I, *3rd Australasian Instrumentation and Measurement Conference*, 26–29 April, Adelaide, Institution of Engineers Australia, Barton (pp. 1–6).)

The test and evaluation measurement scenario is expressed in Figure 1.

In Figure 1, the technical performance measures refer to the measures of physical quantities of fundamental kinds of manifestation such as length, mass, temperature, and time, expressed in terms of standard units. The system performance parameters describe system performance in terms of derived units, which combine basis units, and describe aspects of the performance of the whole systems, such as velocity, or power consumption. Measures of performance concern the performance of the system in performing its design tasks, and include measures such as reliability, and maintainability. Measures of effectiveness concern whether the system satisfies the need for which it was conceived and developed.

The pyramid of Figure 1 shows a progression from the lowest level of data, through information, knowledge to wisdom, at each higher level in the pyramid.

25: Introduction to Signals in Physical Systems

Eugen Georg Woschni
Technical University Chemnitz, Chemnitz, Germany

1 General Remarks on Signals 147
2 Task of Measurement and Mathematical Description 147
3 Two Fundamental Problems: Signal and System Identification 148
Further Reading 148

1 GENERAL REMARKS ON SIGNALS

Within measuring systems, communications take place between the various parts. These communications take place on signal carriers; today, these are predominantly electrical, but other energy formats are sometimes used. The theory given here can be applied to them also.

In addition to the useful signal **x**, interfering signals **z** occur (Figure 1). Both types of signals are carriers of information: wanted information in the case of the useful signal, and unwanted in the case of the interfering signal. Both signals can be treated the same way.

In a signal $\mathbf{x}(a_r)$, for the purpose of information transmission as found in measuring systems, it must be possible to change these information parameters. Information parameters are those parameters of the signal upon which the behavior of the information to be transmitted is mapped. Thus:

$$\text{Transmitted information I} = \text{Fnc. signal } \mathbf{x}(a_r) \quad (1)$$

2 TASK OF MEASUREMENT AND MATHEMATICAL DESCRIPTION

As represented in Figure 1, the task of measurement technology is to establish the characteristics of actually occurring input signals, $\mathbf{x}_r$, from known (measured) output signals $\mathbf{y}_r$. Signals having several components, $\mathbf{x}_r$, $\mathbf{y}_r$, for example, can be summarized to form signal vectors **x, y, z**, in the same way as the disturbances $\mathbf{z}_r$. The output quantities are a function of the input quantities, and the relationship between them is given by the behavior of the measuring system.

The aim is that the behavior should be of a certain type, which is represented by an ideal mathematical operation $\mathbf{O}_{\text{id}}$:

$$\mathbf{y}_{\text{id}} = \mathbf{O}_{\text{id}}\{\mathbf{x}\} \quad (2a)$$

In the individual case, this operation may be a constant with only one dimension, to give an example, but it may also be a differentiation or integration, as for instance, in the case of measuring devices used for averaging.

The practical measuring system with the connection $\mathbf{O}_{\text{real}}$ between its output and input quantities also includes real, falsified output quantities that depend on the disturbances **z**

$$\mathbf{y}_{\text{real}} = \mathbf{O}_{\text{real}}\{\mathbf{x}; \mathbf{y}\} \quad (2b)$$

Hence, an error $\boldsymbol{\varepsilon}$ occurs given by

$$\boldsymbol{\varepsilon} = \mathbf{y}_{\text{id}} - \mathbf{y}_{\text{real}} \quad (2c)$$

These relationships will be dealt with in more detail in later articles (*see* **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1**; **Article 27, Signals in the Frequency Domain, Volume 1**; **Article 28, Signals in the**

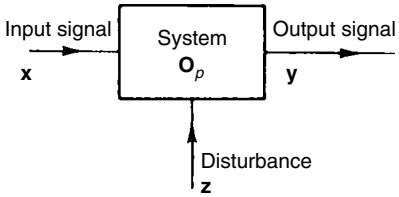

Figure 1. Task of measurement.

Time Domain, Volume 1; and **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**) of this topic, in particular, those with time-varying signals. The discussion has the following four objectives:

1. description of the signals by their characteristic values and functions;
2. description of measuring systems by means of characteristic values and functions;
3. description of the errors and deduction of quality criteria;
4. means for optimizing the system, that is, for minimizing errors.

Objective 1. is discussed in **Article 27, Signals in the Frequency Domain, Volume 1**; **Article 28, Signals in the Time Domain, Volume 1**; **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**; **Article 30, Statistical Signal Representations, Volume 1**; **Article 31, Discrete Signal Theory, Volume 1**; **Article 32, Geometrical Signal Representations, Volume 1**, the other objectives, which are based upon the first, are dealt with in **Article 31, Discrete Signal Theory, Volume 1**; **Article 32, Geometrical Signal Representations, Volume 1**; **Article 35, Systems in the Time Domain, Volume 1**; **Article 36, Systems in the Frequency Domain, Volume 1**; **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1** and **Article 38, Stability Issues, Volume 1**. Reference is made in each case to descriptions in the time and frequency domains.

3 TWO FUNDAMENTAL PROBLEMS: SIGNAL AND SYSTEM IDENTIFICATION

Figure 2 shows the objectives that have been outlined above and that are tailored especially for the following two fundamental problems of measurement technology.

Signal identification. In Figure 2(a), the aim is to determine the signal parameters of the input signals in terms of known (measured) output signals **y**, where, if possible, disturbances should have no influence.

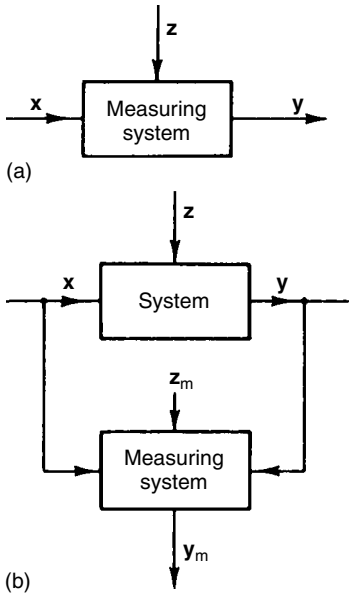

Figure 2. (a) Identification of signals and (b) identification of systems.

System identification. Figure 2(b), on the other hand, depicts measurement of the parameters of a system. In that case, input test signals **x** and associated output signals **y** are both fed to the measuring system. The parameters that are characteristic of the system have to be determined from the output quantities of this measuring system $\mathbf{y}_m$.

FURTHER READING

Many texts have been published on this topic of linear systems and circuit theory. Searches for relevant books with 'signal' as a search word tend to be in the minority now, being largely overtaken by those on digital signals and systems – which are not the same. Digital systems are, in fact, partially based on the application of this linear systems theory. A selection on linear signals and systems is as follows:

1 SIGNALS WITH AND WITHOUT QUANTIZATION OVER TIME

A distinction is made between *analog* signals, which are signals having no quantization of the information parameter, and *discrete* signals in which, because of quantization, the information can assume a finite number of values. An important special case of discrete signals is that involving binary signals in which the information parameter can take only two discrete values: 0 or 1.

In time-dependent signals – most signals are time dependent, or are converted to become time-dependent signals by scanning, as is the case in television – the information parameter can either change at any time (continuous signals), or changes are possible at given cycle times only, due to time quantization.

If the entire behavior of the signal, including future behavior, is known, the signal is said to be a *determined* signal. The transmission or measurement of this signal, naturally, does not produce any gain in information. This type of signal plays a major role as test signals (e.g. impulse function, step function). Contrary to this, a signal to be measured has little a priori information. Signals with unknown characteristics of flow are called *nondetermined* signals. If they are described by a probability distribution, they may also be called *stochastic* signals.

2 TABLE OF SIGNAL CLASSIFICATIONS

Table 1 gives a survey of signal designations as described in detail in Section 1 (Woschni, 1988; Woschni and Krauss, 1976).

3 SIGNAL-FLOW GRAPHS

To trace and represent the flow of the signal, signal-flow graphs are used. Figure 1 gives a survey of the graphical

representation of the branching, addition, subtraction, multiplication, or division of signals. The arrows point to the direction of signal flow.

Figure 2 shows some examples of technical realization. Signals may be represented in the time and frequency (spectral) domains. For the formation of statistical characteristic values, time or statistical means are used. Furthermore, signal representations are applied by making use of geometrical relationships.

More information on this material is given in subsequent articles.

1 SIMPLEST CASE – HARMONIC OSCILLATION

To study the nature of the frequency domain of a signal, the simplest case may be used as a foundation for the explanation. A very important, determined fundamental signal, which is also of major importance as a test signal, is harmonic oscillation

$$x = \widehat{X}\sin(\omega t + \varphi) \tag{1a}$$

where $\widehat{X}$ is the amplitude, $\omega = 2\pi f$ is the angular frequency, $T = 1/f$ is the oscillation period and φ is the phase angle (often zero). Representation in the complex plane, as shown in Figure 1(a), yields according to the so-called 'symbolic method,' complex and oriented indicators x and, consequently, the relationship

$$x = \widehat{X}\exp[\,\mathrm{j}(\omega t + \varphi)] = \widehat{X}\cos(\omega t + \varphi) + \mathrm{j}\widehat{X}\sin(\omega t + \varphi) = \widehat{X}\mathrm{e}^{\mathrm{j}\omega t} \tag{1b}$$

which is equivalent to (1a) and which has the oriented complex amplitude

$$\widehat{X} = \widehat{X}\mathrm{e}^{\mathrm{j}\varphi} \tag{1c}$$

According to Figure 1, the directed quantity $\widehat{X}$ can be split into real and imaginary parts:

$$\widehat{X} = A + \mathrm{j}B \quad |\widehat{X}| = \widehat{X} = \sqrt{(A^2 + B^2)} \quad \varphi = \arctan\left(\frac{B}{A}\right) \tag{1d}$$

The advantage of the symbolic method consists, above all, of the possibility of having a simple and easily understandable addition of several partial oscillations having the same frequency (Woschni, 1988). Periodic signals are particularly useful as test signals, because the same signal characteristic is repeated after each cycle period T and thus can be observed on an oscilloscope synchronized with T.

2 PERIODIC SIGNALS – FOURIER SPECTRUM

According to Fourier, it is possible to represent this type of signal having a cyclic time behavior $x(t)$ by a series of sinusoidal and cosinusoidal oscillations with frequencies that are multiples of the fundamental frequency ω_0 given by

$$\omega_0 = 2\pi f_0 = \frac{2\pi}{T} \tag{2a}$$

This is shown in Figure 2, which depicts two sinusoids (of many) that form the cyclic rectangular oscillation (square

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

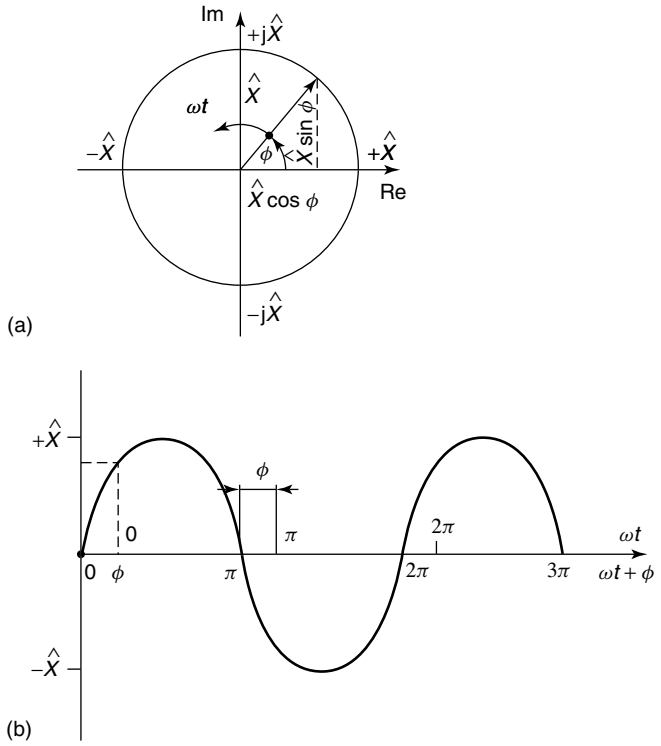

Figure 1. Harmonic oscillation: (a) indicator representation and (b) time representation.

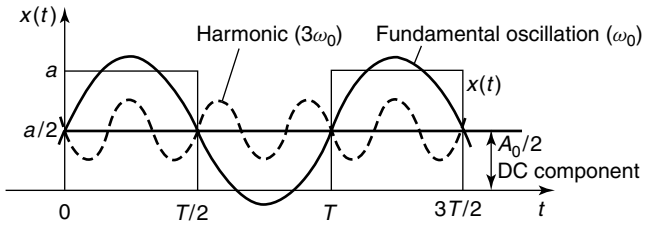

Figure 2. Representation of the rectangular oscillation by sinusoids.

wave signal, see also Figure 7)

$$x(t) = \frac{1}{2}A_0 + \sum_{n=1}^{\infty}[A_n \cos(n\omega_0\, t) + B_n \sin(n\omega_0\, t)] \quad (2b)$$

with the amplitude spectrum

$$C_n = \sqrt{(A_n^2 + B_n^2)} \quad (2c)$$

The Fourier coefficients can be calculated from the relationships

$$A_n = \frac{2}{T}\int_{-T/2}^{+T/2} x(t)\cos(n\omega_0\, t)\,\mathrm{d}t \quad (3a)$$

$$B_n = \frac{2}{T}\int_{-T/2}^{+T/2} x(t)\sin(n\omega_0\, t)\,\mathrm{d}t \quad (3b)$$

From (3a, b), one can see that there are only cosine terms for the even time functions $x(t) = x(-t)$, and only sine terms for the odd functions $x(t) = -x(-t)$.

Transformation with the aid of Euler's theorem, leads to the complex Fourier series

$$x(t) = \frac{1}{T}\sum_{n=-\infty}^{+\infty} \widehat{X}(\mathrm{j}n\omega_0)\mathrm{e}^{\mathrm{j}n\omega_0 t} \quad (4a)$$

with the complex coefficient

$$\widehat{X}(\mathrm{j}n\omega_0) = \int_{-T/2}^{+T/2} x(t)\mathrm{e}^{-\mathrm{j}n\omega_0 t}\,\mathrm{d}t \quad (4b)$$

and the amplitude spectrum $|C_{nk}|$ given by

$$|C_{nk}| = \left|\frac{1}{T}\widehat{X}(\mathrm{j}n\omega_0)\right| \quad (4c)$$

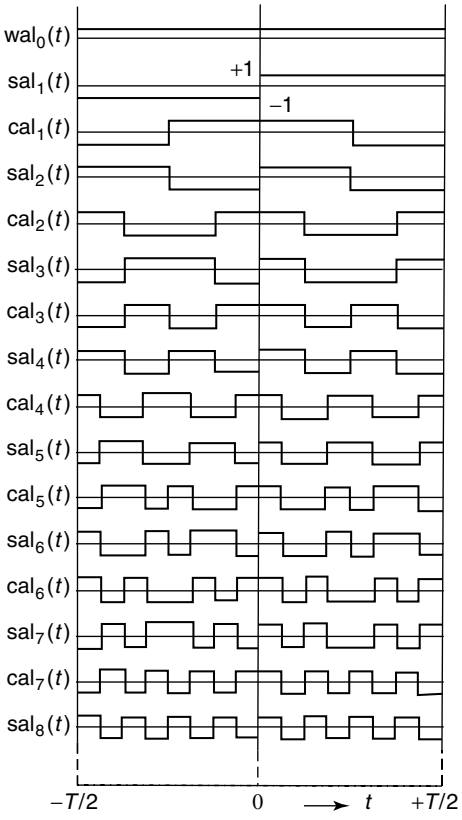

Figure 3. Walsh functions up to eighth order.

3 PERIODIC SIGNALS – WALSH SPECTRUM

In addition to the system of orthogonal functions based upon sine and cosine functions, other orthogonal systems have been introduced, in particular the Walsh functions (Harmuth, 1970), which are shown up to eighth order in Figure 3.

From (2) and (3) respectively, the corresponding relationships are developed:

$$x(t) = W_0 + \sum_{n=1}^{\infty} [W_{c_n} \mathrm{cal}_n(t) + W_{s_n} \mathrm{sal}_n(t)] \qquad (5a)$$

with the Walsh coefficients W_{c_n} and W_{s_n}:

$$W_{c_n} = \frac{1}{T} \int_{-T/2}^{+T/2} x(t)\ \mathrm{cal}_n(t)\, \mathrm{d}t \qquad (5b)$$

$$W_{s_n} = \frac{1}{T} \int_{-T/2}^{+T/2} x(t)\ \mathrm{sal}_n(t)\, \mathrm{d}t \qquad (5c)$$

As one can see, the Walsh spectra, which are also called *sequency spectra*, are superior to the Fourier spectra, in that the multiplication with sine and cosine functions respectively, is obviated by a simple reversal of signs. Therefore, these spectra can be determined more easily by experiment than the Fourier spectra (Figure 4).

4 NONPERIODIC SIGNALS – FOURIER TRANSFORM

Nonperiodic functions are of great importance both as determined signals, that is, test signals (step function, impulse function) and as nondetermined signals (unknown signals that are to be measured).

A discrete Fourier spectrum exists for periodic signals, whereas a continuous spectrum follows for nonperiodic signals. It is obtained from the Fourier series – see (4) – by passing to the limit:

$$T \longrightarrow \infty \quad \omega_0 = \frac{2\pi}{T} \longrightarrow \mathrm{d}\omega$$

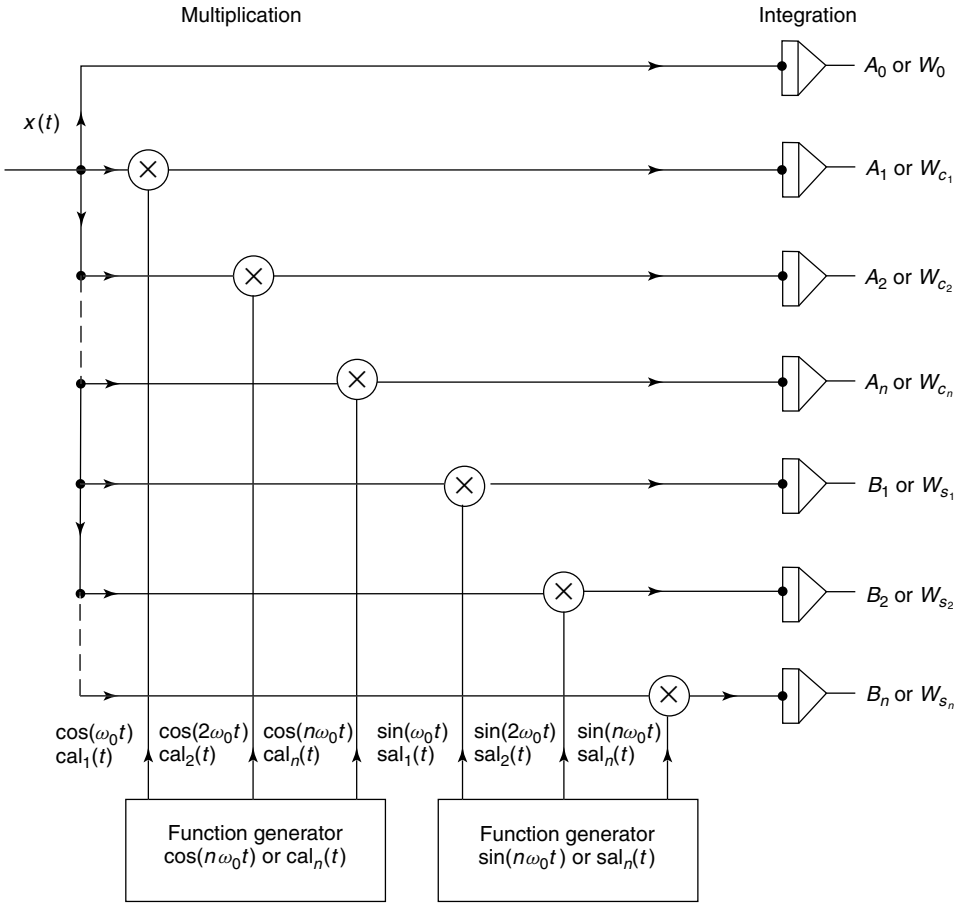

Figure 4. Experimental determination of the Fourier and Walsh coefficients.

$$\frac{1}{T} \longrightarrow \frac{\mathrm{d}\omega}{2\pi} \quad n\omega_0 \longrightarrow \omega \tag{6a}$$

In this case, it yields

$$\widehat{X}(\mathrm{j}\omega) = \int_{-\infty}^{+\infty} x(t)\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t = F\{x(t)\} \tag{6b}$$

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \widehat{X}(\mathrm{j}\omega)\mathrm{e}^{\mathrm{j}\omega t}\,\mathrm{d}\omega = F^{-1}\{\widehat{X}(\mathrm{j}\omega)\} \tag{6c}$$

Here the integrals are to be understood as the Cauchy principal value

$$\lim_{c\to\infty}\int_{-c}^{+c}\cdots$$

F and F^{-1} are the Fourier and inverse-Fourier transforms respectively. Physically, $\widehat{X}(\mathrm{j}\omega)$ represents the complex amplitude related to $\mathrm{d}\omega$, and is therefore also called *spectral amplitude density* having the dimension of amplitude per frequency interval, that is, V s and V Hz^{-1} respectively. Depending on whether the frequency scale [Hz] or the angular frequency scale [s^{-1}] is chosen, the values will differ by a factor 2π.

An identical calculation can be made for Walsh functions. This leads to the sequential amplitude density (Harmuth, 1970).

The Fourier transform has the following important properties and theorems. The transform is linear, that is,

$$\sum_{\nu} a_\nu x_\nu(t)\ \mathrm{O}^- \sum_{\nu} a_\nu \widehat{X}_\nu(\mathrm{j}\omega) \tag{7a}$$

(where O^- is the sign for 'assignment'). For a change in the timescale, the relationship is

$$x(at)\ \mathrm{O}^- \frac{1}{|a|}\widehat{X}\left(\frac{\mathrm{j}\omega}{a}\right) \tag{7b}$$

Particular importance should also be attributed to the displacement theorems, namely, the time displacement

$$x(t-t_0)\ \mathrm{O}^-\widehat{X}(\mathrm{j}\omega)\exp(-\mathrm{j}\omega t_0) \tag{7c}$$

and the frequency shift

$$x(t)\exp(\mathrm{j}\omega t_0)\ \mathrm{O}^-\widehat{X}[\mathrm{j}(\omega-\omega_0)] \tag{7d}$$

For differentiation, one obtains

$$\frac{\mathrm{d}^n x(t)}{\mathrm{d}t^n}\ \mathrm{O}^-(\mathrm{j}\omega)^n\widehat{X}(\mathrm{j}\omega) \tag{7e}$$

and for convolution

$$\int_{-\infty}^{+\infty} x_1(\tau)x_2(t-\tau)\,\mathrm{d}\tau\ \mathrm{O}^-\widehat{X}_1(\mathrm{j}\omega)\widehat{X}_2(\mathrm{j}\omega) \tag{7f}$$

5 SPECTRAL POWER DENSITY

For nondeterministic signals, for instance noise, let us assume in the following text that they are stationary, that is, that their time averages are not time-dependent quantities. To identify such signals $x(t)$, the spectral power density $S_{xx}(\omega)$ is used. It is defined as the part of the power ΔP, which falls into a differentially small frequency range $\Delta\omega$, that is,

$$S_{xx}(\omega) = \lim_{\Delta\omega\to 0}\frac{\Delta P}{\Delta\omega} = \frac{\mathrm{d}P}{\mathrm{d}\omega} \tag{8a}$$

In contrast to the spectral amplitude density, which cannot be determined in the case of random signals, the spectral power density is a real-valued function of the frequency ω. It does not contain any phase information. The latter is lost in the calculation of the average value, which is necessary for the formation of the power. This can also be seen from the relationship existing on the basis of Parseval's equation, by averaging over a time domain T (Zadeh and Desoer, 1963; Woschni, 1988):

$$S_{xx}(\omega) = \frac{1}{2\pi}\lim_{T\to\infty}\frac{|\widehat{X}(\mathrm{j}\omega)|^2}{2T} \tag{8b}$$

Consequently, the spectral power density is real and always positive, and it is an even function for which $S_{xx}(\omega) = S_{xx}(-\omega)$. Since the phase angle is missing, $S_{xx}(\omega)$ does not contain the full information about $x(t)$; a reverse calculation is not possible. The power P of the entire signal existing in the whole frequency domain, can be calculated on the basis of Parseval's equation, for the energy W

$$W = \int_{-\infty}^{+\infty} x^2(t)\,\mathrm{d}t = \frac{1}{2\pi}\int_{-\infty}^{+\infty}|\widehat{X}(\mathrm{j}\omega)|^2\,\mathrm{d}\omega$$

(Zadeh and Desoer, 1963; Woschni, 1988):

$$\begin{aligned} P = \overline{x^2(t)} &= \lim_{T\to\infty}\frac{1}{2\pi}\int_{-T}^{+T} x^2(t)\,\mathrm{d}t \\ &= \int_{-\infty}^{+\infty}\lim_{T\to\infty}\frac{1}{2\pi}\frac{|\widehat{X}(\mathrm{j}\omega)|^2}{2T}\,\mathrm{d}\omega \\ &= \int_{-\infty}^{+\infty} S_{xx}\,\mathrm{d}\omega \end{aligned} \tag{8c}$$

From (8a, b) it can be concluded that a random phenomenon contains a periodic component of frequency ω_0

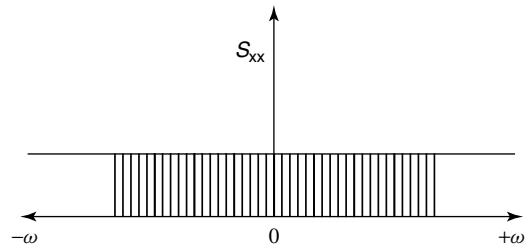

Figure 5. Spectral power density of a white-noise signal.

with amplitude $\widehat{X}$. Dirac delta functions will develop in $S_{xx}(\omega)$ at the frequencies $\pm\omega_0$ (Woschni and Krauss, 1976):

$$S_{xx}(\omega)|_{\omega_0} = \tfrac{1}{2}\widehat{X}^2\delta(|\omega| - \omega_0) \tag{8d}$$

Furthermore, from (8c) it follows that the power density $S_{xx}(\omega)$ must decrease rapidly from a certain critical frequency and must vanish at higher frequencies because of the requirement of boundedness of the power P. Depending on the critical frequency ω_c, a distinction is made between narrowband and wideband signals.

A typical wideband (broadband) signal is the white-noise signal with a constant power density, as shown in Figure 5.

There is a relation between time spectral power density and the auto correlation function, *see* **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**.

6 PRACTICAL INVESTIGATIONS TO STUDY SIGNALS

The foundation for investigations in practice is the possibility of determining the characteristic functions and values by experiment. For the registration of spectral amplitude density and power density respectively, one applies the same principles. In the case of filtering, several filters of bandwidth $\Delta\omega$ are used, which are staggered in the frequency, and whose outputs will be connected one after the other to a display unit for the voltage that is proportional to $|\widehat{X}(\mathrm{j}\omega)|$. According to Figure 6(a), it is likewise possible to synchronize the switch with a sweep voltage that deflects the beam of an oscilloscope in the x-direction, proportionally to ω; consequently, the spectrum $|\widehat{X}(\mathrm{j}\omega)| = f(\omega)$ can be recorded.

Figure 6(b) shows another method that is characterized by the fact that only one filter of bandwidth $\Delta\omega$ and of center frequency ω_{IF} (which is also called *intermediate frequency*) is required. Tuning is carried out by mixing with the continuously tunable auxiliary frequency ω_{A}, where the following frequencies will be allowed to pass:

$$\omega = \omega_{\mathrm{IF}} - \omega_{\mathrm{A}}; \quad \omega^* = \omega_{\mathrm{IF}} + \omega_{\mathrm{A}} \tag{9a, b}$$

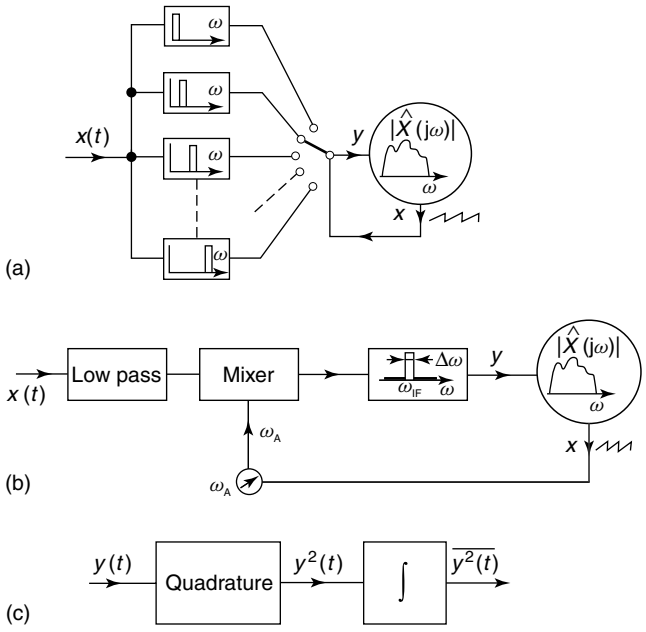

Figure 6. Spectral analyzer: (a) switched-filter principle of operation; (b) variable center frequency of single filter method; and (c) formation of the power density.

The low-pass filter at the input eliminates the image frequency $\omega*$, so that one can cover the entire frequency domain required by tuning ω_{A}. Synchronizing the sweep signal with the x-axis sweep will generate the amplitude spectrum on the oscilloscope display. It is important to ensure that the filter has enough time to respond to the starting surge. For the transient time t_{tr} of the filter, according to Shannon's sampling theorem, *see* **Article 31, Discrete Signal Theory, Volume 1**:

$$t_{\mathrm{tr}} = \frac{1}{2\Delta f} = \frac{\pi}{\Delta\omega} \tag{9c}$$

The sampling of the spectrum must, therefore, be carried out relatively slowly (low sweep frequency of the oscilloscope), for which reason long-persistence cathode ray oscilloscope methods are required. During the scanning run, the spectrum must be practically stable; it must be a steady signal in the statistical sense.

In addition to filtering and variable frequency methods, increasing techniques are used today, which make use of computers to implement the Fourier transform directly according to (6b). This will be discussed in detail in **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**, where specially adapted techniques for the fast Fourier transform will be dealt with. The computing advantages that arise when the amplitude sequential spectrum defined by the Walsh functions is used instead of the amplitude frequency

spectrum, have already been pointed out in connection with Figure 4. While the techniques described in Figure 6(a, b) supply the amplitude response of the spectrum $|\widehat{X}(\mathrm{j}\omega)|$ only, it is possible to obtain additional phase information from the relationship $\varphi = \arg[\widehat{X}(\mathrm{j}\omega)]$ using computing methods.

To display the power spectrum, the formulation $\Delta P/\Delta\omega = \overline{\Delta x^2(t)}/\Delta\omega$ is implemented, as outlined in Figure 6(c), between the filter output and the input of the display unit and the oscilloscope.

7 EXAMPLE OF RECTANGULAR PULSE SIGNAL

For a periodic sequence of rectangular pulses having the pulse width ΔT or the repetition ratio $\tau = \Delta T/T$ (see Figure 7a), after substitution into (3a, b) and (2c) or (4b, c) and after an elementary calculation, one obtains pure cosinusoidal oscillations having the amplitudes

$$C_n = A_n = 2\tau \frac{\sin(n\pi\tau)}{n\pi\tau} = 2\tau \sin(n\pi\tau) \qquad (10a)$$

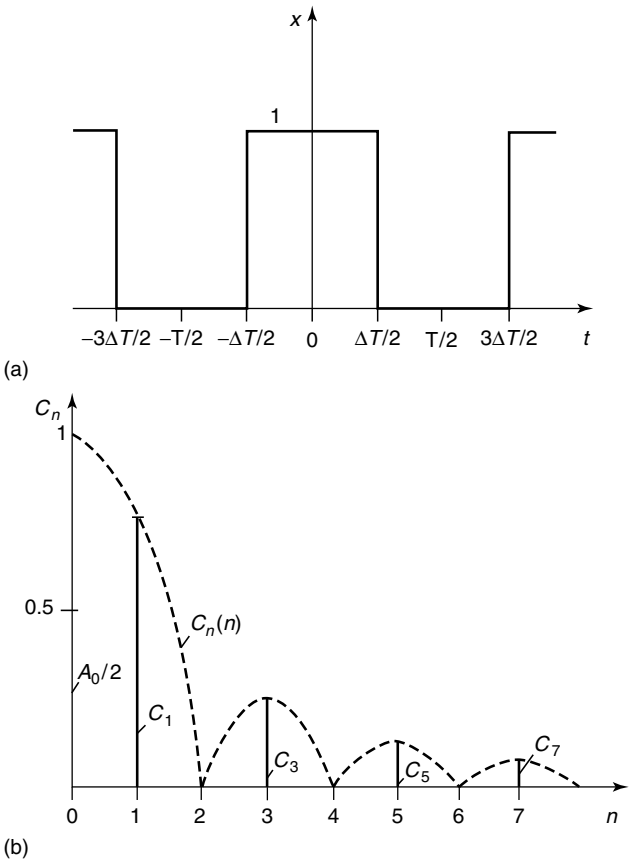

Figure 7. (a) Sequency of pulses and (b) spectrum for $\tau = 0.5$.

Figure 7 shows the spectrum as well as the envelope curve for $\tau = 0.5$. This signal was already treated in Section 2 of this article.

The relationship with Figure 2 becomes immediately evident: the smaller the pulse width, that is, $t_{\mathrm{tr}} = \Delta T$, the more complicated the problem is in general. The pulse height is still correctly indicated in the region up to the first zero of the envelope curve. For $\tau \to 0$, a constant spectrum results because the first zero shifts towards $\omega = \infty$. This case is significant as a test signal. For $\tau \to 0$, the unit impulse becomes the Dirac function $\delta(t)$ with the normalization

$$\int_{-\infty}^{+\infty} \delta(t)\,\mathrm{d}t = \int_{-0}^{+0} \delta(t)\,\mathrm{d}t = 1$$

According to (4b), this has a spectral amplitude density $\widehat{X}(\mathrm{j}\omega) = 1$, with only cosine oscillations of constant amplitude occurring.

Some more signals that are used as test signals as well as the approximate representation of measurement signals are treated in **Article 28, Signals in the Time Domain, Volume 1**.

1 MEAN VALUES

A time function $x(t)$ can be characterized by time averages of the nth order, which are also called moments of nth order:

$$\overline{x^n(t)} = \frac{1}{2T}\int_{-T}^{+T} x^n(t)\,\mathrm{d}t \tag{1a}$$

or, for nonperiodic signals:

$$\overline{x^n(t)} = \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{+T} x^n(t)\,\mathrm{d}t \tag{1b}$$

For $n = 1$, one obtains the (arithmetic) linear average, which, from the physical point of view, can be interpreted to be the zero-frequency component (DC value) of the signal or, according to **Article 27, Signals in the Frequency Domain, Volume 1**, the Fourier coefficient $A_0/2$.

Of particular importance is the average value for $n = 2$, which, as a mean square value according to (8c) of **Article 27, Signals in the Frequency Domain, Volume 1**, represents a measure of the power. The root of the mean square value is the effective value X_{eff} given by

$$X_{\mathrm{eff}} = \sqrt{\overline{[x^2(t)]}} \tag{2a}$$

The following relationship exists between the component $\overline{x(t)}$, the AC component $\underset{\sim}{x}(t)$, and the mean square value X_{eff}:

$$X_{\mathrm{eff}} = \overline{x^2(t)} = [\overline{x(t)}]^2 + \overline{\underset{\sim}{x}^2(t)} \tag{2b}$$

For a harmonic oscillation, one obtains $X_{\mathrm{eff}} = \widehat{X}/\sqrt{2}$ for the effective value, see Section 5. If the Ergodic-theorem is fulfilled, normally in practice the effective value X_{eff} is equal to the standard deviation δ and the mean square value X_{eff}^2 to the variance δ^2, *see* **Article 30, Statistical Signal Representations, Volume 1**.

2 CORRELATION FUNCTION

The correlation function $\psi(\tau)$ represents a generalized mean square value, where a function is multiplied by the function displaced by time τ, and then the mean value is formed. If this function is the same function x, we call it an autocorrelation function $\psi_{xx}(\tau)$,

$$\psi_{xx}(\tau) = \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{+T} x(t)x(t+\tau)\,\mathrm{d}t = \overline{x(t)x(t+\tau)} \tag{3a}$$

as Figure 1 shows.

It is suitable for making statistical statements about the internal relationships between function sections, as is now shown in a survey of its typical properties:

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

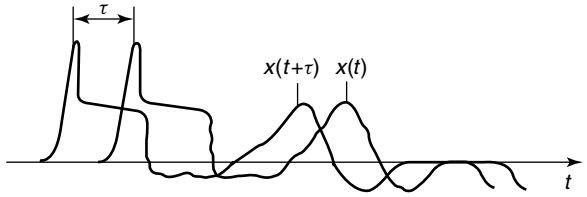

Figure 1. Definition of the autocorrelation function $\psi_{xx}(\delta)$.

1. In averaging, the phase information is lost, as is the case for the spectral power density (**Article 27, Signals in the Frequency Domain, Volume 1**). Therefore, there are also direct relationships between the autocorrelation function $\psi_{xx}(\tau)$ and the spectral power density $S_{xx}(\omega)$, which is discussed in detail in **Article 27, Signals in the Frequency Domain, Volume 1**. However, periodic components in the signal $x(t)$ will be maintained without giving consideration to the phase position, because the following expression applies to the autocorrelation function of the harmonic oscillation, independent of the phase position:

$$\psi_{xx}(\tau) = \tfrac{1}{2}\widehat{X}^2 \cos(\omega\tau) = X_{\text{eff}}^2 \cos(\omega\tau) \tag{3b}$$

2. The value for $\tau = 0$ represents, according to (3a), the mean square value and is the maximum value of the autocorrelation function

$$\psi_{xx}(0) = \overline{x^2(t)} = X_{\text{eff}}^2 \tag{3c}$$

The other threshold value for $\tau \to \infty$ is the square of the linear mean value:

$$\lim_{\tau\to\infty} \psi_{xx}(\tau) = [\overline{x(t)}]^2 \tag{3d}$$

3. Since it is of no significance whether the function $x(t)$ in (3a) is displaced toward positive or negative times, the autocorrelation function is an even function:

$$\psi_{xx}(\tau) = \psi_{xx}(-\tau) = \overline{x(t)x(t+\tau)} = \overline{x(t)x(t-\tau)} \tag{3e}$$

If two different signals $x(t)$, $y(t)$ are being compared one with the other, the measure used for the statistical relationship between them is the cross-correlation function $\psi_{xy}(\tau)$ according to the definition:

$$\psi_{xy}(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{+T} x(t)y(t+\tau)\,\mathrm{d}t = \overline{x(t)y(t+\tau)} \tag{4a}$$

In measurement technology, the cross-correlation function plays a major role in solving system identification tasks during normal operation by means of the disturbances. The solution of this measurement problem is the foundation for adaptive systems (Davies, 1970).

In contrast to the autocorrelation function, the cross-correlation function has the following features:

1. It has no even functions, but the following relationship holds:

$$\psi_{xy}(\tau) = \psi_{yx}(-\tau) \tag{4b}$$

2. It contains relative phase information concerning the two events $x(t)$, $y(t)$. In particular, the cross-correlation function of two harmonic signals with the same frequency disappears if the phase shift is $\pm\pi/2$, as can be seen following substitution into (4a). Likewise, the cross-correlation of two harmonic oscillations is zero if the frequencies are unequal.
3. The limiting cases are

$$\psi_{xy}(0) = \psi_{yx}(0) = \overline{x(t)y(t)} \tag{4c}$$

$$\lim_{\tau\to\infty} \psi_{xy}(\tau) = \overline{x(t)} \times \overline{y(t)} \tag{4d}$$

Experimental registration of the correlation function is discussed in Section 4 of this article.

3 RELATIONSHIPS TO SPECTRAL POWER DENSITY

The autocorrelation function, like the spectral power density, contains no phase information; this is lost in both cases because of the averaging operation. There is a relationship between both functions, as is the case between the time behavior of the signal $x(t)$ and the corresponding spectral amplitude density $X(\mathrm{j}\omega)$, via the Fourier transform; this relationship is known as the Wiener–Chinchine theorem (Woschni, 1988; Davies, 1970):

$$S_{xx}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \psi_{xx}(\tau) \mathrm{e}^{-\mathrm{j}\omega\tau}\,\mathrm{d}\tau = \frac{1}{2\pi} F\{\psi_{xx}(\tau)\} \tag{5a}$$

$$\psi_{xx}(\tau) = \int_{-\infty}^{+\infty} S_{xx}(\omega) \mathrm{e}^{\mathrm{j}\omega\tau}\,\mathrm{d}\omega = 2\pi F^{-1}\{S_{xx}(\omega)\} \tag{5b}$$

Since the autocorrelation function is an even function (see Section 2 of this article), cosinusoidal oscillations only occur. Consequently, (5a, b) can be rewritten

$$S_{xx}(\omega) = \frac{1}{\pi} \int_0^{\infty} \psi_{xx}(\tau) \cos(\omega\tau)\,\mathrm{d}\tau \tag{5c}$$

$$\psi_{xx}(\tau) = 2 \int_0^{\infty} S_{xx} \cos(\omega\tau)\,\mathrm{d}\omega \tag{5d}$$

If the autocorrelation function in (5a, b) is substituted by the cross-correlation function $\psi_{xy}(\tau)$, then the corresponding relationships with the cross-power density will be obtained:

$$S_{xy}(\mathrm{j}\omega) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \psi_{xy}(\tau)\mathrm{e}^{-\mathrm{j}\omega\tau}\,\mathrm{d}\tau = \frac{1}{2\pi}F\{\psi_{xy}(\tau)\} \quad (6a)$$

$$\psi_{xy}(\tau) = \int_{-\infty}^{+\infty} S_{xy}(\mathrm{j}\omega)\mathrm{e}^{\mathrm{j}\omega\tau}\,\mathrm{d}\omega = 2\pi F^{-1}\{S_{xy}(\mathrm{j}\omega)\} \quad (6b)$$

A survey of these relations is given in **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**.

4 PRACTICAL INVESTIGATIONS IN THE SIGNAL TIME DOMAIN

The characteristic functions and values that have been introduced can be found by experiment.

For the measurement of the linear mean value, $\overline{x(t)}$, either moving-coil instruments or transistor voltmeters having a series-connected integration link is used; compare Figure 2(a), with Figure 2(b) showing a simple analog circuit for finding the average value according to the equation

$$u_\mathrm{o} = \frac{1}{C}\int i_C\,\mathrm{d}t \approx \frac{1}{RC}\int u_\mathrm{i}\,\mathrm{d}t \quad (7)$$

using the assumption $R \gg 1/\omega C$.

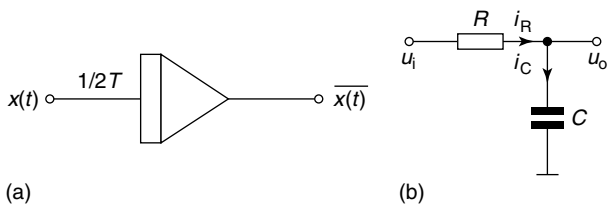

Figure 2. Measurement of the linear mean value: (a) basic circuit and (b) simple realization.

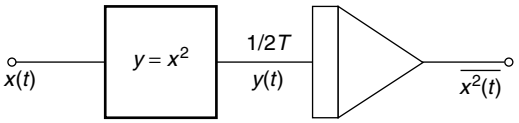

Figure 3. Measurement of the mean square value.

The mean square value can be found by means of the principle shown in Figure 3. To obtain the square of a value, either electronic circuits with a square-law characteristic, for example, diodes or transistors (as in the case of transistor voltmeters), or a measuring device having a square-law characteristic, such as a soft-iron or hot-wire instrument (heating $\approx P \approx I^2R$) is used.

Figure 4 shows the classical basic system for determining the autocorrelation function or the cross-correlation function. Delay is due to a delay section, multiplication, and averaging yield, according to (3a), the autocorrelation function (switch in position A) or, according to (4a), the cross-correlation function (switch in position B). Since the integration time T cannot be chosen to be infinite, only the short-term correlation function

$$\psi_\mathrm{k}(\tau) = \frac{1}{2T}\int_{-T}^{+T} \cdots\,\mathrm{d}t \quad (8)$$

will be measured in practice; under certain circumstances it reflects the actual behavior of $\psi(\tau)$ with sufficient accuracy.

The just treated classical analog methods have been increasingly displaced by digital methods using the principles of digital signal processing. There the signal function $x(t)$ is sampled leading to sampled values $x(rT_\mathrm{s})$ with the sampling time T_s. These values are processed due to the algorithms given by (1a), (3a), or (4a), leading to the mean values or the correlation functions.

To fulfil the sampling theorem conditions, high sampling rates are necessary to avoid aliasing errors, *see* **Article 31, Discrete Signal Theory, Volume 1**. On the other hand, online processing that is often demanded in signal processing, means that the necessary processing time has to be

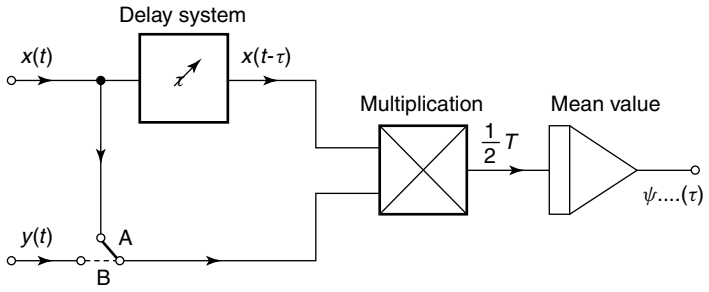

Figure 4. Experimental determination of the correlation function: (a) autocorrelation function $\psi_{xx}(\tau)$ and (b) cross-correlation function $\psi_{xy}(\tau)$.

smaller than the sampling time. Therefore, in general, the numbers of samples n are chosen due to $n = 2^s$ so that the time for the division through n can be small, because instead of the time-consuming division now only a shifting is necessary.

Methods based on the application of Fast Fourier Transform (FFT) are used to calculate the correlation functions from power density functions and vice versa, *see* **Article 27, Signals in the Frequency Domain, Volume 1**; **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**. *See also* **Article 143, DFT and FFTs, Volume 3**.

5 EXAMPLES OF MEAN VALUE AND CORRELATION FUNCTIONS

As a first example, we find the mean values of a harmonic oscillation

$$\overline{x(t)} = \frac{1}{2T}\int_{-T}^{+T} \widehat{X}\sin\omega t\,\mathrm{d}t = 0 \tag{9a}$$

$$\overline{x^2(t)} = \frac{1}{2T}\int_{-T}^{+T} \widehat{X}\sin^2\omega t\,\mathrm{d}t = \frac{\widehat{X}^2}{2} \tag{9b}$$

This means the effective value is

$$X_{\text{eff}} = \widehat{X} = \frac{\widehat{X}}{\sqrt{2}} \tag{9c}$$

The next example is the rectifier unit as used in measurement instruments. The signal is shown in Figure 5 for half-wave (thin) or full-wave (thick) rectification.

The results are

1. for half-wave rectification

$$\overline{x(t)} = \frac{a}{T}\int_0^{\frac{T}{2}} \sin\omega_0 t\,\mathrm{d}t = \frac{a}{\pi} \tag{10a}$$

$$\overline{x^2(t)} = \frac{a}{T}\int_0^{\frac{T}{2}} \sin^2\omega_0 t\,\mathrm{d}t = \frac{a^2}{4} \tag{10b}$$

$$X_{\text{eff}} = \sqrt{\overline{x^2(t)}} = \frac{a}{2} \tag{10c}$$

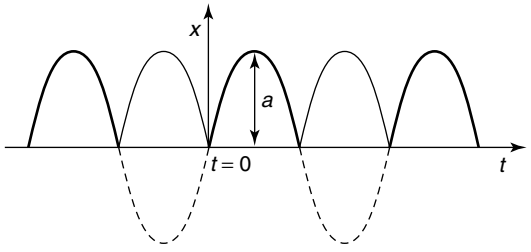

Figure 5. Half-wave (thin) and full-wave (thick) rectification.

2. for full-wave rectification

$$\overline{x(t)} = \frac{2a}{T}\int_0^{\frac{T}{2}} \sin\omega_0 t\,\mathrm{d}t = \frac{2a}{\pi} \tag{11a}$$

$$\overline{x^2(t)} = \frac{2a}{T}\int_0^{\frac{T}{2}} \sin^2\omega_0 t\,\mathrm{d}t = \frac{a^2}{2} \tag{11b}$$

$$X_{\text{eff}} = \sqrt{\overline{x^2(t)}} = \frac{a}{2} \tag{11c}$$

Let us deal now with an example of correlation functions for a rectangular pulse according to Figure 6(a). The

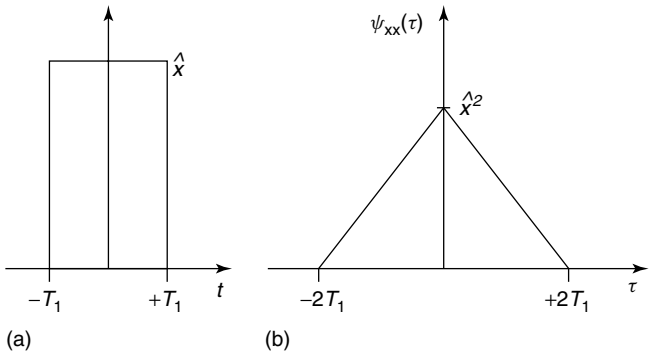

Figure 6. (a) Rectangular pulse and (b) corresponding autocorrelation function.

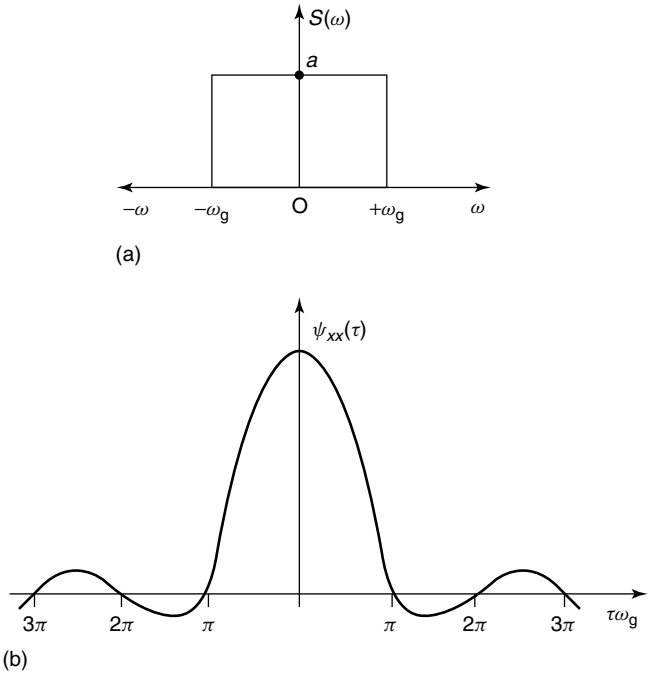

Figure 7. (a) Narrowband noise and (b) corresponding autocorrelation function.

autocorrelation function is given in (12).

$$\psi_{xx}(\tau) = \frac{1}{2T_1} \int_{-T_1+\tau}^{+T_1} \widehat{X} \times \widehat{X}\, \mathrm{d}t = \widehat{X}^2 \left(1 - \frac{|\tau|}{2T_1}\right) \quad (12)$$

The result shown in Figure 6(b) reveals that if the pulse width $2T_1$ decreases in the limiting case $T_1 \to 0$, that is, for the unit impulse $\delta(t)$, the autocorrelation function is also a delta function. This also follows immediately from the calculation of the autocorrelation function of white noise having a constant power spectrum $S_{xx}(\omega) = \text{constant}$, as is the case for unit impulse. For this calculation, (5a, b) are used.

The relationship between the width of the power spectrum and the corresponding autocorrelation function can also be seen if the autocorrelation function for narrowband noise is calculated in accordance with Figure 7(a):

$$\psi_{xx}(\tau) = a \int_{-\omega_g}^{+\omega_g} \mathrm{e}^{-\mathrm{j}\omega t}\, \mathrm{d}\omega = 2a\omega_g \frac{\sin(\omega_g \tau)}{\omega_g \tau} \quad (13)$$

As shown in Figure 7(b), the autocorrelation function becomes smaller as the noise bandwidth increases, degenerating into a delta function for white noise.

This shows clearly that statistical relationships cease to exist if two noise signals are slightly displaced relative to each other.

1 NATURE OF RELATIONSHIPS AND TRANSFORMS

To show the main ideas of time–frequency transform, the square wave time signal, given in Figure 1, may be considered.

Figure 1(a) shows the fundamental harmonic and the harmonic of first order with three times the basic frequency. The addition of these two frequencies as a first approximation already yields a similar function (Figure 1b). If one takes into consideration all harmonics, a reasonably exact square wave signal appears, which shows that the addition of frequencies leads to the appropriate time function. This means that the amplitude spectrum of sinusoidal functions, as given in Figure 2, is the equivalent representation in the frequency domain of Figure 1 in the time domain.

2 FOURIER TRANSFORM AS THE MEANS TO MOVE BETWEEN THE DOMAINS

As given in detail in **Article 27, Signals in the Frequency Domain, Volume 1**, the mathematical relation between the time and frequency domain and vice versa is given by the Fourier transform

$$\underline{\widehat{X}}(\mathrm{j}\omega) = \int_{t=-\infty}^{+\infty} x(t)\mathrm{e}^{\mathrm{j}\omega t}\,\mathrm{d}t = F\{x(t)\} \tag{1a}$$

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \underline{\widehat{X}}(\mathrm{j}\omega)\mathrm{e}^{\mathrm{j}\omega t}\,\mathrm{d}\omega = F^{-1}\{\widehat{X}(\mathrm{j}\omega)\} \tag{1b}$$

With regard to mathematics, this is a transformation between the original range – physically the time domain – and the image range – physically the frequency domain. This transformation is bidirectional, which means that it is possible to move into the frequency domain if the time domain is given and vice versa, as the example in Section 5 of this article demonstrates.

The fact that the convergence of this transformation is limited is known so that, especially in system theory, another transformation with no restriction due to the convergence is used, the Laplace transformation –

3 THEOREMS OF FOURIER TRANSFORM

A survey of the theorems of the Fourier transform is given in Table 1 and these correspond to the theorems of Laplace transformation as treated in **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**.

Of great importance are the differentiation and the integration theorems. Corresponding to the differentiation of a sinusoidal function $\mathrm{d}/\mathrm{d}t\, e^{j\omega t} = j\omega e^{j\omega t}$, the multiplication with $j\omega$ in the frequency domain means a differentiation in the time domain and appropriate the division with $j\omega$ an integration. In **Article 36, Systems in the Frequency Domain, Volume 1** and **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**, these results are used to describe the behavior of systems. The shifting theorem is the key to solve problems of discrete signal theory and system theory as sampled data systems as well as prediction or delay elements.

4 TABLE OF TIME–FREQUENCY RELATIONSHIPS

A summary is now given of the relationships established so far between the various signal representations in both the time domain and the frequency domain. Consideration is also given to the possibilities of conversion indicated above. Table 2 contains a survey of such relationships.

While the time function $x(t)$ and the spectral amplitude density $\widehat{X}(j\omega)$ contain the full information concerning the signal, this is not the case for the functions resulting from averaging (autocorrelation function and power density). Phase information is lost due to averaging. For this reason, conversions are possible only in the direction indicated by the arrow.

Conversions are possible, via the Fourier transform, between functions in the time domain and corresponding functions in the frequency domain. Therefore, it does not matter, as far as the significance of the statement is concerned, which of these two functions is measured; rather it is a question of convenience. For instance, it is useful to carry out measurements in optical communications predominantly in the time domain. In vibration measuring technology, however, it is preferable to carry out the measurements in the frequency domain.

The importance of the conversions has already been discussed. Mention should again be made of the fact that $x(t)$ and $X(j\omega)$ are related in the same way as are $\psi_{xx}(\tau)$

Table 1. Theorems of Fourier Transform.

(1) Addition theorem

$$\mathbf{F}\{f_1(t) + f_2(t)\} = \mathbf{F}\{f_1(t)\} + \mathbf{F}\{f_2(t)\}$$

(2) Multiplication theorem

$$\mathbf{F}\{af(t)\} = a\mathbf{F}\{f(t)\}$$

(3) Shifting theorem

$$\text{for } a > 0 \quad \mathbf{F}\{f(t-a)\} = \mathrm{e}^{-\mathrm{j}\omega a} F(\mathrm{j}\omega)$$

$$\text{or } \mathbf{F}\{f(t+a)\} = \mathrm{e}^{\mathrm{j}\omega a}\left(\mathbf{F}(\mathrm{j}\omega) - \int_0^a \mathrm{e}^{-\mathrm{j}\omega a} f(t)\,\mathrm{d}t\right)$$

(4) Likeness theorem

$$\mathbf{F}\{f(at)\} = \frac{1}{a}\mathbf{F}\left(\frac{p}{a}\right) \text{ if } a > 0$$

(5) Attenuation theorem

$$\mathbf{F}\{\mathrm{e}^{-at} f(t)\} = F(\mathrm{j}\omega + a)$$

(6) Limit theorem

$$\lim_{t\to\infty} f(t) = \lim_{\mathrm{j}\omega\to 0} \mathrm{j}\omega F(\mathrm{j}\omega) \lim_{t\to 0} f(t) = \lim_{\mathrm{j}\omega\to\infty} \mathrm{j}\omega F(\mathrm{j}\omega)$$

(7) Integration theorem

$$\mathbf{F}\left\{\int_0^t f(\tau)\,\mathrm{d}\tau\right\} = \frac{1}{\mathrm{j}\omega}\{f(t)\}$$

(8) Differentiation theorem

$$\mathbf{F}\{f^{(n)}(t)\} = \mathrm{j}\omega^n \mathbf{F}\{f(t)\} - \mathrm{j}\omega^{n-1} f(+0) - \cdots - f^{(n-1)}(+0)$$

if the limits

$$\lim_{t\to 0} f(t) = f(+0);\ \lim_{t\to 0} \dot{f}(t) = \dot{f}(+0); \ldots;$$

$$\lim_{t\to 0} f^{(n-1)}(t) = f^{(n-1)}(+0), \text{exist}$$

Table 2. Relationships between time- and frequency-domain signals.

Time domain			Frequency domain	
	Function of time		Amplitude density	
Real function of a real variable	$x(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \widehat{X}(\mathrm{j}\omega)\mathrm{e}^{\mathrm{j}\omega t}\,\mathrm{d}\omega$	$\Longleftarrow F \Longrightarrow$	$\widehat{X}(\mathrm{j}\omega) = \int_{-\infty}^{+\infty} x(t)\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t$	Complex function of a real variable
Mean value operation; phase information is lost	$\psi_{xx}(\tau) = \lim_{\tau\to\infty}\frac{1}{2T}\int_{-T}^{+T} x(t)x(t+\tau)\,\mathrm{d}t$	$\downarrow$	$S_{xx}(\omega) = \frac{1}{2\pi}\lim_{T\to\infty}\frac{\lvert\widehat{X}(\mathrm{j}\omega)\rvert^2}{2T}$	Only unilateral conversion possible
	Autocorrelation function			
Real function of a real variable	$\psi_{xx}(\tau) = \int_{-\infty}^{+\infty} S_{xx}(\omega)\mathrm{e}^{\mathrm{j}\omega\tau}\,\mathrm{d}\omega$	$\Longleftarrow F \Longrightarrow$	$S_{xx}(\omega) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \psi_{xx}(\tau)\mathrm{e}^{-\mathrm{j}\omega\tau}\,\mathrm{d}t$	Real function of a real variable

Note: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.

and $S_{xx}(\omega)$. For instance, a constant amplitude density has the delta function, which is a time function, as an autocorrelation function, just as the constant power density in white noise has, *see also* **Article 28, Signals in the Time Domain, Volume 1**.

5 EXAMPLE OF TIME–FREQUENCY TRANSFORM

As an example with great relevance to practical application, let us deal with two signals used as test signals: The unit step $\omega(t)$ and the unit pulse or Delta function $\delta(t)$ as shown in Figure 3(a, b).

The spectral amplitude density of the unit pulse function is 1

$$\underline{\widehat{X}}(\mathrm{j}\omega)_{\vartheta} = F\{\delta(t)\} = \int_{-\infty}^{+\infty} \delta(t)\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t = 1 \qquad (2)$$

This means that only cosine functions with constant spectral amplitude appear, as also follows from the physical interpretation; only, in this case at $t = 0$ all spectral amplitude will be strengthened leading at least to the Dirac pulse (Figure 4a). The amplitude density of the unit step function is

$$\underline{\widehat{X}}(\mathrm{j}\omega)_{\omega} = F\{\omega(t)\} = \int_{0}^{+\infty} 1.\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t = 1 \qquad (3a)$$

This integral does not converge, so we have to solve the following integral

$$\lim_{\Delta\to 0}\int_0^{\infty} \mathrm{e}^{-\Delta t}\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t = \lim_{\Delta\to 0}\left[\frac{1}{-(\Delta+\mathrm{j}\omega)}\mathrm{e}^{-(\Delta+\mathrm{j}\omega)t}\right]_0^{\infty} = \frac{1}{\mathrm{j}\omega} \qquad (3b)$$

and we get a hyperbolic spectrum as shown in Figure 4(b), containing only sine functions: the step function is an uneven function so that only a sum of sine functions could approximate the course of the time function.

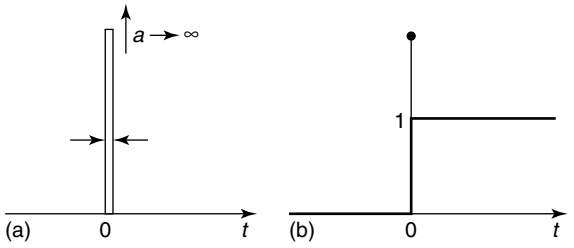

Figure 3. (a) Unit pulse function and (b) unit step function.

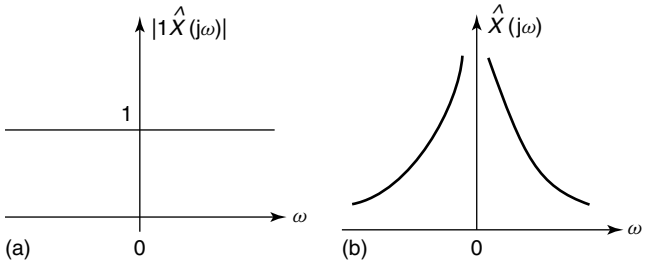

Figure 4. (a) Spectrum of a unit pulse function and (b) spectrum of a unit step function.

Another typical example is treated in **Article 28, Signals in the Time Domain, Volume 1**, Section 5.

6 FAST FOURIER TRANSFORM CONCEPT AND ITS APPLICATION

To accomplish the Fourier transform today, digital computers are used. The basis for this is the Fast Fourier Transform (FFT). Using a transform specially tailored to fit the way in which the digital computer operates, Discrete Fourier Transform (DFT) programs have been established, which save computing time, and where at least 1024 graph support points are quite usual. The calculation supplies the Fourier coefficients. As the number of support points is limited, the short-term correlation function is determined, which however, is practically identical with the correlation function, provided the correlation time is $\tau_k < T_s$.

To show the main ideas of FFT, we start from the equation of the Fourier transformation (1a), writing this equation for a sampled input signal with the sampling time T_s.

$$X^*(t) = \sum_{k=-\infty}^{+\infty} x(kT_s)\underline{\widehat{X}}^*(\mathrm{j}\omega) = T_s \sum_{k=-\infty}^{+\infty} x(kT_s)\mathrm{e}^{-\mathrm{j}\omega kT_s} \tag{4a}$$

Because it is not possible to use an infinite number of sampling values, a time boundary is realized, which means that instead of $k_{max} = \infty$ the maximum value of k is limited to N and instead of (4a) we get

$$\underline{\widehat{X}}^*(\mathrm{j}n\omega_0) = T_s \sum_{k=-\frac{N}{2}}^{+\frac{N}{2}} x(kT_s)\mathrm{e}^{-\mathrm{j}kn\omega_0 T_s} \tag{4b}$$

or with the fundamental frequency $\omega_0 = 2\pi/NT$

$$\underline{\widehat{X}}^*(\mathrm{j}n\omega_0) = \underline{\widehat{X}}^*\left(\mathrm{j}\frac{2\pi n}{NT_s}\right) = T_s \sum_{k=-\frac{N}{2}}^{+\frac{N}{2}} x(kT_s)\mathrm{e}^{-\frac{\mathrm{j}2\pi nk}{N}} \tag{4c}$$

From (4c) N complex Fourier coefficients arise. To get these coefficients due to (4c), N^2 multiplications are necessary. If $N = 2^S$ – that means N is a power of 2 – it is possible by means of division in subsumes and using an appropriate algorithm – the so-called Cooley–Tuckey Algorithm (Cooley and Tuckey, 1965) – to need only $N/2$ lb($N/2$) multiplications. For the often used value of $N =$ 1024, the number of multiplications thus can be reduced from 1048576 to 4608, which means that the calculation time is reduced to 1/227 of the original value!

Before microelectronics and microprocessors were developed, the application of Fourier transform was limited to special cases because it was extremely expensive to realize the transformation using analog methods. The classical application example in the beginning of the 1960s has been the testing of gears at the Volkswagen company using a spectral analyzer implemented in the analog technique. Today, the field of application is very broad. Signal analyzer, test equipment, and software tools now routinely make use of the FFT algorithms. *See also* **Article 143, DFT and FFTs, Volume 3**.

1 PROBABILITY DISTRIBUTION

In the following text, it is assumed that the probability functions are not dependent on time. In this situation, the process is a stationary stochastic one. In most cases – for instance, with noise – this proposition is met. If the stochastic parameters are changing relatively slowly, the process can be approximated by a stationary one for a determined time (Mendenhall and Sincich, 1992).

To describe randomly fluctuating events $\xi(t)$, use is made of characteristic functions, which are based on the theory of probabilities.

The probability distribution $W(x)$, which is also called the first-order distribution function, indicates the probability p that the signal $\xi(t)$ remains smaller than a barrier x,

$$W(x) = p[\xi(t) < x] \tag{1a}$$

as shown in Figure 1 with

$$W(x) = \frac{\sum \Delta t_r}{T} \tag{1b}$$

The limiting values of the probability distribution

$$\lim_{x \to -\infty} W(x) = 0 \tag{1c}$$

$$\lim_{x \to +\infty} W(x) = 1 \tag{1d}$$

are also clearly understandable, because they mean the impossibility of a value smaller than $-\infty$ as well as the certainty of the occurrence of any signal value $\xi(t) < \infty$. For continuous functions $\xi(t)$, the probability distribution $W(x)$ is a monotonically increasing function, see also Figure 3.

2 PROBABILITY DENSITY AND RELATION TO PROBABILITY DISTRIBUTION

Now we are interested in the probability $p(x)$ of the function $\xi(t)$ to be within a small region Δx near the value x

$$x \leq \xi(+) < x + \Delta x \tag{2a}$$

As Figure 2 shows, this probability is

$$p(x) = \frac{\sum \Delta t_r^*}{T} \tag{2b}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

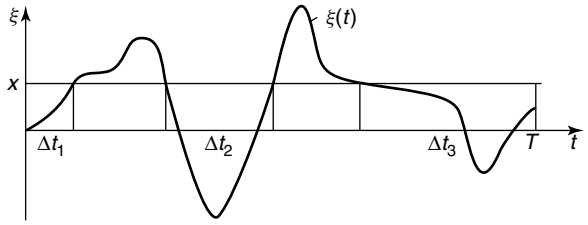

Figure 1. The definition of probability distribution.

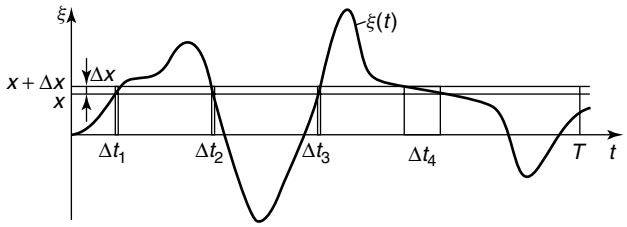

Figure 2. The definition of probability density.

This function is also a relation of Δx. Therefore, one relates to Δx and gains the probability density $w(x)$

$$w(x) = \frac{1}{\Delta x} p[x \leq \xi(t) < x + \Delta x]; \Delta x \to \mathrm{d}x \qquad (3a)$$

When comparing the Figures 3(a) and 3(b) it can be seen that the following relations exist

$$\int_{-\infty}^{x} w(u)\,\mathrm{d}u = W(x) \qquad (3b)$$

and

$$\frac{\mathrm{d}W(x)}{\mathrm{d}x} = w(x) \qquad (3c)$$

Taking into consideration the limit (1d), the normalization is

$$\int_{-\infty}^{+\infty} w(x)\,\mathrm{d}x = 1 \qquad (3d)$$

As shown in Figure 3, the probability that $\xi(t)$ lies within the interval x_2 to x_1 is calculated by

$$p[x_1 \leq \xi < x_2] = W(x_2) - W(x_1) = \int_{x_1}^{x} w(x)\,\mathrm{d}x \qquad (3e)$$

3 MULTIDIMENSIONAL PROBABILITY FUNCTIONS

If the stochastic process consists of not only one, but n fluctuating events $\xi(t)_1 \ldots \xi(t)_n$, then the same considerations

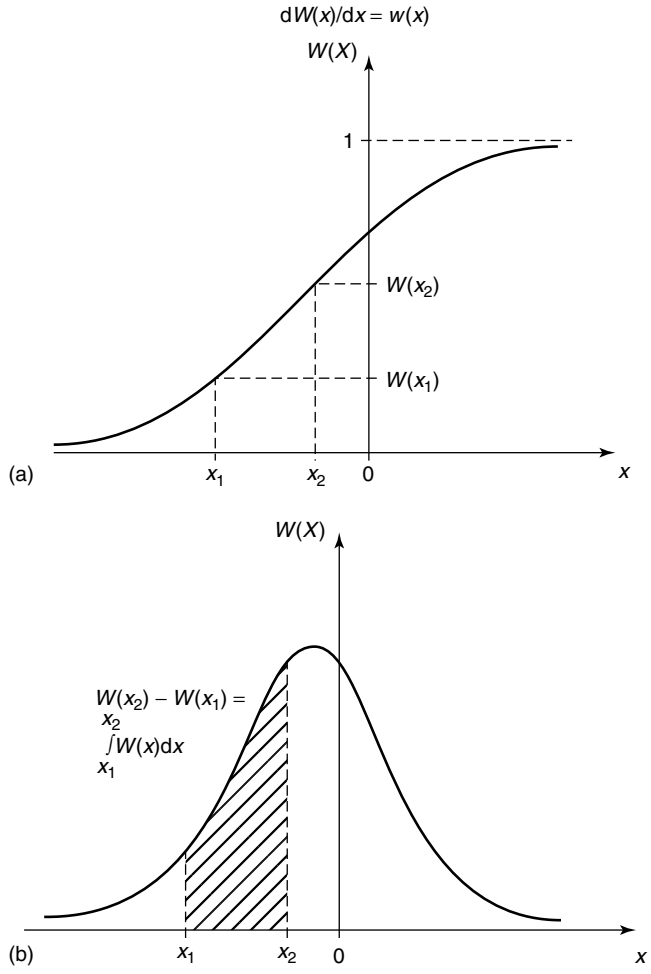

Figure 3. (a) Probability distribution and (b) corresponding probability density.

lead to n probability distribution functions or probability density functions with the limits $x_1 \ldots x_n$

$$W_1(x) \ldots W_n(x) \qquad (4)$$

and

$$w_1(x) \ldots w_n(x) \qquad (5)$$

To describe the relations between these functions, the compound probability distribution densities $w(x_1, x_2, \ldots, x_n)$ are introduced

$$W(x_1, x_2, \ldots, x_n) = p[\xi_1(t) < x_1, \xi_2(t) < x_2, \ldots, \xi_n(t) < x_n] \qquad (6a)$$

$$w(x_1, x_2, \ldots, x_n) = \frac{\partial^n}{\partial x_1 \partial x_2, \ldots, \partial x_n} W(x_1, x_2, \ldots, x_n) \qquad (6b)$$

Furthermore, conditional probability distributions $W(x_1/x_2)$ and conditional probability distribution densities $w(x_1/x_2)$ are defined. They indicate the probability that the value x_1 occurs on condition that the value x_2 already exists. The following relationships hold for the compound probability density:

$$w(x, y) = w(x|y) \times w(y) = w(y|x)w(x) \qquad (6c)$$

4 GAUSSIAN DISTRIBUTION

Of utmost importance in practice is the Gaussian distribution density (Buja, 1991; Jaffe, 2000)

$$w(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(\frac{-(x-a)^2}{2\sigma^2}\right) \qquad (7a)$$

where $a = \overline{x(t)}$ is the linear mean value and σ the standard deviation, related to the square mean value, $\overline{x^2(t)}$, by

$$\sigma = \sqrt{[\overline{x^2(t)} - a^2]} \qquad (7b)$$

Figure 4 shows the Gaussian distribution density for $a = 0$.

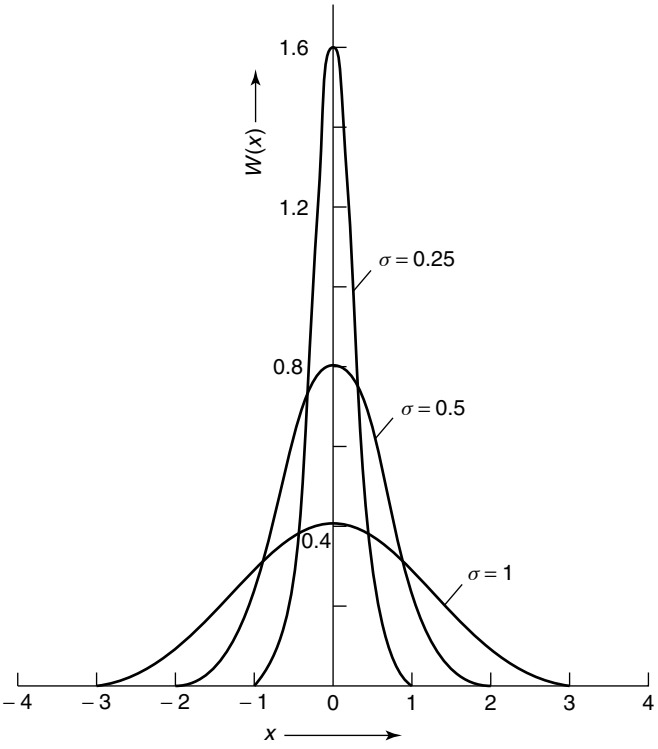

Figure 4. Gaussian distribution density.

Table 1. Gaussian probability integral $\Phi(x)$ evaluated for a range of x (Jahnke and Emde, 1966).

Source: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.

The Gaussian distribution describes all stochastic processes represented by a very great number of single processes running independent of each other in the same overall event. Typical examples are the arrival of rain droplets or, in electronics, the thermal noise.

Very useful in the application of Gaussian distribution is the Gauss error integral in the form

$$\Phi(x) = \frac{2}{\pi} \int_0^x \mathrm{e}^{-\mu^2}\, \mathrm{d}\mu \qquad (7c)$$

with the values given in Table 1.

Some examples of importance in measurement are treated in Section 7.

5 RELATIONSHIP TO MEAN VALUES; ERGODIC THEOREM

The expectation value E of a function $f(x)$ is defined as follows:

$$E\{f(x)\} = \int_{-\infty}^{+\infty} f(x)w(x)\,\mathrm{d}x \qquad (8a)$$

For $f(x) = x^n$, the moment M_n of nth order is obtained. Of particular importance is the moment of first order, denoted as statistical linear mean value $\tilde{x}$:

$$\tilde{x} = M_1 = E\{x\} = \int_{-\infty}^{+\infty} x\,w(x)\,\mathrm{d}x \qquad (8b)$$

and the statistical square mean value phase space average:

$$\tilde{x}^2 = M_2 = E\{x^2\} = \int_{-\infty}^{+\infty} x^2\,w(x)\,\mathrm{d}x \qquad (8c)$$

Accordingly, the expectation value for the simultaneous occurrence of $x_1(t)$ and $x_2(t+\tau)$ is obtained:

$$\begin{aligned} &x_1(t)x_2(t+\tau) \\ &= E\{x_1(t), x_2(t+\tau)\} \\ &= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} x_1(t)x_2(t+\tau)w[x_1(t), x(t+\tau)]\mathrm{d}x_1\mathrm{d}x_2 \end{aligned} \qquad (8d)$$

If this is an ergodic event, that is, if the ergodic theorem is satisfied, the statistical mean values $\tilde{x}^n$ and time mean values $\overline{x^n(t)}$ are equal

$$E\{x^n\} = \tilde{x}^n = \int_{-\infty}^{+\infty} x^n w(x)\,\mathrm{d}x = \overline{x^n(t)} = \lim_{T\to\infty} \frac{1}{2T}\int_{-T}^{+T} x^n(t)\,\mathrm{d}t \qquad (9a)$$

With (8d), a definition can be obtained of the correlation function $\psi_{xy}(\tau)$, which is based on the generalized mean value:

$$\psi_{xy}(\tau) = \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{+T} x(t)y(t+\tau)\,\mathrm{d}t = \overline{x(t)y(t+\tau)} = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} x(t)y(t+\tau)w[x(t),\, y(t+\tau)]\,\mathrm{d}x\,\mathrm{d}y \qquad (9b)$$

For the particularly important Gaussian distribution density according to (7a), one calculates

$$M_1 = \tilde{x} = \overline{x(t)} = \int_{-\infty}^{+\infty} \frac{x}{\sqrt{2\pi}\sigma}\exp\left(\frac{-(x-a)^2}{2\sigma^2}\right)\mathrm{d}x = a \qquad (9c)$$

$$M_2 = \tilde{x}^2 = \overline{x^2(t)} = \int_{-\infty}^{+\infty} \frac{x^2}{\sqrt{2\pi}\sigma}\exp\left(\frac{-(x-a)^2}{2\sigma^2}\right)\mathrm{d}x = a^2 + \sigma^2 \qquad (9d)$$

6 PRACTICAL INVESTIGATIONS

In order to display the probability distribution and density, electronic majority decision elements having an adjustable threshold value x are used, as outlined in Figure 5. Explanation in terms of analog processing assist appreciation of the process used.

This can be done in analog systems using either a triggering circuit or a voltage divider having a biased diode. With this, a normalization is to be carried out such that the corresponding conditions, (1d) and (3d), are observed. The arrangement has been for long also used for displaying these parameters on an oscilloscope screen, provided the voltage of the sweep generator for the x-deflection of the oscilloscope is used to control the threshold value x. The sweep frequency must be slow enough to ensure that adequate averaging occurs.

By coupling several installations in accordance with Figure 5(b), compound probability distributions $W(x, y)$ can also be recorded. For this purpose, the trigger outputs of one arrangement for each event x, y will be connected with an AND element and further processed as shown in Figure 5(b) (Woschni, 1988). Today, displays use digital processing to perform the task following digitization of the signal in an analog to digital (A/D) converter.

In practice it is possible to describe many events, at least approximately, by the Gaussian distribution of (7a). The probability for the fluctuation process to lie within the range $-x \le \xi(t) < +x$, or $a - x \le \xi(t) < a + x$, where a is a constant, is

$$p[-x \le \xi(t) < +x] = \frac{1}{\sqrt{2\pi}\sigma}\int_{-x}^{+x}\exp\left(\frac{-\xi^2}{2\sigma^2}\right)\mathrm{d}\xi \qquad (10a)$$

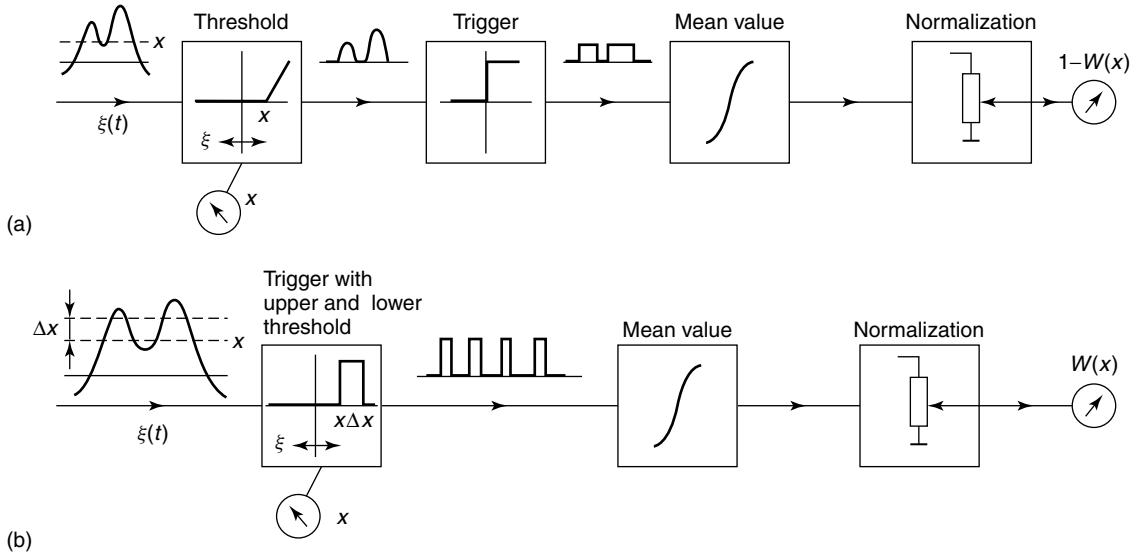

Figure 5. (a) Registration of the probability distribution and (b) probability density.

Table 2. Values of the example.

ϕ/rad	0.31	0.32	0.30	0.29	0.29	0.30	0.28	0.31	0.31	0.29
t/s^{-1}	2.39	2.40	2.41	2.43	2.40	2.38	2.39	2.41	2.37	2.42

To evaluate this, the probability integral is used, which is tabulated in the following form (Jahnke and Emde, 1966):

$$\phi(x) = \frac{2}{\sqrt{\pi}} \int_0^x \exp(-u^2)\, \mathrm{d}u \qquad (10b)$$

Extracts are shown in Table 1, see Section 4.

Some examples with importance in measurement will be treated in Section 7.

7 EXAMPLE OF USE IN METROLOGY

Where a number of measured values x_r are given, we are first interested in obtaining the standard deviation σ of the distribution as given by Hart, Lotze and Woschni (1997)

As an example, consider the rotation of the arm of an industrial robot being tested for preciseness of placement to the same position. The measured repeated values of the angle ϕ/rad and the time t s^{-1} are as shown in Table 2.

Using (10a) the standard deviation of the angle is $\sigma = 1.247 \times 10^{-2}$ rad and of the time $\sigma = 1.826 \times 10^{-2}$ s.

The mean value of the angular velocity is $\overline{\omega} = \overline{\varphi}/\overline{t} = 0.3/2.40 = 0.1250\,\mathrm{rad\ s^{-1}}$.

As an example, it may have been found by measurement that the length of workpieces having an average value of $a = 10\,\mathrm{cm}$ satisfies a Gaussian distribution and shows a standard deviation using (10a) of $\sigma = 3\,\mathrm{mm}$. What matters then might be the number of workpieces that lie within an admissible tolerance range of $10 \pm 4\,\mathrm{mm}$. Evaluation according to (10) shows that with the values of Table 1, some 82% of the pieces are within the tolerance range, and that the remaining pieces lie outside this range.

1 DISCRETE TIME SEQUENCES

The principle of gaining a discrete time sequence $x^*(t)$ by sampling the original analog signal $x(t)$ is shown in Figure 1. There, the signal $x(t)$ is multiplied with a switching-function $s(t)$ leading to the sampled signal sequence $x^*(t)$. This signal is then converted into a digital form using the methods of coding as treated in **Article 33, Coding Theory and its Application to Measurement, Volume 1**.

The basic mathematical formulation is

$$x^*(t) = x(t)s(t) \tag{1a}$$

Thus, by means of pulse-amplitude-modulation, the original analog signal is transformed into a digital signal. The switching function may be written as

$$s(t) = \sum_{r=0}^{\infty} \delta(t - rT_s) \tag{1b}$$

with the sampling time T_s.

The time sequence that results is given by

$$x^*(t) = x(t) \sum_{r=0}^{\infty} \delta(t - rT_s) = \sum_{r=0}^{\infty} x(rT_s) \tag{1c}$$

The coding of the time sequences $x(rT_s)$ into a digital signal is treated in **Article 33, Coding Theory and its Application to Measurement, Volume 1**. The inverse process, to gain $x(t)$ again if $x^*(t)$ is known is shown in Figure 2. This smoothing function can be realized in electrical systems by means of a capacitor connected to a voltage holding circuit.

A key design issue is to decide how many samples are necessary to retain all of the information of the signal $x(t)$. This consideration leads to the sampling theorem, treated in the next section.

Another important issue is what happens if the sampling theorem is violated. In this case, aliasing errors appear, as treated in the relevant section of this article. Here also the signal processing following the sampling stage has to be taken into consideration as shown in this section.

2 SAMPLING THEOREM

There exist exact mathematic foundations for the sampling theorem (Johnson, 1989; Oppenheim and Schafer, 1989). Here, however, another approach using physical explanations is used because this is very suitable for dealing with the problem of aliasing errors.

If the spectral amplitude density $\underline{\hat{X}}(\mathrm{j}\omega)$ given in **Article 27, Signals in the Frequency Domain, Volume 1** is limited to the critical frequency ω_c as shown in Figure 3 we get, applying the Fourier transform, the corresponding

ISBN: 0-470-02143-8.

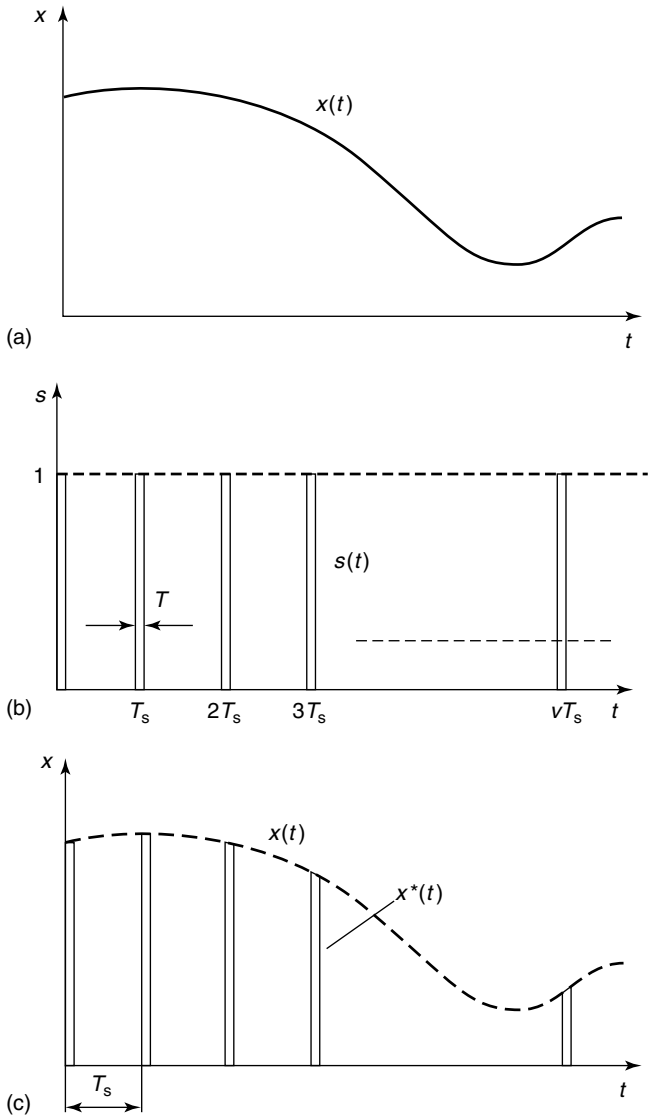

Figure 1. Principle of gaining the discrete signal sequence by means of sampling.

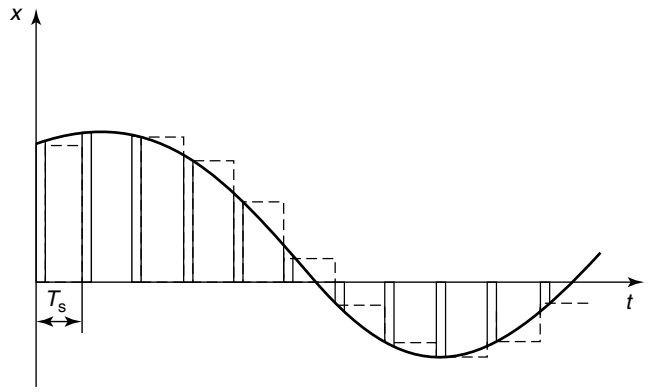

Figure 2. Smoothing with holding circuit.

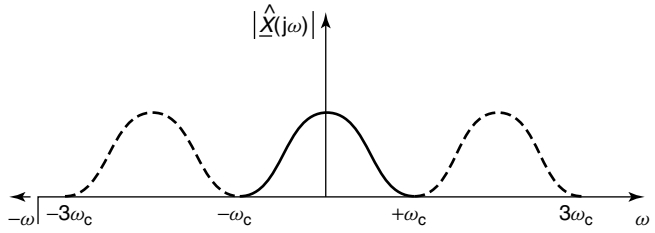

Figure 3. Band-limited spectral amplitude density.

time function $x(t)$ (Woschni, 1988).

$$x(t) = \frac{1}{2\pi} \int_{-\omega_c}^{+\omega_c} \hat{\underline{X}}(j\omega) e^{j\omega t} \, d\omega \tag{2a}$$

The spectral amplitude density function may be periodically continued as marked with dashed lines in Figure 3. Expansion of the series of this periodical frequency function yields

$$\underline{\hat{X}}_{\text{period}}(j\omega) = \frac{1}{2\,\omega_c} \sum_{r=-\infty}^{+\infty} x\left(\frac{r\pi}{\omega_c}\right) e^{-\frac{jr\pi\omega}{\omega_c}} \tag{2b}$$

In this series, the only values are

$$x\left(\frac{r\pi}{\omega_c}\right) = x(rT_s) \tag{2c}$$

Applying the sampling time (from the sampling theorem)

$$\frac{r\pi}{\omega_c} = rT_s \tag{2d}$$

where $T_s = \pi/\omega_c = 1/2f_c$

In reality, the amplitude density is not a band-limited entity as required by the sampling theorem. It is, therefore, necessary to carry out low-pass filtering before sampling called *antialiasing filtering*. Figure 4 shows that this leads to a cutoff error calculated due to system theory, where $S_{xx}(\omega)$ is the spectral power density of the signal (Woschni, 1988)

$$\overline{\varepsilon^2} = 2 \int_{\omega_c}^{\infty} S_{xx}(\omega) \, d\omega \tag{2e}$$

This error will be treated in detail together with the aliasing error in the next section.

Another approach also demonstrates the main points and leads to the aliasing errors if the sampling theorem is violated. We are starting with the switching function $s(t)$ due

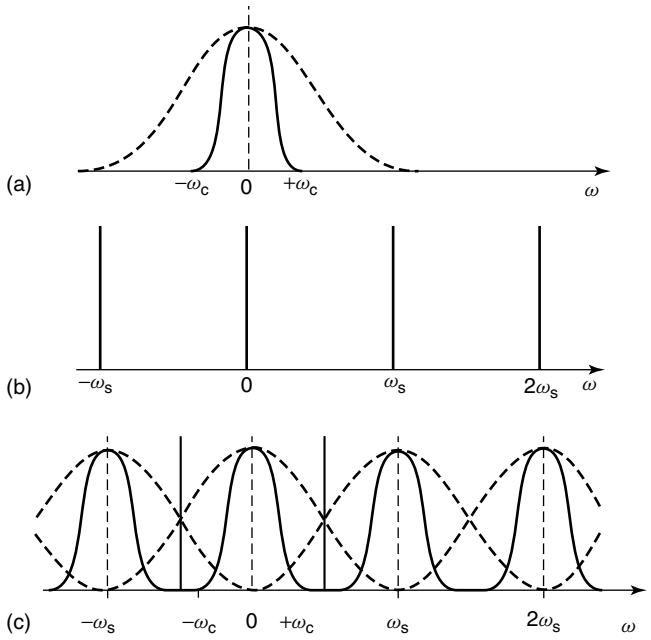

Figure 4. Explanation of sampling in the frequency domain.

to (1b). This periodic time function means a spectral function as shown in Figure 4(b).

$$s(t) = \frac{\tau}{T_s} \sum_{r=-\infty}^{+\infty} e^{jr\omega_s t} \tag{2f}$$

The multiplication with $x(t)$ due to (1a) represents an amplitude modulation as treated in **Article 34, Modulation Theory, Volume 1**. Figure 4(a) shows the spectral amplitude density of the signal $x(t)$, and the amplitude modulation has the spectral amplitude density as given in Figure 4(c). While in the case of a band-limited signal (thick line in Figure 4c), the spectra are separated from each other, in the case marked with dashed lines the spectra overlap. Here, the sampling theorem is violated and aliasing errors arise.

3 ALIASING ERRORS

Different error definitions are used in measurement. As shown in **Article 32, Geometrical Signal Representations, Volume 1** and especially in **Article 50, Errors in Signal Systems, Volume 1** the mean-square error introduced by Gauss has the advantage that it leads to closed mathematical solutions because of the validity of Euclidean geometry.

If the sampling theorem is fulfilled, the cutoff error due to the low-pass filtering is given by (2e). As shown in

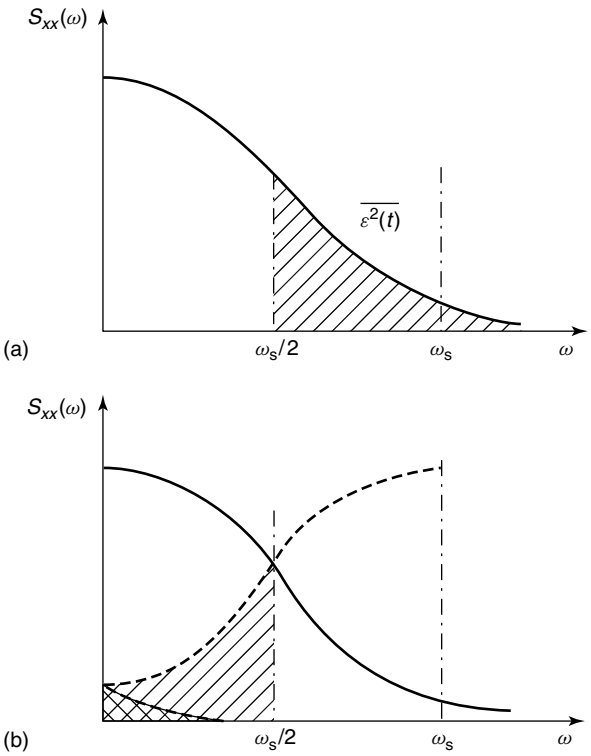

Figure 5. Calculation of the sampling errors in the frequency domain.

Figure 5(a), this error means the power of the cutoff part of the spectral power density of the signal $S_{xx}(\omega)$.

Figure 5 clearly shows the overlapping of the lower side band falling into the frequency range $0 \ldots \omega_s/2$ and leading to aliasing error.

$$\overline{\varepsilon^2} = 2 \int_{\frac{\omega_s}{2}}^{\infty} S_{xx}(\omega)\, d\omega \tag{3a}$$

Because the frequencies of the lower side band are mirrored, one can suppose the two error components – the cutoff and the aliasing errors – are not correlated to each other unless they originate from the same signal source. This means that the total sampling error is given by the sum of both components.

In measurement, these errors originate if it is not possible to realize a low-pass filtering before sampling. This case is typically for sensors with direct digital output, as, for instance, in the case treated in **Article 33, Coding Theory and its Application to Measurement, Volume 1**, because there a low-pass filtering is not feasible. These errors are becoming of decreasing importance because the development of microelectronics leads to ever higher pulse frequencies and then oversampling is possible (Woschni, 2001).

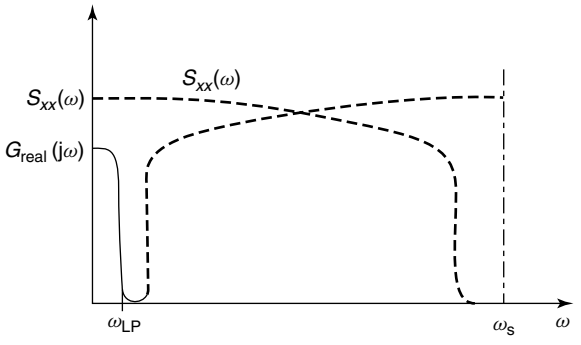

Figure 6. Mean-value operation after sampling.

Another example that is important in measurement science is the influence of a signal processing after sampling. A typical case arises in surface measurement. Here, instead of the whole information of the surface profile, only the average roughness is of interest. As demonstrated in Figure 6, low-pass filtering ω_{LP} after sampling is necessary to gain the mean value. This means only half of the value of the sampling frequency due to the sampling theorem is to be used without the generation of errors (Woschni, 1996a,b).

4 LEAKAGE DISTORTION

Another problem of analog-to-digital conversion is that of windowing. The signal function $x(t)$ has to be time limited, for example, by means of a time window instead of the infinite function. A time-limited function is used called the *truncation window*. This truncation in time leads to a variation of the spectrum, called *leakage distortion* (Thrane, 1979).

As shown in Figure 3, in the time domain a periodic time function appears leading to cutoff errors known as *leakage errors*. The main statements are demonstrated in Figure 7.

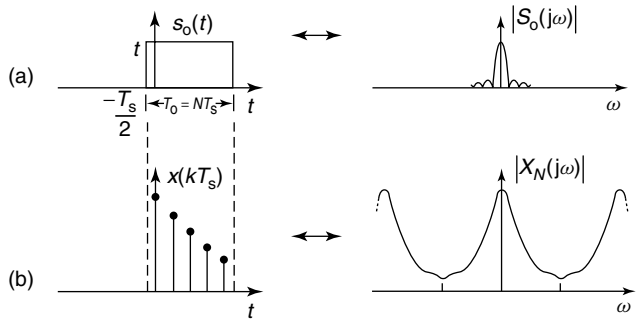

Figure 7. (a) Truncation window and its transform; (b) truncated sequence and its transform.

The truncated sampled signal function may be written as (Figure 7b)

$$x(kT_s) \quad k = 0, 1, 2, \ldots, N-1 \tag{4a}$$

This is the product of the infinite sequence $x_s(kT_s)$ and a rectangular time domain truncation window $s_o(t)$ as shown in Figure 7(a).

$$x_s(kT_s) = x(kT_s)s_o(t) \tag{4b}$$

With the switching function, as treated in Section 1 of this article, (1a)

$$x_s(kT_s) = x(t)s_o(t)s(t) \tag{4c}$$

The Fourier transform of this yields

$$X_N(j\omega) = X(j\omega)^* S_o(j\omega)^* S(j\omega) \tag{4d}$$

With the modulus of the Fourier transform of a rectangular time window being as treated in detail in Section 7

$$|S_o(j\omega)| = \mathrm{si}(\pi\alpha) = \frac{(\sin\pi\alpha)}{\pi\alpha} \tag{4e}$$

The results obtained mean that in Figure 7(a) the time window leads to the spectrum given by (4e) and the convolution with the spectrum of $x_s(kT_s)$ results in the spectrum demonstrated in Figure 7(b) where a rippling distortion can be seen.

Figure 8 shows the case of discrete components within the signal spectrum $X_s(j\omega)$. Convolution with the function $S_o(j\omega)$ would be replaced by a si-function due to (4e), which is explained later.

In general, the amount of leakage distortion depends on the length of the truncation window in comparison to the sampling interval as the following example shows.

A typical example is now given (Hart, Lotze and Woschni, 1997). A sinusoidal signal may be sampled with a normalized time truncation window Tf_c. Using the methods given above the relative mean-square error F is calculated as a function of k – the sampling time T_s due to the sampling theorem related to a shorter real sampling time T_s' –

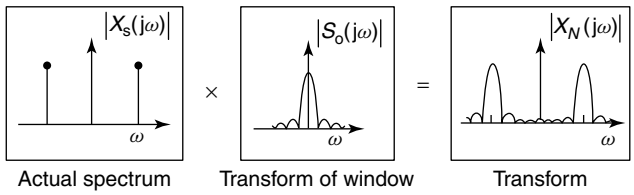

Figure 8. Leakage distortion of discrete components.

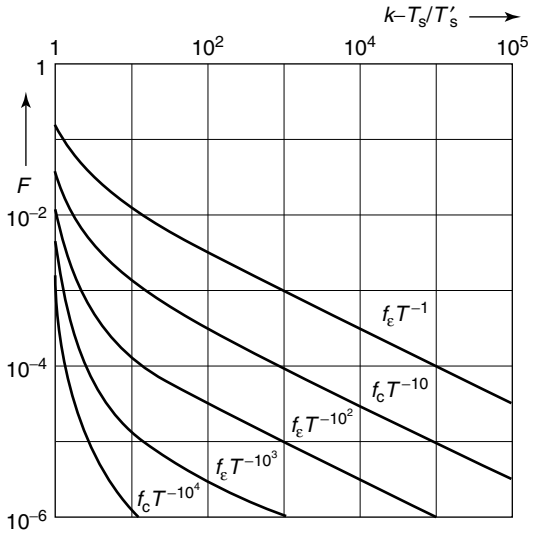

Figure 9. Errors as a function of the relative sampling time k with the relative truncation time as parameter.

Figure 9. It is evident that because of the leakage distortion shorter sampling times are necessary to avoid errors.

5 FREQUENCY DOMAIN SAMPLING

As treated in the last section, a truncated time sequence originates an infinite spectrum $X(\mathrm{j}\omega)$. Figure 7(b) demonstrates that a periodic spectrum appears. For computer application, this frequency function has to be sampled and limited to a finite number of samples. This procedure, therefore, is the same as the one realized in the last section; only time and frequency are now exchanged. Thus, here also the same problems of aliasing errors and leakage distortion arise.

Owing to (4a–d), $X(k\mathrm{j}\omega_\mathrm{s})$ may be the sampled frequency function gained from the original function $X(\mathrm{j}\omega)$ by means of a sampling function $S_\mathrm{f}(\mathrm{j}\omega)$ in the same way as in the time domain in Section 4

$$X(k\mathrm{j}\omega_\mathrm{s}) = X(\mathrm{j}\omega)S_\mathrm{f}(\mathrm{j}\omega) \tag{5a}$$

This infinite frequency function has to be frequency truncated to N numbers of samples by means of a frequency domain truncation window $S_\mathrm{o}(f)$ leading to the relation equivalent to (4c)

$$X_N(k\mathrm{j}\omega_\mathrm{s}) = X(\mathrm{j}\omega)S_\mathrm{o}(\mathrm{j}\omega)S_\mathrm{f}(\mathrm{j}\omega) \tag{5b}$$

This equation may be transformed to the time domain where the multiplication will be a convolution and $x(t)$ will be a

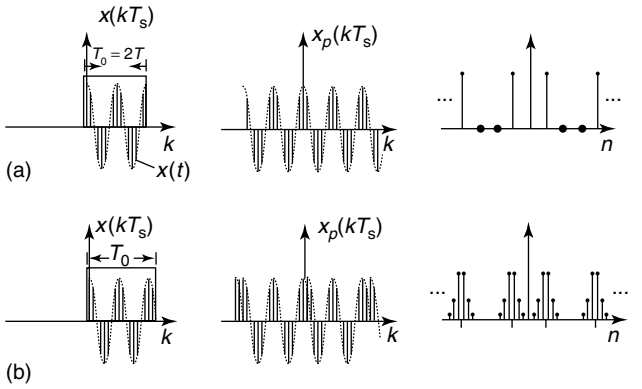

Figure 10. (a) Width of truncation window equal to two periods of $x(t)$; (b) width not equal to two periods.

periodic repetition of the sample function $x_p(kT_\mathrm{s})$

$$x_p(kT_\mathrm{s}) = x(t)^* s_\mathrm{o}(t)^* s_\mathrm{f}(t) \tag{5c}$$

So we get, in principle, the same relation between sampled spectrum and time function as shown in Figure 7(b), only now with a periodically repeated time function.

There exists an important case, found especially in measurement, when $x(t)$ is a periodic signal. Here, two different situations may be distinguished, as demonstrated in Figure 10. If the width of the truncation window contains an integral number of periods of the signal, then no error arises as Figure 10(a) shows. Otherwise errors appear (Figure 10b).

Other applications of frequency domain sampling concern the design of digital filters (Johnson, 1989).

6 DISCRETE FOURIER, LAPLACE, AND Z-TRANSFORM

As treated in **Article 27, Signals in the Frequency Domain, Volume 1**, between the time and the frequency domain there exists a relationship known as the *Fourier transform*. In the case of analog continuous signals, use of this transform yields (from (6b, c) of **Article 27, Signals in the Frequency Domain, Volume 1**)

$$\hat{X}(\mathrm{j}\omega) = \int_{-\infty}^{+\infty} x(t)\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t = F\{x(t)\} \tag{6a}$$

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \hat{X}(\mathrm{j}\omega)\mathrm{e}^{\mathrm{j}\omega t}\,\mathrm{d}\omega = F^{-1}\{\hat{X}(\mathrm{j}\omega)\} \tag{6b}$$

In technical systems, it is reasonable to assume that the signals start at $t = 0$. Then, under the limit (6a) is zero

(so-called unilateral Fourier or Laplace transform)

$$\hat{X}(\mathrm{j}\omega) = \int_0^\infty x(t)\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t \tag{6c}$$

As shown in Section 1 of this article, instead of the time function $x(t)$ by means of sampling with T_s, the discrete time sequence

$$x^*(t) = x(t)\Sigma\delta(t - rT_s) = \Sigma x(rT_s) \tag{6d}$$

originates leading to the infinite sequence due to (6c)

$$\hat{X}^*(\mathrm{j}\omega) = \sum_{r=0}^{\infty} x(rT_s)\mathrm{e}^{-\mathrm{j}\omega rT_s} \tag{6e}$$

In Section 4, it is demonstrated that this function has to be time truncated. This means a limitation to N samples applies, that is, the function $x(t)$ is replaced by a periodic one. Instead of (6b), it follows

$$X(r) = \frac{1}{N}\sum_{k=0}^{N-1} X^*(k)\mathrm{e}^{\mathrm{j}(2\pi/N)kr} \tag{6f}$$

The Fourier coefficients are

$$X^*(k) = \sum_{k=0}^{N-1} X(r)\mathrm{e}^{\mathrm{j}(2\pi/N)kr} \tag{6g}$$

With the definition

$$W_N = \mathrm{e}^{-\mathrm{j}(2\pi/N)} \tag{6h}$$

The discrete Fourier transformation is (Oppenheim and Schafer, 1989)

$$X^*(k) = \sum_{r=0}^{N-1} X(r)W_N^{kr} \tag{6i}$$

$$X(r) = \frac{1}{N}\sum_{k=0}^{N-1} X^*(k)W_N^{-kr} \tag{6j}$$

Using this definition, the algorithms of Cooley and Tuckey (1965) now well known as Fast Fourier Transform (FFT) are introduced as treated in Section 6 of **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**.

Using the same procedure, the Laplace transform may be applied to discrete signals leading to the relations – *see* **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**.

$$X^*(s) = \sum_{r=0}^{\infty} X(rT_s)\mathrm{e}^{-rsT_s} \tag{6k}$$

$$X(rT_s) = \sum_{r=0}^{\infty} X^*(s)\mathrm{e}^{rsT_s} \tag{6l}$$

With the substitution

$$Z = \mathrm{e}^{sT_s} \tag{6m}$$

the Z-transformation results that is especially used in the theory of digital signal processing and filters – see Section 8 of this article.

7 SPECTRAL ANALYSIS OF SIGNAL SAMPLES

A periodic rectangular signal may be considered as shown in Figure 11. It is built by means of rectangular truncation windows in the time domain.

Using the method of Fourier spectrum as treated in Section 2 of **Article 27, Signals in the Frequency Domain, Volume 1** one obtains only cos functions with the coefficients

$$A_n = \frac{4}{T}\int_0^{\frac{\tau}{2}} a\cos n\omega_0 t\,\mathrm{d}t = \frac{4a}{Tn\omega_0}\sin\left(n\omega_0\frac{\tau}{2}\right) = \frac{2a\tau}{T}\mathrm{si}\left(n\omega_0\frac{\tau}{2}\right) \tag{7a}$$

or the complex Fourier coefficients

$$\hat{X}(\mathrm{j}n\omega_0) = a\int_{-\tau/2}^{+\tau/2} \mathrm{e}^{-\mathrm{j}n\omega_0 t}\,\mathrm{d}t = \frac{2a}{n\omega_0}\sin n\omega_0\frac{\tau}{2} = \frac{a\tau}{T}\mathrm{si}\left(n\omega_0\frac{\tau}{2}\right) \tag{7b}$$

The spectrum consists of harmonics with an envelope well known as the si(x) function that is demonstrated in

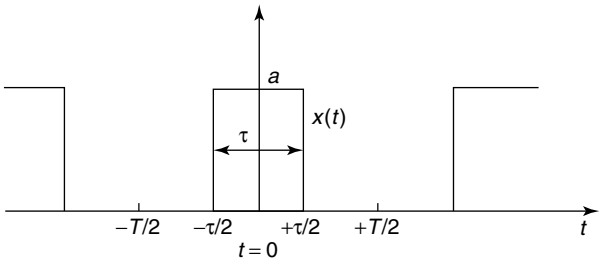

Figure 11. Periodic rectangular signal.

Figure 12. The smaller the pulse duty factor τ/T is the more harmonics that fall into the region up to the first zero point.

Because of the existence of the side maximums, the required spectrum is relatively wide. On the other hand, a truncation of the spectrum leads to a time function of $\mathrm{si}(x)$ form instead of the rectangular one of the original signal. To avoid these disadvantages, other time truncation windows with better performance, for example, smaller spectra are used (Johnson, 1989) or (Oppenheim and Schafer, 1989).

For instance, the bell-shaped window leading to the bell-shaped pulse is as shown in Figure 13. From this

$$x(t) = a\mathrm{e}^{-\beta^2 t^2} \tag{7c}$$

has a spectrum – using Fourier transform as treated in Section 4 of **Article 27, Signals in the Frequency Domain, Volume 1**

$$\begin{aligned}\underline{\hat{X}}(\mathrm{j}\omega) &= a\int_{t=-\infty}^{+\infty} \mathrm{e}^{-\beta^2 t^2}\mathrm{e}^{-\mathrm{j}\omega t}\,\mathrm{d}t \\ &= a\mathrm{e}^{-\frac{\omega^2}{4\beta^2}}\int_{-\infty}^{+\infty} \mathrm{e}^{-(\beta t-\mathrm{j}\omega 2\beta)^2}\,\mathrm{d}t \\ &= \frac{2a}{\beta}\mathrm{e}^{-\frac{\omega^2}{4\beta^2}}\int_0^{\infty} \mathrm{e}^{-x^2}\,\mathrm{d}x = \frac{a\sqrt{\pi}}{\beta}\mathrm{e}^{-\frac{\omega^2}{4\beta^2}}\end{aligned} \tag{7d}$$

This is also a bell-shaped spectrum having no side maximums and therefore leading to signals with a smaller required frequency range. Other time truncation windows

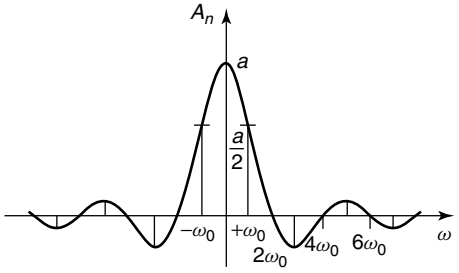

Figure 12. Spectrum of the periodic rectangular signal.

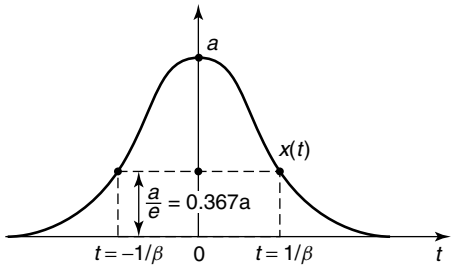

Figure 13. Bell-shaped pulse.

and their advantages are treated in (Johnson, 1989) or (Oppenheim and Schafer, 1989).

The method of periodograms may be useful here (Oppenheim and Schafer, 1989).

8 EXAMPLES OF SIGNAL PROCESSING

To illustrate the main methods of signal processing using the results of the investigations of this article, consider first the integration of a signal $x(t)$.

The first approximation is a rectangular one described by the algorithm

$$y(t) = y(t - T_A) + Tx(t) \tag{8a}$$

Using the discrete Fourier, Laplace, or Z-transform, the frequency response or Z-transform is

$$G_{\mathrm{R1}}(\mathrm{j}\omega) = T\frac{1}{1-\mathrm{e}^{-\mathrm{j}\omega T}} \tag{8b}$$

$$G_{\mathrm{R1}}(s) = T\frac{1}{1-\mathrm{e}^{-sT}} \tag{8c}$$

$$G_{\mathrm{R1}}(z) = T\frac{z}{z-1} \tag{8d}$$

The next better approximation is a trapezoidal one with the algorithm

$$y(t) = y(t - T) + \frac{T}{2}[x(t) + x(t - T)] \tag{8e}$$

leading to the frequency functions

$$G_{\mathrm{R2}}(s) = \frac{T}{2}\frac{1+\mathrm{e}^{-sT}}{1-\mathrm{e}^{-sT}} \tag{8f}$$

$$G_{\mathrm{R2}}(z) = \frac{T}{2}\frac{z+1}{z-1} \tag{8g}$$

$$G_{\mathrm{R2}}(\mathrm{j}\omega) = \frac{T}{2}\frac{1+\mathrm{e}^{-\mathrm{j}\omega T}}{1+\mathrm{e}^{-\mathrm{j}\omega T}} \tag{8h}$$

The frequency response of the ideal integration is

$$G(\mathrm{j}\omega) = \frac{1}{\mathrm{j}\omega} \tag{8i}$$

As Figure 14 shows, the trapezoidal approximation is better because here only an amplitude error and no phase error appears. On the other hand, we have to pay for this advantage by using more processing time!

The mean-square error in using the results of **Article 50, Errors in Signal Systems, Volume 1** for the

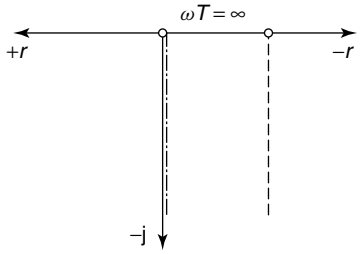

Figure 14. Frequency responses of integration algorithms; —— ideal; - - - - rectangular.; —·—·—· trapezoidal.

rectangular integration and a model signal $S(x) = S_o/(1 + \omega/\omega_0)$ (Woschni, 1996a,b) is given by

$$\overline{\varepsilon^2} = 2\int_0^{\frac{x}{T}} \frac{S_o}{1+\left(\frac{\omega}{\omega_0}\right)} \left|\frac{1}{j\omega} - \frac{T}{1-e^{-j\omega T}}\right|^2 d\omega \qquad (8j)$$

Another example is the prediction problem. The ideal frequency response reads as follows:

$$G_R(s) = e^{sT},\ G_R(z) = z,\ G_R(j\omega) = e^{+j\omega T} \qquad (9a)$$

The first approximation is the linear continuation of $x(t)$, for example, the algorithm is

$$y(t) = x(t) + x(t) - x(t - T_s) = 2x(t) - x(t - T) \qquad (9b)$$

The frequency functions are, using the same method as before

$$G_{R1}(j\omega) = 2 - e^{-j\omega T} \qquad (9c)$$

$$G_{R1}(s) = 2 - e^{-sT} \qquad (9d)$$

$$G_{R1}(z) = 2 - z^{-1} \qquad (9e)$$

The next better approximation includes the two last values with the algorithm

$$y(t) = 3x(t) - 3x(t - T) + x(t - 2T) \qquad (9f)$$

leading to the frequency functions

$$G_{R2}(s) = 3 - 3e^{-sT} + e^{-2sT} \qquad (9g)$$

$$G_{R2}(z) = 3 - 3z^{-1} + z^{-2} \qquad (9h)$$

$$G_{R2}(j\omega) = 3 - 3e^{-j\omega T}s + e^{-j2\omega T} \qquad (9i)$$

Figure 15 shows the results where the general principle is evident. In general, the better the algorithm, that is, the smaller the error – the longer the time needed for processing. Owing to the development of ever faster microelectronic circuitry having increased processing performance good approximations are possible with smaller errors.

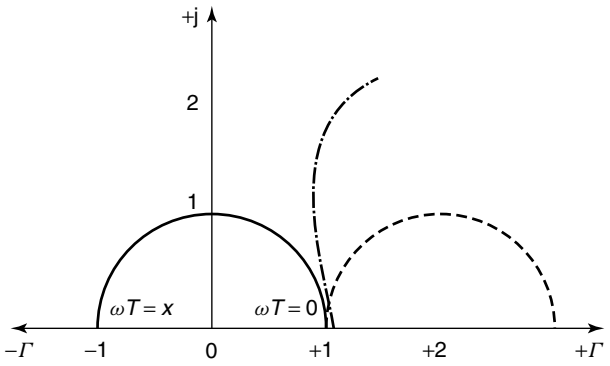

Figure 15. Frequency responses of prediction algorithms; —— ideal; - - - - first approx.; —·—·—· second approx.

Finally, it may be hinted at the limitation of the frequency range from $f = 0$ to $f = f_s/2$ due to the Sampling theorem. Furthermore, the processing error is a function of the word length s in bits of the code used. Between the signal-to-noise ratio S/N in dB and the word length s in bits there exist the general relation (Woschni, 1988)

$$S/N = 20 \log 1/2^s = -20\, s/^2 \log 10 = 6\, s \qquad (9j).$$

1 REPRESENTATION OF SIGNALS IN EUCLIDEAN SPACE

Signals with n components $x_1, \ldots, x_n$ can be represented by a signal vector $\mathbf{x}$ in the n-dimensional space:

$$\mathbf{x} = (x_1, x_2, x_3, \ldots, x_n) \tag{1a}$$

where the end point of the vector determines the corresponding signal.

For analog signals, use is made of Euclidean space, wherein the Pythagorean theorem applies. Thus, for the magnitude of the vector, also called the *norm* in geometry, one obtains

$$\|\mathbf{x}\| = \left(\sum_{r=1}^{n} x_r^2 \right)^{\frac{1}{2}} \tag{1b}$$

The various components are then the projections onto the different axes of the n-dimensional space, which is called the *signal space*.

The notion of the distance d between two or more signals is of great practical importance. This distance results as a norm of the difference between two signal vectors $\mathbf{x}$ and $\mathbf{y}$ as follows:

$$\mathrm{d}(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\| = \left(\sum_{v=1}^{n} |x_v - y_v|^2 \right)^{\frac{1}{2}} \tag{1c}$$

The scalar product

$$\mathbf{x} \times \mathbf{y} = \sum_{v=1}^{n} x_v y_v \tag{2a}$$

can be used to write the angle α between the two vectors in the following way:

$$\cos \alpha = \frac{\mathbf{xy}}{\|\mathbf{x}\| \|\mathbf{y}\|} \tag{2b}$$

Figure 1 explains the relations.

For continuous analog signals $x(t)$, which are defined in the range $a \leq t < b$, one can accordingly indicate a norm:

$$\|\mathbf{x}\| = \left(\int_a^b x^2(t)\, \mathrm{d}t \right)^{\frac{1}{2}} \tag{3a}$$

Physically, it represents the square root of the energy of the signal. A special Hilbert space is thus defined (Blumenthal, 1961). The distance between two signals corresponds to the root mean square error

$$\mathrm{d}(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\| = \left(\int_a^b |x(t) - y(t)|^2\, \mathrm{d}t \right)^{\frac{1}{2}} \tag{3b}$$

It is often used in measurement technology and cybernetics as a measure for the error – *see* **Article 50, Errors in Signal Systems, Volume 1**.

2 REPRESENTATION OF SIGNALS IN NON-EUCLIDEAN SPACE

The above representation in the Euclidean space is suitable for analog signals. Use is made of a representation in non-Euclidean signal space for discrete signals whose importance is constantly increasing as digital systems replace evermore the analog ones. In this space, the distance between two vectors **x, y** is defined to be the sum of the differences of the individual components (Blumenthal, 1961)

$$\mathrm{d}(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\| = \sum_{v=1}^{n} |x_v - y_v| \qquad (4a)$$

according to the norm of this space:

$$\|\mathbf{x}\| = \sum_{v=1}^{n} x_v \qquad (4b)$$

The most important discrete signals are binary signals, that is, signals in which the individual components can assume the values 1 and 0 only. For such signals, the signal space constitutes an n-dimensional hypercube having the edge length 1, where the various edges are occupied by possible signals only.

Figure 2 shows such signal words with one, two, and three bits. Obviously, the representation in non-Euclidean space with the norm according to (4b) has the advantage that the distance d indicates the number of digits by which two signal words differ from each other. Similarly defined minimum distance in a signal alphabet is called the Hamming distance and constitutes an important characteristic value for the investigation into a system's sensitivity to noise (Peterson, 1962). To investigate distances between signals, use is also made of distance matrices as shown in the next section. In the analog-to-digital conversion of signals – *see* **Article 132, Data Acquisition Systems (DAS) in General, Volume 3** and **Article 139, Analog-to-Digital (A/D) Converters, Volume 3**, a transform between the corresponding signal spaces takes place.

3 HAMMING DISTANCE

The distance between two code words in Figure 1 is the minimum length that can be taken only along the axis x_1, x_2, x_3. Another possibility to obtain the distances uses the so-called distance matrix as demonstrated for the signals of Figure 2 in Table 1.

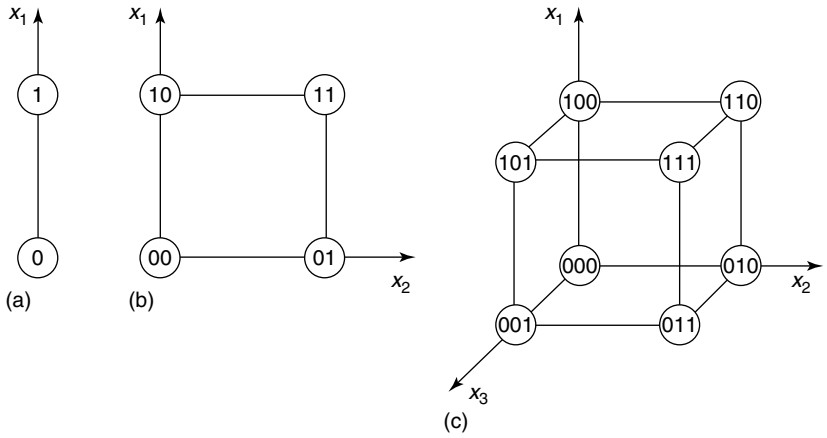

Figure 2. Representation of a binary signal in the signal space: (a) one bit; (b) two bits; (c) three bits.

Table 1. Distance matrices for the signals of Figure 2. a) $n = 1$; b) $n = 2$; c) $n = 3$.

a)

	1	0
	0	1
0	1	0

b)

	00	10	01	11
00	0	1	1	2
10	1	0	2	1
01	1	2	0	1
11	2	1	1	0

c)

	000	001	010	011	100	101	110	111
000	0	1	1	2	1	2	2	3
011	1	0	2	1	2	1	3	2
010	1	2	0	1	2	3	1	2
011	2	1	1	0	3	2	2	1
100	1	2	2	3	0	1	1	2
101	2	1	3	2	1	0	2	1
110	2	3	1	2	1	2	0	1
111	3	2	2	1	2	1	1	0

Because the distance d between two words is equal to the number of bits by which the two words differ from each other, the number of the possible code words between them is $d - 1$. If in an alphabet not all possible words are used, the minimal distance in this alphabet is called the *Hamming distance* $d_{\min}$ or d_{Hamming}. This means, for instance, for $d_{\min} = 2$, that between each word of the alphabet, one not used word is situated. From this fact it follows that 1-bit error leads to a not used word. So bit errors of first order f_{e1} can be noticed. If there are two vacant words between two used words – it means that $d_{\min} = 2$ – errors of second order f_{e2} can be noticed and so on, leading to the general relation between the order n of noticed errors and the Hamming distance

$$f_{en} = d_{\min} - 1 \tag{5}$$

Similar reflections lead to the relation between the order n of correctable errors f_{cn} and the Hamming distance $d_{\min}$. For instance, with $d_{\min} = 2$ in Figure 2, only the words 000 and 111 are used. So errors of first and second order lead to unused words and can be noticed due to (5). But the probability that the first-order error word belongs to the original word is very much higher than for the second-error word. Therefore, a correction can be done to correct the words with first-order error, the order of correction is 1. From this reflection there follows the general relation

$$f_{cn} = \frac{(d_{\min} - 1)}{2} \tag{6}$$

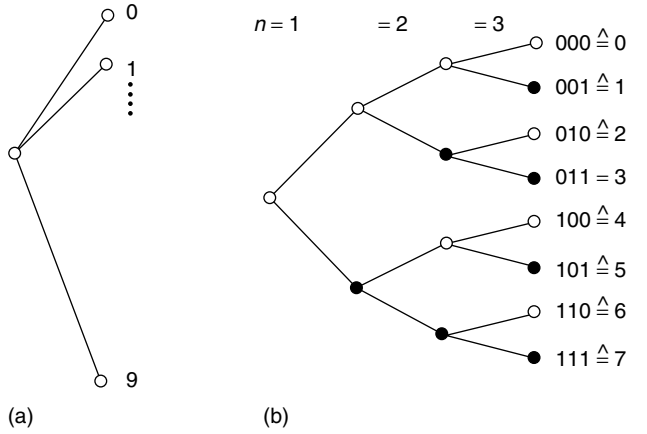

Figure 3. Representation as a codegraph: (a) signal with $m = 10$ possible states and (b) binary signal with the length $n = 3$.

Equation (6) – the application of the principle of an additional redundancy (Woschni, 1988; Shannon, 1948; Goldman, 1953) – is the key to designing data transmission lines with a very small error probability although the original transmission line is of low performance.

4 REPRESENTATION WITH CODEGRAPHS

For an easily understandable explanation of the signal structure, the codegraph may be used. On the basis of the results of the graph theory, the m possible states (symbols) of a signal are shown as an assembly according to Figure 3(a). Figure 3(b) shows the application of this type of representation to a binary signal having three digits. Where the individual code words are of the same length, they can be separated one from the other by counting. No characters are required for the separation of the individual words; the code is irreducible. Obviously, this is the case if the end points of the codegraph are occupied by code words only.

For more details, especially concerning code theory and its application to measurement, *see* **Article 33, Coding Theory and its Application to Measurement, Volume 1**.

1 CODERS AND DECODERS IN MEASUREMENT SYSTEMS

The task of measurement as a part of communication is the transmission of a message from an information source to a receiver, as shown in Figure 1. The output of this information source may be a digital or a continuous signal. In measurement, it is the unknown quantity that is to be measured: the output is generated by a random mechanism having a probabilistic nature. Otherwise, the signal would be completely known and there would be no need to obtain the output by means of measurement. The signal coming from the information source is the input signal of the encoder, modulator, or transmitter. If the signal is digital, the term *encoder* is used, while for analog signals the term *modulator* is used. This subsystem is treated in **Article 34, Modulation Theory, Volume 1**. The overall function of this communication system is to transform the signal where there are several information sources by multiplexing them onto the same transmission channel, or to make the signal reasonably immune to unwanted disturbances.

The modulated or coded signal is transmitted by the channel or processed by the processor. This channel may be a microwave or uhf relay link, a wire or cable transmission, or an optical fiber, as are commonly used in measurement systems. Noise arising in the channel is considered to be additive.

In measurement, the signal is usually processed by a microprocessor containing a memory. As in the case of an analog system – still favored in some measurement applications – the behavior of this system may be described by a transfer function provided the computer program is a linear one (Woschni, 1988).

The next link in the serial chain is the decoder or demodulator, whose task is to reconstruct an estimate of the original signal as correctly as possible. In the sense of describing the signal as a vector in the signal space (*see* **Article 32, Geometrical Signal Representations, Volume 1**), it means that the distance between the output and input signals should be kept to a minimum. Many similarities link this problem to the problems of character recognition (Finkelstein, 1976).

2 CODING THEORY

As treated in Section 1 of this article, the first subsystem of a communication system is the encoder, converting the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

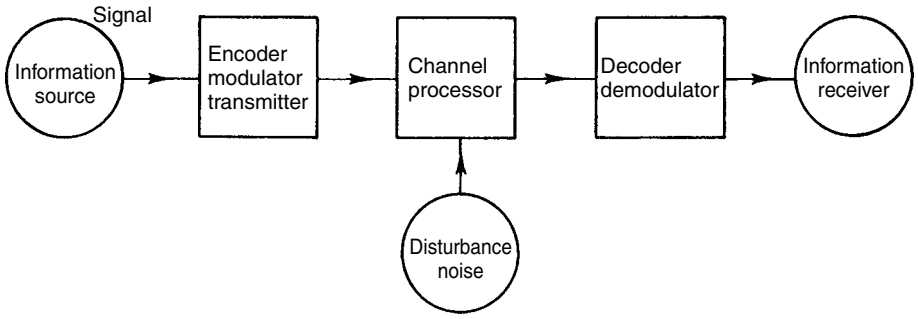

Figure 1. Communication system.

input signal into a series of code words. The task of this coding is the adaptation (interfacing) of the information source to the channel or processor.

In communication systems, the redundancy-diminishing (optimal) source coding, having the purpose of economizing the time needed for communication, often plays an important role. In measurements, however, security of the message against disturbances is the most needed criterion. Here, therefore, error-detecting or error-correcting codes are applied (Peterson, 1962).

For the representation of codes, geometrical descriptions or codegraphs are used in the n-dimensional space (*see* **Article 32, Geometrical Signal Representations, Volume 1**). Many coding and decoding theorems exist. The decoding theorem deals with the problem of identifying a code word by the receiver. For this purpose, the decoder compares the incoming code words with the words of the code alphabet deciding which code word the transmitter has sent. In the case in which the end of a code word is not marked by a special symbol, only the endpoints of the codegraph may be filled with a code word, otherwise a part of a code word would be another code word. The equation that guarantees this is

$$\sum_{k=1}^{K} M^{-l_k} \leq 1 \tag{1a}$$

where M is the number of symbols and l_k is the length of the kth code word. In (1a), the equality sign represents the most advantageous case without code redundancy. Otherwise, the factor c in the equation

$$c \sum_{k=1}^{K} M^{-l_k} = 1 \tag{1b}$$

is a measure of the code redundancy.

This decoding theorem is of great importance in measurement because codes with redundancy are often used, see Sections 6 and 7 of this article. The theorem of optimal coding plays a great role in redundancy-diminishing coding used in communication, giving an equation for the optimum length of the source code words l_k:

$$-\frac{\mathrm{lb}\, p_k}{\mathrm{lb} M} \leq l_k < -\frac{\mathrm{lb}\, p_k}{\mathrm{lb} M} + 1 \tag{1c}$$

where p_k is the probability of the appearance of the kth code word. Some important codes, including those applied in measurement, are now considered.

3 BINARY CODES USED IN MEASUREMENT

There are a lot of binary codes used in several fields of measurement. The data-transmission error-correcting codes are treated in Section 6 of this article.

The simplest code is the counting code, mostly seen in decimal counting. Today, this easily learnable code is displaced in machines that use the binary-coded decimal notation because of the smaller number of bits. As an example, in Figure 2, the 1-out-of-10 code is presented. For manual data coding (data input), a particular form of the binary code

$$\begin{aligned} Z_{\mathrm{bin}} &= A_n 2^n + A_{n-1} 2^{n-1} + \cdots + A_1 2^1 + A_0 2^0 \\ &= A_n A_{n-1} \cdots A_1 A_0 \end{aligned} \tag{2a}$$

the binary-coded decimal system or BCD code, is used. Here, digit-by-digit, the decimal number is converted into

99	1001	1001	1100	1100

the binary code. For each digit, four bits, the so-called tetrad, is necessary (Table 1).

In binary notation, the numbers complement necessary for subtraction in a computer, sometimes leads to a nonexistent code word. The complement of 3 (=0011), for instance, is 1100, which does not exist in the BCD code (Table 1). This disadvantage is avoided by use of the notation of the BCD code, also presented in Table 1. To each decimal number, 3 is added. This code is well known as the excess-three code or the Stiebitz code.

As an example, the conversion of the excess-three code to the binary code is now considered. With the relationships between x and y shown, Table 1 yields in Boolean algebra form

$$x_0 = \bar{y}_0 \tag{2b}$$

$$x_1 = (y_0 \times y_1) + (\bar{y}_0 \times y_1) \tag{2c}$$

$$x_2 = (\bar{y}_1 \times \bar{y}_2) + (\bar{y}_0 \times \bar{y}_2) + (y_0 \times y_1 \times y_2) \tag{2d}$$

$$x_3 = (y_2 \times y_3) + (y_0 \times y_1 \times y_3) \tag{2e}$$

where

$\times$ is the logical AND operation

$+$ is the logical OR operation

The realization of these logic equations leads to the digital logic circuit of Figure 3.

Of importance in measuring systems are the Gray code and the improved variation of this code, the Glixon code

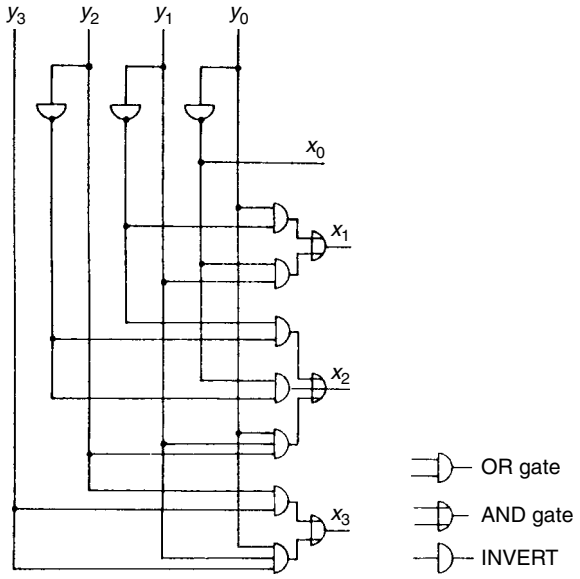

Figure 3. Circuit for conversion of the excess-three code to the binary code.

used especially with optical absolute encoders as described in the next section.

In data transmission, the ISO-CCIT code No. 5 or the teletype CCITT code No. 3 are used in combination with error-correcting codes as treated in Section 6.

4 ABSOLUTE OPTICAL ENCODERS AND CODES USED

There exist two types of encoders – the absolute and the incremental encoders (Carstens, 1993; Pallas-Areny and Webster, 2001). With the absolute encoders, each input has a unique output, while, with the incremental codes, only the difference between two inputs is given in the output (see also next section).

The principle of an optical encoder is seen in the digital shaft encoder demonstrated in Figure 4. It is used to transform the rotational angle directly into a computer recognizable signal. The same principle may be used with a linear encoding scale to transduce length. For them to work correctly, it must be emphasized that the sampling theorem has to be fulfilled in operation. Otherwise, aliasing errors occur, because normally it is not possible to realize the necessary low pass before sampling.

To minimize the errors when counting from one segment to the other, it is appropriate to have a code that differs only in one digit step from one segment to the next.

This group of codes is the reflected codes, arising by counting at first forward, that is, from 0 to 9, and then backward from 19 to 10. One of this group is the Gray code.

Table 2. Formation of the Gray code.

Decimal number	0	1	2	3	4	5	6	7
Binary number	000	001	010	011	100	101	110	111
Shifted binary number	000	001	010	011	100	101	110	111
Σ	0000	00011	0110	0101	1100	1111	1010	1001
Gray code	000	001	011	010	110	111	101	100

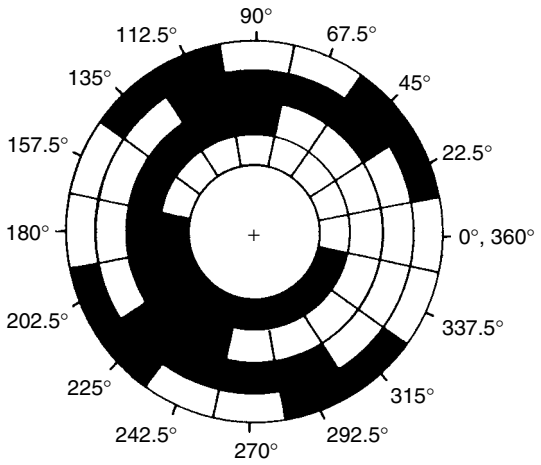

Figure 4. Coding disk (Gray code): code is read radially from outside inward.

Table 3. Glixon code.

Decimal number	Glixon code
0	0000
1	0001
2	0011
3	0010
4	0110
5	0111
6	0101
7	0100
8	1100
9	1000

It is obtained from the binary code as shown in Table 2. The advantage of this code is that any two code words following each other always have unit distance between them, that is, the two code words differ in one digit only. For this reason, this code is often used in measurement for encoding disks or linear encoding scales (Figure 4). The disadvantage of a distance greater than 1 occurring between 9 and 10 is avoided by using the improved Glixon code (Table 3).

5 INCREMENTAL ENCODERS AND LSB

Less expensive to make is the incremental encoder shown in Figure 5. Here, identical lines are counted as they pass

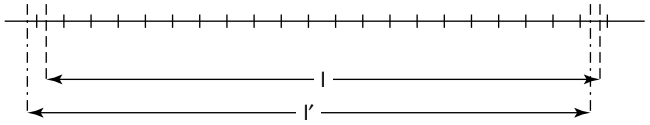

Figure 5. Incremental encoder for coding the length l.

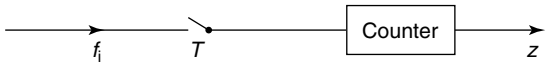

Figure 6. Measuring of frequency f or time T by counting z.

the detector. So counting is made relative to the datum of the starting position, but the starting datum itself is not known. If a count is lost or gained due to noise and so on, the output will be in error from that point on. These, however, have been made to be very reliable in application.

The same principle can be used either to code the length as shown in Figure 5 or the angle shown in Figure 4.

If a pulse frequency f_i is switched on at time T as shown in Figure 6, either the time or the frequency can be coded in the counter z. The relation to get z is

$$z = f_i T \tag{3a}$$

Because it is possible that one more line or pulse is counted as Figure 5 demonstrates – the so-called least significant bit (LSB), the relative error ε is (Woschni, 1988)

$$\varepsilon = \frac{1}{f_i T} \tag{3b}$$

More details are given in Carstens (1993) and in Pallas-Areny and Webster (2001).

6 ERROR CORRECTION BY REDUNDANT CODES

During data input, transmission, or processing procedures, errors may arise, as has already been mentioned in the design of the Gray code in the previous section. Error-detecting and error-correcting codes having additional code redundancy have been designed. The Hamming distance d_{min}, that is, the minimum distance between two code words

of an alphabet, has to be maintained (Peterson, 1962), for error-detecting codes with the degree f_d for errors to be detected,

$$d_{min} = f_d + 1 \tag{4a}$$

and for error-correcting codes, if f_c is the degree of error to be corrected

$$d_{min} = 2f_c + 1 \tag{4b}$$

If correction to the degree $f_c^* < f_c$ only is used, it is possible to detect additional errors up to degree f_d^*:

$$f_d^* = d_{min} - 2f_c^* - 1 \tag{4c}$$

Details concerning the Hamming distance as the procedure of error detection and error correction in the signal space are treated in **Article 32, Geometrical Signal Representations, Volume 1**.

A very simple, but often used method for data input, is the addition of parity bits or parity check. This additional bit is chosen in such a way that the sum of all digits (the so-called weight of the code) is either an even or an odd number. Table 4 presents the BCD code with parity check, detecting all errors with odd weight (1, 3, ...).

Other and more complicated error-detecting or error-correcting codes are the selector code (w-out-of-n code), the Hamming codes produced by feedback shift registers (Hamming, 1986), the recurrent or cyclic code (Peterson, 1962), and codes with block protection (Heise and Quattrocchi, 1995).

If the transmission is bidirectional, it is possible to correct wrong data blocks by means of retransmission (Sydenham, Hancock and Thorn, 1989). A typical example is given in the next section.

Table 4. BCD code with parity check.

First tetrad	Second tetrad	Parity check	Decimal number	Σ1
0000	0000	1	0	1
0000	0001	0	1	1
0000	0010	0	2	1
0000	0011	1	3	3
0000	0100	0	4	1
0000	0101	1	5	3
0000	1001	1	9	3
0001	0000	0	10	1
0001	0001	1	11	3
0010	0000	0	20	1
0101	0000	1	50	3
1001	1001	1	99	5

7 AN EXAMPLE OF ERROR CORRECTION CODE APPLICATION

As an example of error correction by redundant codes, a digital data transmission with a bit error rate (BER) of 10^{-2} is assumed: this corresponds to a normal telephone, hard wire line. The line should have a capacity of 2400 bps, a small value by modern speeds of communication.

We are first interested in the number of bit errors per year that arise in such a link. With 365 days, there will be 756 864 000 bit errors per year!

Now we ask what is the Hamming distance d_H necessary to get no more than one bit error in one year. If the bit error rate is to be 10^{-10}, there will still be 756 864 bit errors per year. The necessary bit error rate has to be 10^{-12} leading to 0.07564 bit errors in one year. From (4b) it follows that $f_c = 5$ a Hamming distance of $d_H = 2 \times 5 + 1 = 11$.

If the capacity of the line were to be 48 kbps, the bit error rate necessary would be 10^{-14} because the value 10^{-12} would lead to $20 \times 0.07564 = 1513$ bit errors per year. Now f_c has to be six, which means that due to (4b), the Hamming distance has to be 13. The realization of the necessary Hamming distance is made by means of checking digits in addition to the information digits (Peterson, 1962) and (Hamming, 1986).

1 SURVEY OF MODULATION METHODS

A special form of processing of a source signal to suit a transmission channel is that of modulation. Transmission of signals together from several sources all over a single channel can be accomplished using frequency-division or time-division multiplexing systems.

In measurement, the problem of transmitting the output signals of many sensors or transmitters over one line is often solved by means of the time-division multiplexing. This time-sharing method is shown in Figure 1. A switch sequentially connects the several input channels into the single output line. The length of the connection time gives the pulse interval t_p and the time between switching back to the same channel again is period t_o. Pulse modulation, with the interleaving of the different signals, is applied for parallel-to-serial conversion.

In general, a modulator may be interpreted as a controlled system with the carrier signal as one input and the modulation signal $x(t)$ as the control input (Figure 2). In the following text, a survey is first given of the several kinds of modulation.

In analog modulation methods (see Figure 3), one, or several, parameters of the sinusoidal oscillation $u(t)$, termed the *carrier oscillation* having a carrier frequency Ω_0 gives

$$u(t) = \widehat{U} \sin(\Omega_0 t + \phi) = \widehat{U} \sin\theta(t) \tag{1a}$$

Thus, the input signal is caused to vary by the modulation signal $x(t)$. If the amplitude $\widehat{U}$ is altered by the input signal $x(t)$, amplitude modulation (AM) results:

$$\widehat{U} = f(x(t)) \tag{1b}$$

Angle modulation is generated by using $x(t)$ to vary the argument of $u(t)$:

$$\phi(t) = f(x(t)) \tag{1c}$$

As $\theta = \Omega_0 t + \phi$, two kinds of angle modulation can be implemented.

Frequency modulation (FM) occurs when Ω_0 is varied as

$$\Omega(t) = f(x(t)) \tag{1d}$$

Phase modulation (PM) occurs when ϕ is varied as

$$\phi(t) = f(x(t)) \tag{1e}$$

Figure 2 shows the modulation methods mentioned above for a sinusoidal modulation signal with the modulation frequency ω:

$$x(t) = \widehat{X} \sin(\omega t) \tag{1f}$$

Pulse modulation methods use the principle of sampling – *see* **Article 31, Discrete Signal Theory, Volume 1**.

As shown in Figure 4, parameters of a regular pulse sequence are changed by the modulation signal $x(t)$ in one of several ways.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

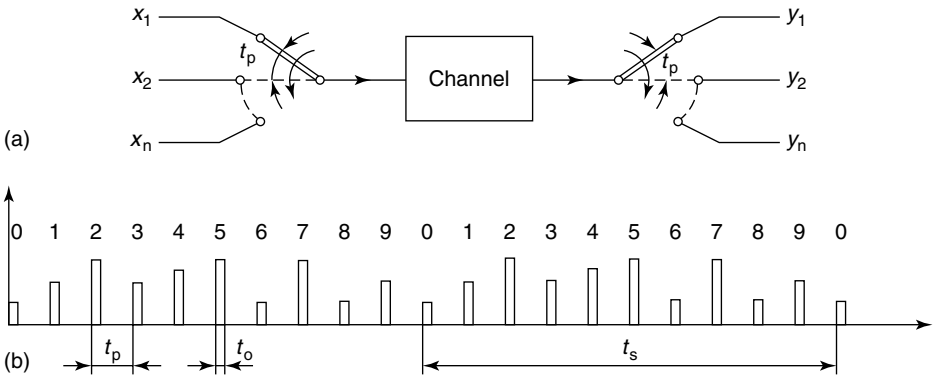

Figure 1. Time-division multiplexing: (a) system and (b) pulse frame (for 10 transmitters).

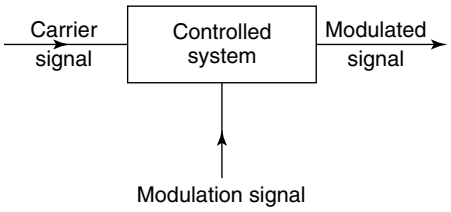

Figure 2. Generalized modulation system.

Variation of the pulse amplitude provides pulse-amplitude modulation (PAM), while with the pulse-duration or pulse-width modulation, the lengths of the pulses correspond to the modulation signal.

A pulse modulation method of great importance, especially in communication because of its good signal-to-noise ratio, is the pulse-code modulation (PCM) (Figure 5).

In the usual case, a pulse-amplitude modulation signal is first generated, which is then converted to a coded pulse sequence using one of the codes of **Article 33, Coding Theory and its Application to Measurement, Volume 1**.

2 AMPLITUDE MODULATION

We now deal with some details of the bandwidth needed and application in measurement.

A sinusoidal modulation signal

$$x(t) = \widehat{X} \sin(\omega t + \varphi) \tag{2a}$$

operating on a carrier $\widehat{U}_0 \sin(\Omega_0 t)$ yields the amplitude-modulated oscillation

$$u(t) = \widehat{U}_0[1 + m \sin(\omega t + \varphi)] \sin(\Omega_0 t) \tag{2b}$$

where the modulation depth is $m = k\widehat{X}$. Representation of (2b) in the frequency domain is (Woschni, 1988;

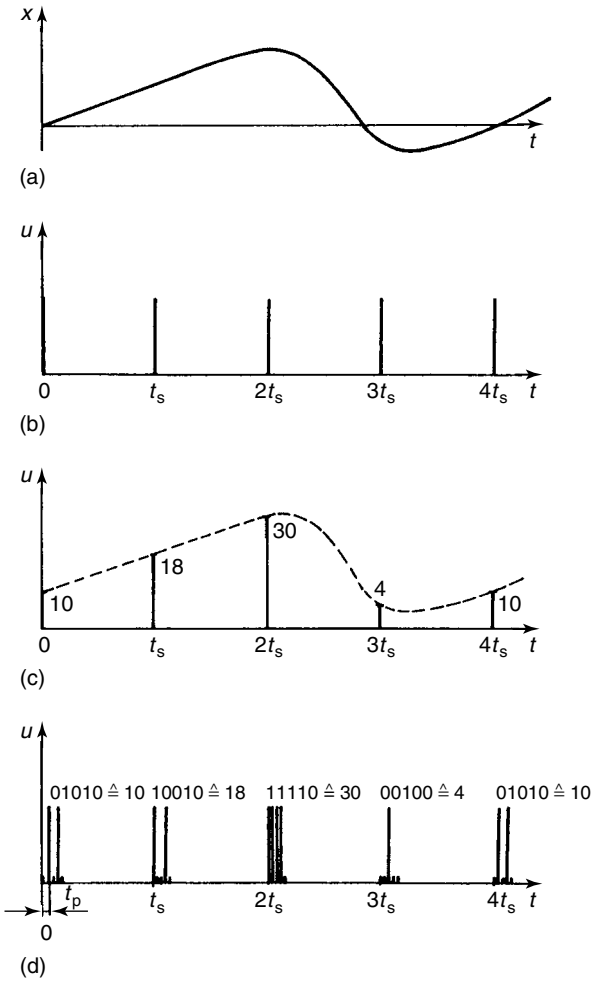

Figure 5. Pulse-code modulation: (a) modulation signal; (b) carrier pulse sequence; (c) pulse-amplitude modulation and (d) pulse-code modulation (binary code).

Wozencraft and Jacobs, 1965)

$$u(t) = \widehat{U}_0 \left\{ \sin(\Omega_0 t) \pm \tfrac{1}{2} m \cos[(\Omega_0 \mp \omega)t \mp \varphi] \right\} \qquad (2c)$$

showing that the resultant is a signal with the carrier frequency and two side frequencies (Figure 6a). The composition of the several spectral frequencies provides the time function, as shown in Figure 6b.

In the general case of an input signal with bandwidth $\omega_1 - \omega_c$ to be modulated, the bandwidth needed by the transmission link is

$$b = 2\,\omega_c \qquad (2d)$$

around the carrier frequency Ω_0. An amplifier, therefore, has to have at least this bandwidth otherwise distortion of the original form of the modulated signal will arise in the later recovered signal (Woschni, 1988).

In measurement, amplitude modulation results at the output of an AC bridge – *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**, operating with inductive sensors, as presented in Figure 7. To obtain satisfactory dynamic behavior, the condition between the limiting frequency of the measured input ω_c and the carrier frequency Ω_0 needs to be

$$\Omega_0 \geq 5\,\omega_c \qquad (2e)$$

If this condition is not met, it will not be possible to correctly demodulate the amplitude-modulated oscillation.

The condition given by (2e) is very important, for it is the key to avoiding errors in dynamic measurements as shown in detail in **Article 50, Errors in Signal Systems, Volume 1**.

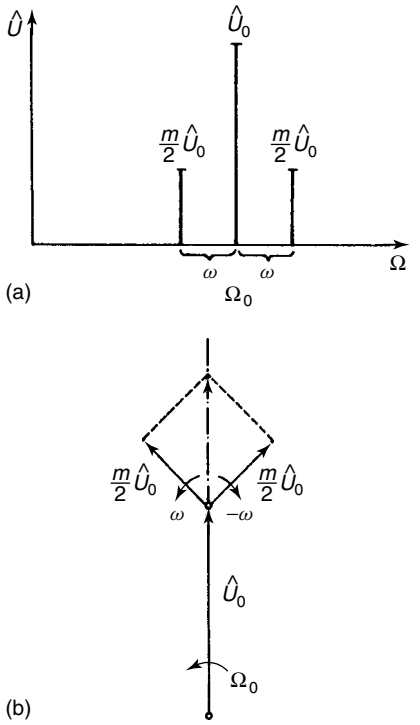

Figure 6. (a) Frequency spectrum of sinusoidal amplitude modulation and (b) phasor representation.

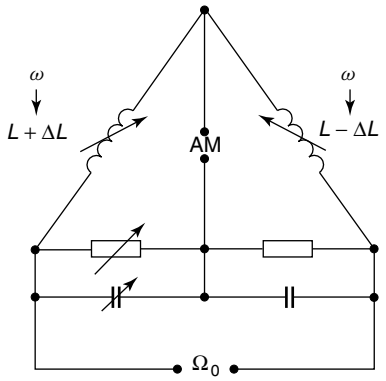

Figure 7. Bridge circuit, delivering an amplitude modulation.

3 FREQUENCY OR PHASE MODULATION

For the operation of capacitive sensors having high sensitivity, and in certain cases for inductive sensors, frequency modulation is used (Figure 8). For sinusoidal variation of the capacitance of the sensor

$$C = C_0 + \Delta C = C_0 \left(1 + \frac{\Delta C}{C_0} \sin(\omega t)\right) \tag{3a}$$

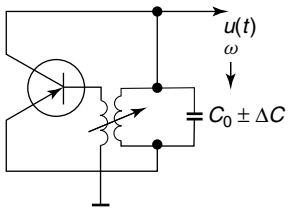

Figure 8. Circuit for the operation of a capacitive sensor to provide frequency-modulated output.

the variation of the natural frequency $\Omega = 1/\sqrt{(LC)}$ is given by (Woschni, 1962)

$$\Omega = \Omega_0 + \Delta\Omega \sin(\omega t) = \frac{1}{\sqrt{(LC_0)}} \left[1 - \frac{\Delta C}{2C_0} \sin(\omega t) + \frac{3}{8} \left(\frac{\Delta C}{C_0}\right)^2 \sin^2(\omega t) - \cdots\right] \tag{3b}$$

Because of the nonlinear characteristic differential capacitance, sensing methods are often used.

The time function yields

$$u(t) = \widehat{U}_0 \sin\left(\int [\Omega_0 + \Delta\Omega \sin(\omega t)]\, \mathrm{d}t\right) = \widehat{U}_0 \sin\left(\Omega_0 t - \frac{\Delta\Omega}{\omega} \cos(\omega t)\right) \tag{4a}$$

The corresponding function for sinusoidal phase modulation is given by

$$u(t) = \widehat{U}_0 \sin[\Omega_0 t + \Delta\phi \sin(\omega t)] \tag{4b}$$

A comparison between both equations shows that

$$\Delta\phi = \frac{\Delta\Omega}{\omega} \tag{4c}$$

Table 1. Relations between frequency and phase modulation.

	Frequency modulation	Phase modulation
Frequency deviation	$\Delta\Omega$	$\Delta\Omega = \Delta\Phi\omega$
Phase deviation	$\Delta\Phi = \dfrac{\Delta\Omega}{\omega}$	$\Delta\Phi$

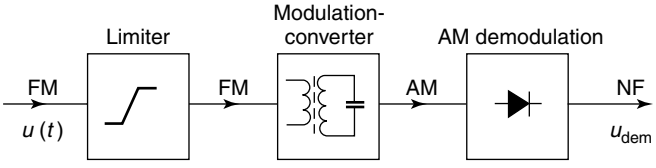

Figure 9. Principle of demodulation of frequency modulation.

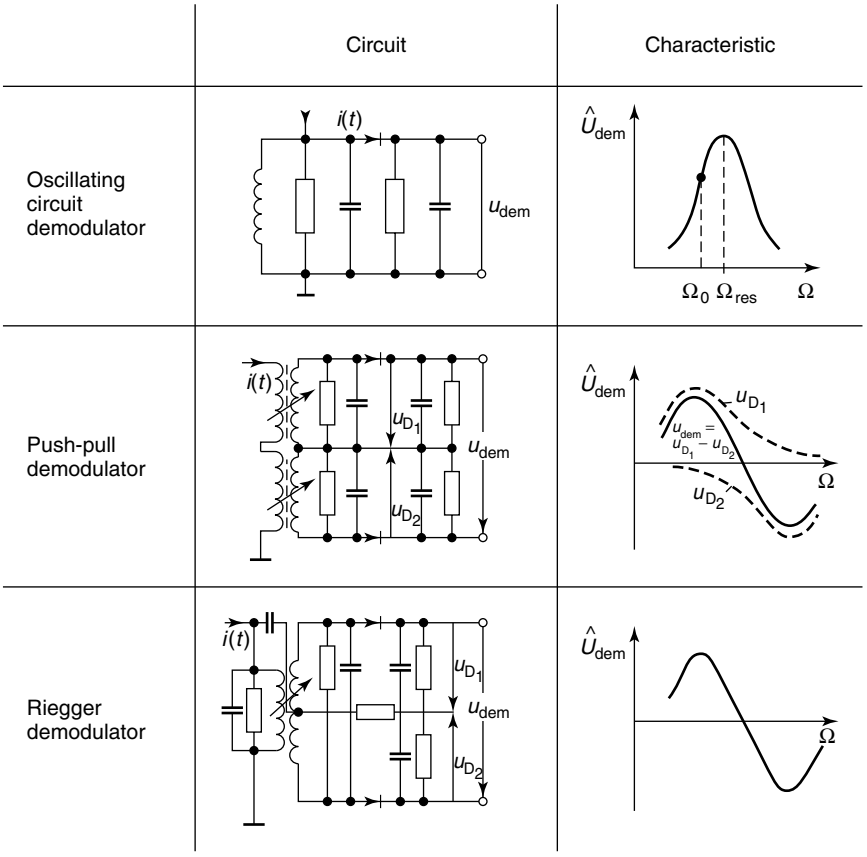

Figure 10. Circuits for realizing FM demodulation.

represents the equivalent phase deviation called the *modulation index*. Therefore, the relationships contained in Table 1, between frequency and phase modulation, are valid (Woschni, 1962). The spectrum of a frequency or phase-modulated signal is derived by means of a series expansion of Bessel functions (Woschni, 1962), leading to a bandwidth necessary for distortion-free transmission given by

$$b \cong 2[\Delta\Omega + k\omega] \tag{4d}$$

with $1 < k < 2$.

The demodulation of a frequency-modulated oscillation is realized as demonstrated in Figure 9. A limiting stage is followed by a modulation converter that converts the frequency modulation into an amplitude modulation, which is rectified by means of a diode.

Some example circuits for FM demodulation are shown in Figure 10 (Woschni, 1962). See also Webster (1999) or Wilson (1996).

1 CLASSIFICATION OF TECHNICAL SYSTEMS

According to Figure 1, a system can be interpreted as a black box with a family of input variables x_r, which can be regarded as a signal vector **x**, and a family of corresponding output variables y_r, forming a vector **y**. The interior of the black box may consist of several elements being either of electrical, hydraulic, pneumatic, or other energy forms.

The overall behavior of these systems is given by a common mathematical equation of the general form:

$$\mathbf{y} = \mathbf{O}\{\mathbf{x}\} \tag{1}$$

Different systems may have the same overall behavior so this means they follow the relationship of (1). This shows that it is possible for a system to be substituted by another one having the same mathematical equation, for example, by a computer of either analog, or today more likely digital form (an aspect of modeling).

Because of the convenience afforded by a computer to study the behavior of a given system, the role of programming modeling methods plays an important part in the field of cybernetics. Measurement as a part of cybernetics – the general science of feedback – can be comprehended as a mapping of the input signals onto the space of the output signals (Finkelstein, 1977).

Technical systems are characterized as those with active or only passive elements (so-called active or passive systems) or they are described by the number of ports (two-port, three-port, etc.) – *see also* **Article 73, Overview of Electrical and Electronic Technique, Volume 2**.

Table 1 gives a survey of the classification of technical systems. With respect to the difficulties in the treatment of a system, it is of great importance to know whether the system is linear or not, because in the linear case the superposition law is valid. In this article, it is assumed the system is a linear one. Methods of linearization are treated in Section 4.

Another typical characteristic of a system is whether the parameters describing the behavior are functions of time or not. Furthermore, most of the systems used in cybernetics are so-called unidirectional systems, meaning that the parameters of the system are independent of those of the following system. We will only deal with systems that fulfill this assumption. Otherwise, the results of the four-pole theory must be applied (Feldtkeller, 1962).

As an example of practical importance in the field of measurement, the spring–mass–damper system, as illustrated in Figure 2, will be considered. This system makeup is used in numerous sensors, for, among others, in the measurement of length or force. If force F is the input variable

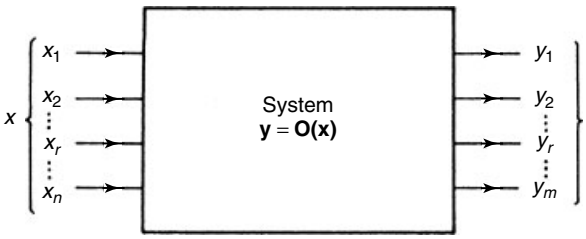

Figure 1. Definition of a system.

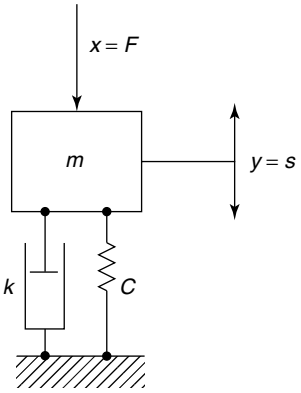

Figure 2. Spring–mass–damper system.

x, and length s is the output variable y, the following special equation corresponding to the general relation (1) is obtained:

$$m\ddot{y} + k\dot{y} + cy = x \tag{2}$$

This second-order differential equation describes the system's dynamic behavior. For more depth of explanation *see* **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**; **Article 60, Zero-order System Dynamics, Volume 1**; **Article 61, First-order System Dynamics, Volume 1**; and **Article 62, Second-order System Dynamics, Volume 1**.

2 MODELING BY MEANS OF ANALOGIES

As mentioned before, systems with different interior elements or forms of energy can have the same mathematical relationship between output and input variables. From this fact it follows that a given system can be represented by some other system having the same overall behavior. This modeling opportunity has the advantage that with response investigations of a given system its model system can have the parameters and structures changed by simply programming a computer. Furthermore, it is possible to observe the input and output quantities in a convenient way by means of oscilloscopes, computer displays, or plotters and to change the scale of coordinates or time axes to suit the needs of the investigation. Important methods of modeling are the analogies, application of block diagram representation, and linearization.

Of importance is the fact that mechanical systems, in the same way as pneumatic, hydraulic, and other systems, can be presented by electrical systems, as shown in Figure 3. In the cases illustrated in this arrangement, the following equations are valid:

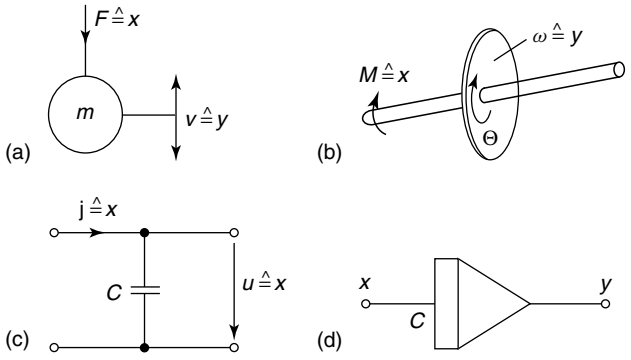

Figure 3. Examples of mechanical and electrical systems: (a) translation, (b) rotation, (c) capacity and (d) computer format.

Table 1. Classification of technical systems.

System	Linear system	Nonlinear system
Mark	Parameters are constant, independent of amplitude Superposition law is valid	Parameters are a function of amplitude Superposition law is not valid
Parameters are time invariant	Examples: most measurement systems with small input levels: amplifiers; filters; transducers	Examples: systems with large input levels: output amplifiers, driver stages; Often linearization is possible
Parameters are functions of time	Examples: controlled amplifiers with multiplicative properties and small input levels: modulators, frequency multipliers, parametric amplifiers	Examples: controlled amplifiers with multiplicative properties and large input levels: modulators, frequency modulators, frequency multipliers

1. In the mechanical example (mass m, velocity v, force F)

$$v = \frac{1}{m}\int F\,\mathrm{d}t \tag{3a}$$

2. In the case of rotary motion (moment of inertia Θ, angular velocity ω, torque M)

$$\omega = \frac{1}{\Theta}\int M\,\mathrm{d}t \tag{3b}$$

3. In the electrical system (voltage u, capacitance C, current i)

$$u = \frac{1}{C}\int i\,\mathrm{d}t \tag{3c}$$

4. In the general case of an analog computer, or more likely today, the digital computer (constant c)

$$y = c\int x\,\mathrm{d}t \tag{3d}$$

Generalizing the dependencies illustrated in Figure 3 realizes the survey of analogies between electrical and mechanical systems shown in Table 2. For the spring–mass–damper system with differential (2) and the representation of Figure 2, the electrical models shown in Figure 4 are obtained. Direct analogy (see Table 2) yields the parallel circuit Figure 4(a) with the equation

$$C\frac{\mathrm{d}u}{\mathrm{d}t} + \frac{1}{R}u + \frac{1}{L}\int u\,\mathrm{d}t = i \tag{4a}$$

while use of indirect analogy provides the series circuit given in Figure 4(b):

$$\frac{1}{C}\int i\,\mathrm{d}t + Ri + L\frac{\mathrm{d}i}{\mathrm{d}t} = u \tag{4b}$$

As can be seen from a comparison of Figures 2 and 4, the indirect analogy is more convenient in this instance because

Table 2. Survey of electromechanical analogies.

Electrical system	Mechanical system			
	Translation		Rotation	
	Direct	Indirect	Direct	Indirect
i	F	v	M	ω
u	v	F	ω	M
R	$\frac{1}{k}$	k	$\frac{1}{k}$	k
C	m	$\frac{1}{m}$	θ	$\frac{1}{\theta}$
L	$\frac{1}{C}$	C	$\frac{1}{C}$	C

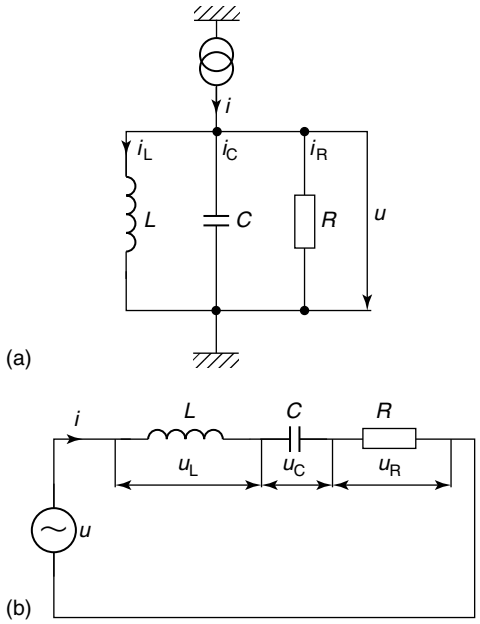

Figure 4. Electrical model of the spring–mass–damper system of Figure 2 (a) parallel circuit and (b) series circuit.

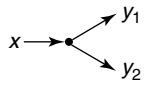
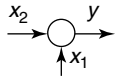
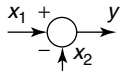
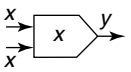
a mechanical parallel circuit is modeled as an electrical parallel circuit.









Similar analogies exist between acoustic, hydraulic, and pneumatic systems and to a limited extent to optical systems. Their theory, first ordered in Olson (1943), is paramount in the design and testing of measuring systems. For details, refer to Koenig and Blackwell (1961) and Shearer, Kulakowski and Gardner (1997). The analogies are also the foundation of modern disciplines as mechatronics and micromechanics. Another example is the surface-acoustic wave (SAW) filters.

3 BLOCK DIAGRAMS

Measurement systems are built up from particular combinations of subsystems. Therefore, it is suitable to represent each subsystem by its own block including a symbol indicating the operation the subsystem has to realize. Table 3 contains some of these symbols and signs used for the demonstration of the interconnections between the systems. (It must be pointed out that many standards for such are in use.) It is therefore assumed that the systems are unidirectional and thus it is possible to describe the behavior of such a system by means of an interconnection between several unidirectional systems. Figure 5 illustrates three typical methods of interconnection of systems. The output–input relation of a system is given by the equation

$$y = Gx \tag{5}$$

Table 3. Symbols for block diagrams.

Function	Branch	Summation	Subtraction	Sign inversion	General system
Symbol					
Equation	$y_1 = y_2 = x$	$y = x_1 + x_2$	$y = x_1 - x_2$	$y = -x$	$y = f(x, t)$
Function	Constant factor	Integrator	Nonlinear system	Root calculation	Multiplier
Symbol					
Equation	$y = kx$	$y = \int x\,dt$	$y = f(x)$	$y = \sqrt[n]{x}$	$y = x_1 x_2$

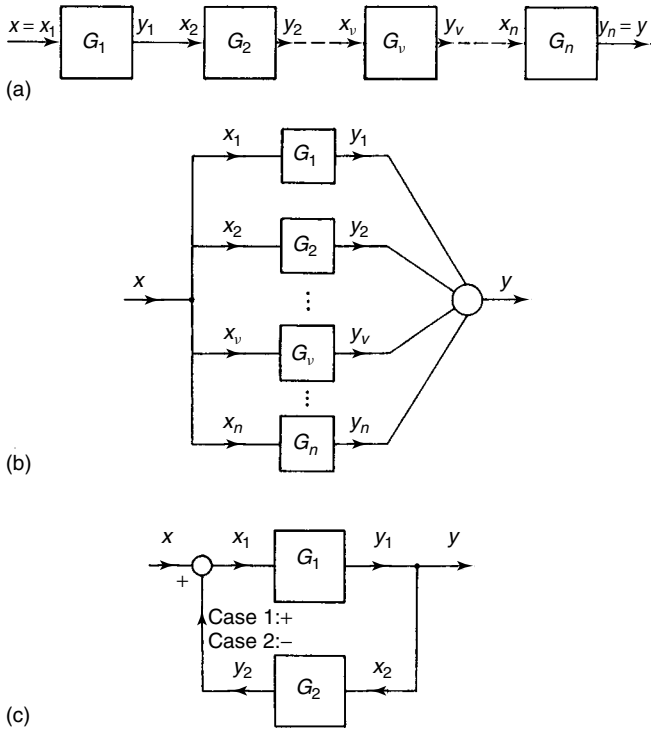


Figure 5. Typical system connections: (a) series circuit, (b) parallel circuit and (c) connection in opposition.

The frequency response G_e for an equivalent system having the same overall behavior as that of the interconnection of the subsystems shown is given by the following:

1. Series circuit (Figure 5a)

$$G_e = \prod_{r=1}^{n} G_r \tag{6a}$$

2. Parallel circuit (Figure 5b)

$$G_e = \sum_{r=1}^{n} G_r \tag{6b}$$

3. In opposition (Figure 5c)

$$G_e = \begin{cases} \dfrac{G_1}{1 - G_1 G_2} & \text{feedforward, oscillator} \quad (6c) \\ \dfrac{G_1}{1 + G_1 G_2} & \text{negative feedback, control} \quad (6d) \end{cases}$$

The product $G_1 G_2$ in (6c, d) describes the frequency response of the open control loop (Levine, 1996; Woschni, 1988).

4 LINEARIZATION

Linear systems are distinguished by the validity of the superposition law. Nonlinear systems are not easily modeled with linear equations and to get round this difficulty a nonlinear system is often linearized in small steps that collectively model the whole excursion region. This enables the advantages of linear systems to be used. The following preliminary conditions must be fulfilled in such a strategy:

1. Only small deviations of the characteristics from the linear path can be used.
2. Only a relatively small drive range of the nonlinear characteristic can be tolerated.

For the linearization, the Taylor series expansion of the nonlinear characteristic $y = f(x)$ at the working point $y_0 = f(x_0)$ is employed. Writing only the deviations from the working point $\Delta x, \Delta y$ yields

$$y - y_0 = \Delta y = \left.\frac{\partial f}{\partial x}\right|_{x_0} \Delta x + \frac{1}{2} \left.\frac{\partial^2 f}{\partial x^2}\right|_{x_0} \Delta x^2 + \frac{1}{6} \left.\frac{\partial^3 f}{\partial x^3}\right|_{x_0} \Delta x^3 + \cdots \tag{7a}$$

In practical measurement technique, the input variable is often the sinusoidal function $x = \hat{X} \sin(\omega t)$.

The proportion of the dominant wave with frequency ω at the output $\widehat{Y}_\omega$, expressed as a ratio with the amplitude of the input $\widehat{X}$, gives

$$\frac{\widehat{Y}_\omega}{\widehat{X}} = \left.\frac{\partial f}{\partial x}\right|_{x_0} \left(1 + \frac{1}{8}\frac{\partial^3 \dfrac{f}{\partial x^3}|_{x_0}}{\partial \dfrac{f}{\partial x}|_{x_0}} \widehat{X}^2\right) \tag{7b}$$

This function is the describing function; it expresses the frequency response of a nonlinear system. Depending on the sign of the third-order differential coefficient, the describing function either increases or decreases with the square of the amplitude of the input as Figure 6 shows. In practice, the case $\partial^3 f/\partial x^3|_{x_0} > 0$ can be troublesome because the amplification factor is increasing with increasing amplitude leading to an unstable oscillating regime (Woschni, 1988; Levine, 1996).

Important in the field of measurement is the rectification effect using a square-wave characteristic created as a rectifier unit that switches between on and off without any state between.

$$\Delta y_0 = \frac{1}{4}\left.\frac{\partial^2 f}{\partial x^2}\right|_{x_0} \widehat{X}^2 \tag{7c}$$

In this case, distortion appears that is described by the distortion factors

$$k_2 = \frac{\widehat{Y}_{2\,\omega}}{\widehat{Y}_\omega} = \frac{1}{4}\left(\frac{\partial^2 \dfrac{f}{\partial x^2}|_{x_0}}{\partial \dfrac{f}{\partial x}|_{x_0}}\right)\widehat{X}, \tag{7d}$$

$$k_3 = \frac{\widehat{Y}_{3\,\omega}}{\widehat{Y}_\omega} = \frac{1}{24}\left(\frac{\partial^3 \dfrac{f}{\partial x^3}|_{x_0}}{\partial \dfrac{f}{\partial x}|_{x_0}}\right)\widehat{X}^2 \tag{7e}$$

5 DESCRIPTION WITH DIFFERENTIAL EQUATIONS

The oldest classical method used in solving problems of system analysis is the method of differential equations. A linear system is described by a linear differential equation of the following form:

$$a'_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_r y^{(r)} + \cdots + a_2 \ddot{y} + a_1 \dot{y} + a_0 y = b_0 x + b_1 \dot{x} + \cdots + b_m x^{(m)} \tag{8a}$$

This equation may be written as

$$T_n^n y^{(n)} + T_{n-1}^{n-1} y^{(n-1)} + \cdots + T_r^r y^{(r)} + \cdots + T_2^2 \ddot{y} + T_1 \dot{y} + y = G_0 x + \frac{b_1}{a_0}\dot{x} + \cdots + \frac{b_m}{a_0} x^{(m)} \tag{8b}$$

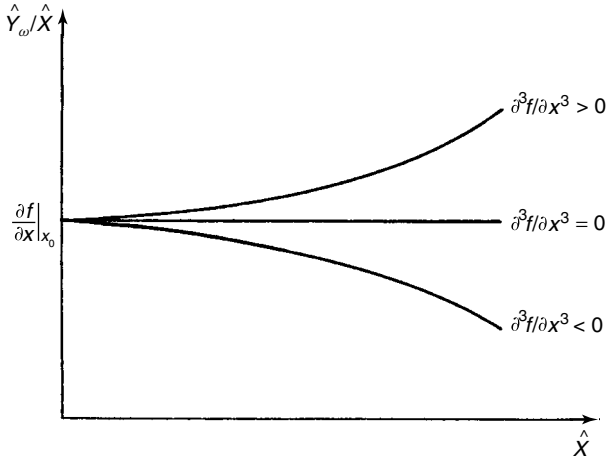

Figure 6. Ratio of the amplitude of the dominant wave of the output Y_ω to the amplitude of the input X (describing function).

where G_0 is the static sensitivity:

$$G_0 = \frac{b_0}{a_0} = \frac{\Delta y}{\Delta x} \tag{8c}$$

G_0 can be measured as an amplification factor by means of a small alteration Δx as stated in (8c). The coefficients

$$T_r = \sqrt[r]{\left(\frac{a_r}{a_0}\right)} \tag{8d}$$

are time constants. For a differential equation of nth order, n time constants are defined, the greatest of which is used to estimate the duration of the transient function. The solution of the differential equation consists of two additive components, a stationary and a dynamic portion:

$$y(t) = y_{\text{st}} + y_{\text{d}}(t) \tag{9a}$$

To solve the homogeneous differential equation leading to the dynamic portion $y_{\text{d}}(t)$, the assumption

$$y_{\text{d}} = C\,\mathrm{e}^{pt} \tag{9b}$$

is used. The zero points of the characteristic equation

$$T_n^n p^n + T_{n-1}^{n-1} p^{p-1} + \cdots + T_2^2 p^2 + T_1 p + 1 = 0 \tag{9c}$$

signify whether the solution is stable or not. In particular, these so-called eigenvalues p_r prove that

1. if the real part is less than zero, that is, $\text{Re}(p_r) < 0$, a stable solution exists;
2. if the real part is greater than zero, that is, $\text{Re}(p_r) > 0$, an unstable solution exists;
3. if the eigenvalues are complex, oscillations with decreasing or increasing amplitudes exist.

With the eigenvalues p_r, the dynamic solution yields (Coddington and Levinson, 1955)

$$y_{\mathrm{d}} = \sum_{r=1}^{n} C_r \exp(p_r t) \tag{9d}$$

If a double root p_0 arises

$$y_{\mathrm{d}} = (C_1 + C_2 t)\exp(p_0 t) \tag{9e}$$

The stationary solution y_{st} is to be found by means of suitable terms satisfying the inhomogeneous differential (8b).

As may be seen from (9d), the eigenvalue p_r corresponds to a time constant $T_r = 1/p_r$, the greatest value of which ($T_{\max}$) is responsible for the duration of the transient process. Because $\mathrm{e}^{-3} = 1/20 = 5\%$ the transient process approximately continues and

$$t_{\mathrm{tr}} = 3T_{\max} \tag{9f}$$

where t_{tr} is the transient time.

6 SIMPLE HARMONIC MOTION

In practice, the special case of a sinusoidal input signal $x(t)$ is very important

$$x(t) = \widehat{X}\mathrm{e}^{\mathrm{j}\omega t} \tag{10a}$$

This test signal is used to gain the frequency response, *see* **Article 36, Systems in the Frequency Domain, Volume 1**. In the steady state regime, which means after a time longer than the transient time since the signal $x(t)$ started, the output signal $y(t)$ will also be a sinusoidal signal but with another amplitude $\widehat{Y}$ and a phase φ

$$y(t) = \widehat{Y}\mathrm{e}^{\mathrm{j}(\omega t+\varphi)} \tag{10b}$$

We use these functions x, y as a statement in the original differential (8b) taking into account that every differentiation means a multiplication with $\mathrm{j}\omega$

$$\begin{aligned}&[T_n^n(\mathrm{j}\omega)^n\widehat{Y}\mathrm{e}^{\mathrm{j}\varphi} + \cdots + T_1\mathrm{j}\omega\widehat{Y}\mathrm{e}^{\mathrm{j}\varphi} + \widehat{Y}\mathrm{e}^{\mathrm{j}\varphi}]\mathrm{e}^{\mathrm{j}\omega t}\\ &= \left[G_0\widehat{X} + \frac{b_1}{a_0}\mathrm{j}\omega\widehat{X} + \cdots + \frac{b_m}{a_0}(\mathrm{j}\omega)^m\widehat{X}\right]\mathrm{e}^{\mathrm{j}\omega t}\end{aligned} \tag{10c}$$

Reducing this equation to the output/input relation, we get the frequency response that is treated in **Article 36, Systems in the Frequency Domain, Volume 1** in detail

$$G(\mathrm{j}\omega) = \frac{\widehat{Y}\mathrm{e}^{\mathrm{j}\varphi}}{\widehat{X}} = \frac{G_0 + \mathrm{j}\omega\dfrac{b_1}{a_0} + \cdots + (\mathrm{j}\omega)^m\dfrac{b_m}{a_0}}{1 + \mathrm{j}\omega T_1 + \cdots + (\mathrm{j}\omega)^n T_n^n} \tag{10d}$$

It may be noted that (10c) is the Fourier transform of the differential (8b) under the supposition of vanishing initial conditions, which means $x(t)_{t=0} = 0$ and so on.

The same is valid under the same suppositions with respect to the Laplace transform, which means $\mathrm{j}\omega \to \mathrm{p}$

$$\begin{aligned}&T_n^n s^n Y(s) + \cdots + T_1 s Y(s)\\ &G_0 X(s) + \frac{b_1}{a_0} s X(s) + \cdots + \frac{b_m}{a_0} s^m X(s)\end{aligned} \tag{10e}$$

leading to the transfer function, *see* **Article 36, Systems in the Frequency Domain, Volume 1**

$$G(s) = \frac{Y(s)}{X(s)} = \frac{G_0 + \dfrac{b_1}{a_0}s + \cdots + \dfrac{b_m}{a_0}s^m}{1 + T_1 s + \cdots + T_n^n s^n} \tag{10f}$$

7 STATE SPACE DESCRIPTION

The basis of the state space description is the classical differential equation discussed above or, in the case of sampled-data systems, the difference equation. The state of a system is described by a set of state variables y_r. The number of these state variables agrees with the degree of the differential equation or in the case of sampled-data systems with the degree of delay. Today, the method is of significant importance because of its suitability for computer simulation of systems.

The nth-order differential equation for such systems

$$T_n^n y^n + T_{n-1}^{n-1} y^{n-1} + \cdots + \dot{y} + y = x \tag{11a}$$

can be transformed into a system of n differential equations of first order:

$$\begin{aligned}y &= y_1\\ \dot{y} &= y_2 = \dot{y}_1\\ \ddot{y} &= y_3 = \dot{y}_2\\ &\vdots\\ y^{(n-1)} &= y_n = \dot{y}_{n-1}\\ y_n &= -\frac{1}{T_n^n}y_1 - \frac{T_1}{T_n^n}y_2 - \frac{T_2^2}{T_n^n}y_3 - \cdots - \frac{T_{n-1}^{n-1}}{T_n^n}y_n\\ &\quad + \frac{1}{T_n^n}x\end{aligned} \tag{11b}$$

This system of equations can be written in the form of a vector differential equation (Zadeh and Desoer, 1963;

Levine, 1996)

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_n \end{bmatrix} = \begin{bmatrix} \dot{y}_1 \\ \dot{y}_2 \\ \dot{y}_3 \\ \vdots \\ \dot{y}_n \end{bmatrix}$$

$$= \begin{bmatrix} 0 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \cdots & \vdots \\ -\dfrac{1}{T_n^n} & -\dfrac{T_1}{T_n^n} & -\dfrac{T_2^2}{T_n^n} & -\dfrac{T_3^3}{T_n^n} & \cdots & -\dfrac{T_{n-1}^{n-1}}{T_n^n} \end{bmatrix}$$

$$\times \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_n \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ \dfrac{1}{T_n^n} \end{bmatrix} x \tag{11c}$$

or with the variables **y, T, b**, and **x**:

$$\dot{\mathbf{y}} = \mathbf{T}\mathbf{y} + \mathbf{b}\mathbf{x} \tag{11d}$$

For sampled-data systems (Woschni, 1988; Levine, 1996), the difference equation is

$$\sum_{\mu=0}^{n} a_\mu y(k+\mu) = \sum_{r=0}^{m} b_r x(k+r) \tag{12a}$$

Defining a delay element as

$$D\{y(k)\} = y(k-1) \tag{12b}$$

We obtain also a system of n difference equations of first order

$$Z_\mu(k) = D\Big\{ -a_{(n-\mu)} Z_\mu(k) + Z_{(\mu-1)}(k) + (b_{(n-\mu)} - b_n a_{(n-\mu)}(k)\Big\} \tag{12c}$$

$$Y(k) = Z_1(k) + b_n(k) \tag{12d}$$

This system of equations can be written in matrix form

$$Z(k+1) = \boldsymbol{A} Z(h) + \boldsymbol{B} x(k); \tag{12e}$$

$$Y_k = \boldsymbol{C} z(k) + \boldsymbol{D} x(k) \tag{12f}$$

With the matrices

$$\boldsymbol{A} = \begin{bmatrix} -a_{(n-1)} & 1 & 0 & \ldots 0 \\ -a_{(n-2)} & 0 & 1 & \cdots 0 \\ \vdots & \vdots & \vdots & \vdots \; 1 \\ -a_0 & 0 & 0 & \ldots 0 \end{bmatrix} \tag{12g}$$

$$\boldsymbol{B} = \begin{bmatrix} b_{(k-1)} & \cdots & -b_n a_{(n-1)} \\ b_{(k-2)} & \cdots & -b_n a_{(n-2)} \\ \vdots & \cdots & \vdots \\ b_0 & \cdots & b_n a_0 \end{bmatrix} \tag{12h}$$

$$\boldsymbol{C} = [1, 0 \ldots 0] \tag{12i}$$

$$\boldsymbol{D} = b_n \tag{12j}$$

Consider as an example the spring–mass–damper system of Figure 2 with the differential equation

$$m\ddot{y} + k\dot{y} + cy = x \tag{13a}$$

The vector equation is given by

$$\begin{bmatrix} \dot{y}_1 \\ \dot{y}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\dfrac{c}{m} & -\dfrac{k}{m} \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} + \begin{bmatrix} 0 \\ \dfrac{1}{m} \end{bmatrix} x \tag{13b}$$

The state variables are the displacement $y = y_1$ of the mass and the velocity $\dot{y} = y_2$.

8 FLOWCHARTING

Let us start with the simple example of the spring–mass–damper system of Figure 2 and (13a, b).

Figures 7 and 8 respectively show the programming of a computer for modeling this system. The relationships between programming and state space description are easy

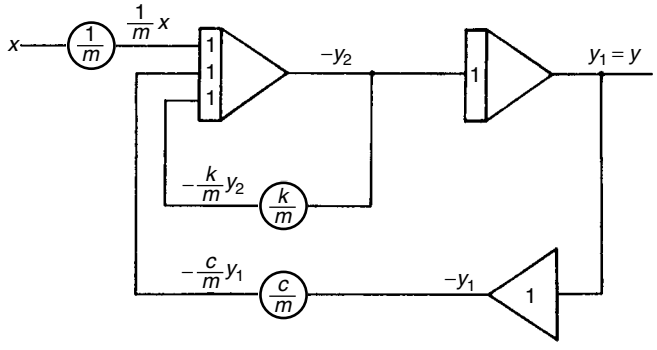

Figure 7. Direct programming of a spring–mass–damper system on a computer.

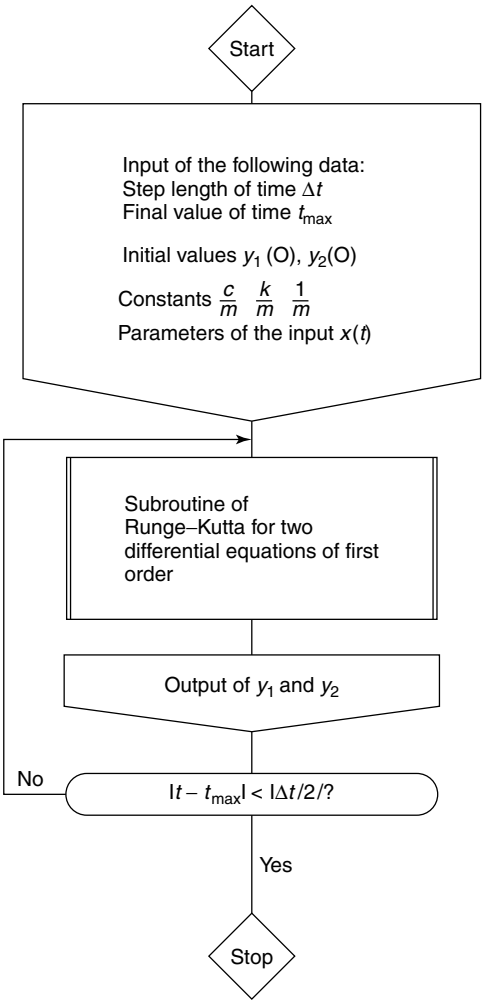

Figure 8. Flowchart for the programming of a spring–mass–damper system on a digital computer.

to recognize, especially due to the equation

$$\dot{z}_2 = \frac{c}{m} z_1 - \frac{k}{m} z_2 + \frac{1}{m} x \qquad (13c)$$

In Figure 9, the path of the five state variables displacement $y = z_1$ and velocity $y' = z_2$ are shown both as a function of time as well as in the state space.

In Figure 10, the programming of a system of nth order is shown as described with the differential (11a) and the state (11c). Here, in the flowchart shown in Figure 8, the subroutine of Runge–Kutta is used to realize n differential equations of first order.

Programming for a sampled-data system, as given by (8c, d) or (8e, f), is presented in Figure 11.

For system description and identification, certain response output functions for test signals at the input are generally used. These are presented here as time-dependent functions but they can be used with any general variable x, spatial distribution being the one used in optical systems.

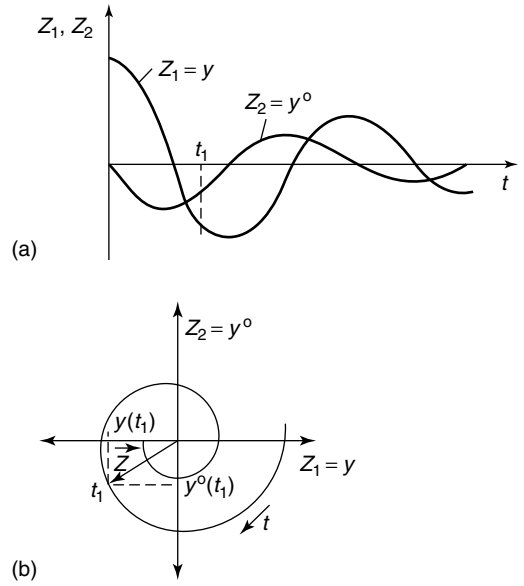

Figure 9. Displacement $y = Z_1$ and velocity $y' = Z_2$ for the spring–mass–damper system (a) as a function of time and (b) in the state space.

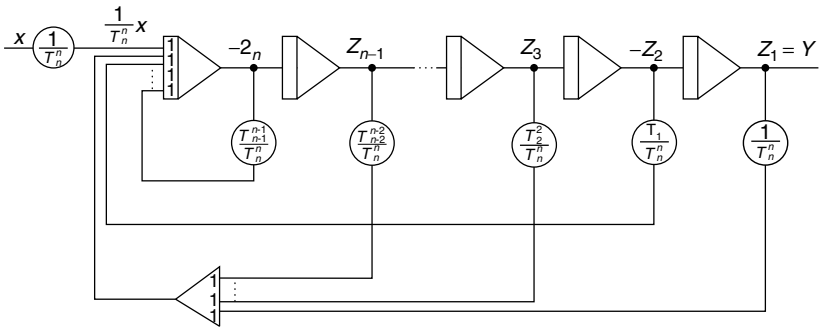

Figure 10. Programming of a system of nth order.

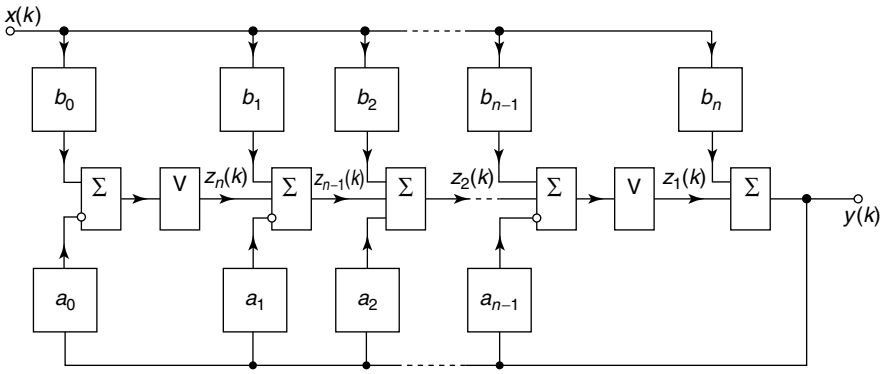

Figure 11. Programming of a sampled-data system.

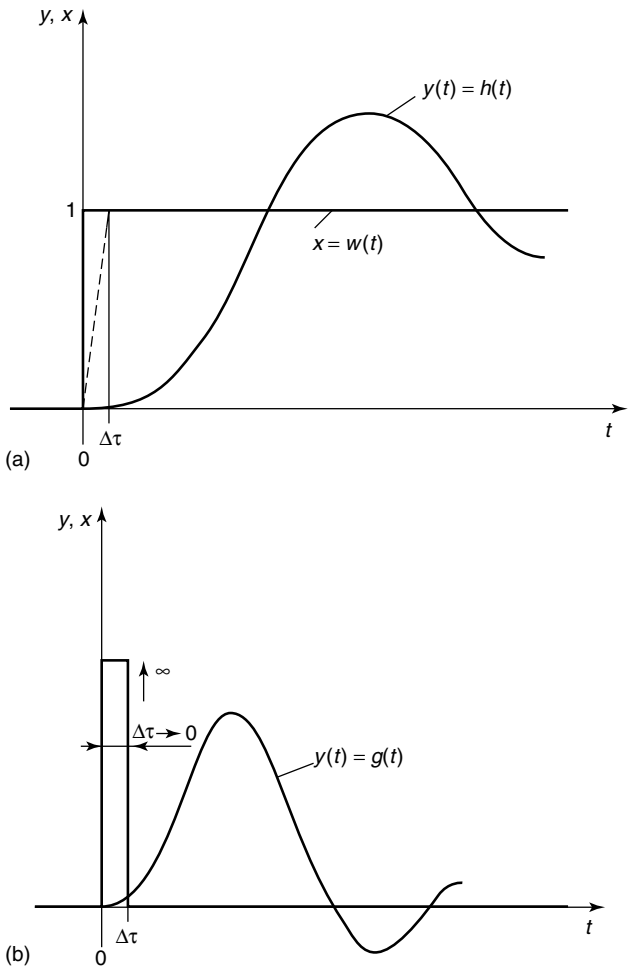

Figure 12. (a) Unit step $w(t)$ and transient response $h(t)$; (b) delta function $\delta(t)$ and weighting function $g(t)$.

1. The response to a step function with a step amplitude of 1 (unit step function, $w(t)$) is the unit step response or transient response $h(t)$ as illustrated in Figure 12(a).
2. The response to a pulse function with an integral value of 1 (Dirac delta function, $\delta(t)$) yields the unit pulse response or weighting function $g(t)$ shown in Figure 12(b).

Because of the linearity of the system, the response function $y(t)$ is to be divided by the step amplitude or the integral value, respectively to get the normalized function. In the case of system identification, if the input function generated by a signal generator is not the ideal function but a function with a rise time $\Delta\tau$ as signified in Figure 12, the condition must be fulfilled that the rise time $\Delta\tau$, or the pulse width $\Delta\tau$, is very much smaller than the transient time t_{tr} of the system (Woschni, 1988).

As can be seen from the comparison of the parts of Figure 12, the pulse function is connected with the step function by means of a differentiation, that is, in the sense of distribution (Gelfand and Schilow, 1960)

$$\frac{\mathrm{d}w(t)}{\mathrm{d}t} = \delta(t) \tag{14a}$$

For linear systems, it is immaterial whether the differentiation is realized at the input or output side of the system, meaning that

$$h(t) = \int g(t)\,\mathrm{d}t \tag{14b}$$

It is only a matter of convenience whether the transient or the weighting functions are used for identification.

For a system with first-order delay, as is used for the approximation of several systems in measurement technology, we gain the differential equation

$$T_1\dot{y} + y = x \tag{14c}$$

with the eigenvalue

$$p_1 = \frac{-1}{T_1} \tag{14d}$$

The stationary solution may be found by means of the assumption

$$y_{st} = c_2$$

for which the total solution yields

$$y = y_{st} + y_d = c_2 + c_1 \exp\left(\frac{-t}{T_1}\right)$$

Using the boundary conditions

$$y|_{t=-\infty} = 0 \quad y|_{t=\infty} = 1$$

we get for the transient response $h(t)$:

$$h(t) = 1 - \exp\left(\frac{-t}{T_1}\right) \tag{14e}$$

The weighting function $g(t)$ follows from (14b):

$$g(t) = \frac{dh(t)}{dt} = \frac{1}{T_1} \exp\left(\frac{-t}{T_1}\right) \tag{14f}$$

The functions $h(t)$ and $g(t)$ are represented in Figure 13. If these functions are obtained experimentally by means of a function generator at the input of the system examined, the time constant T_1 is given by the length of the subtangent (Figure 13). Furthermore, the figure shows the transient time t_{tr} to be nominally three times the time constant T, for $e^{-3} = 1/20$. For more details referring to testing of systems and important examples, *see* **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**.

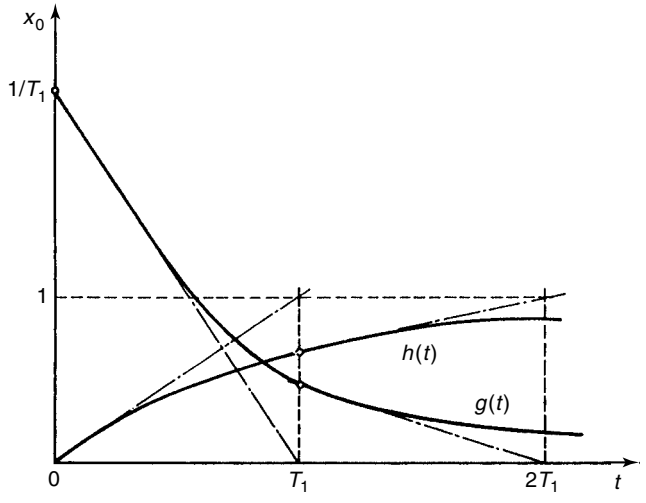

Figure 13. Transient response and weighting function for a first-order system.

9 GENERAL INPUT RESPONSE, CONVOLUTION

Transient response and weighting functions are response functions to special input signals. In the general case, the input function is broken down into a series of weighted Dirac delta functions, which are time delayed as represented in Figure 14. The pulse at the time τ_1 yields the output

$$x(\tau_1)\Delta\tau \times g(t_1 - \tau_1)$$

Because of the linearity of the system the superposition law is valid, which means the entire output is the sum (integral) of all inputs at the time $t - \tau_1 > 0$:

$$\begin{aligned} y(t) &= \int_0^t x(\tau)g(t-\tau)\,d\tau \\ &= \int_0^t x(t-\tau)g(\tau)\,d\tau \\ &= x(t)^* g(t) \end{aligned} \tag{15a}$$

This is the convolution integral, denoted by the sign * for the convolution. The lower limit of the integral may be

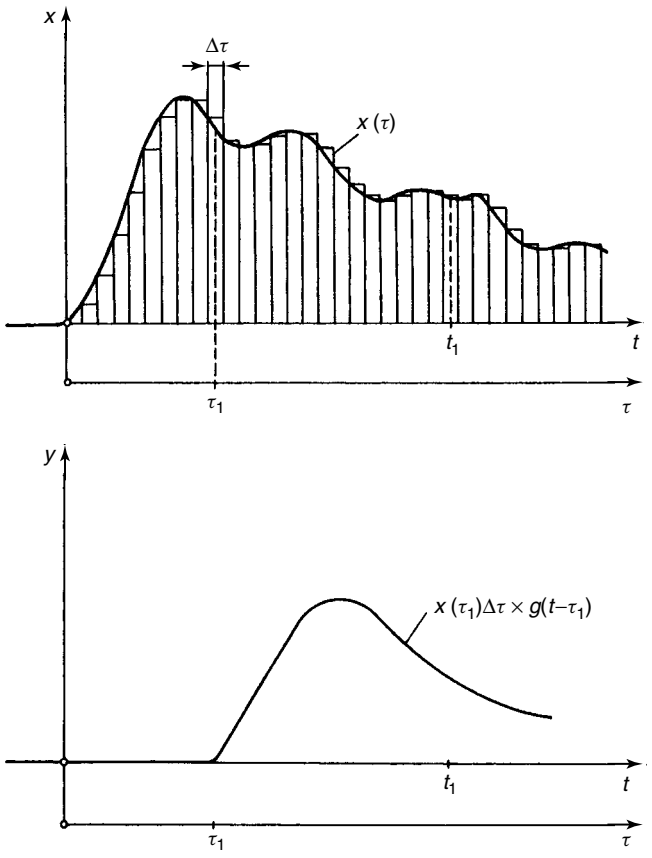

Figure 14. Explanation of the convolution integral.

extended to infinity since the weighting function must be zero before the input is applied. Since the input is zero for $t < 0$, the upper limit may also be extended to infinity, this means (15a) may also be written as

$$y(t) = \int_{-\infty}^{+\infty} x(\tau)g(t-\tau)\,\mathrm{d}\tau = \int_{-\infty}^{+\infty} x(t-\tau)g(\tau)\,\mathrm{d}\tau \tag{15b}$$

Another form of the convolution integral, the Duhamel integral, is obtained by taking into consideration (14b):

$$y(t) = \frac{\mathrm{d}}{\mathrm{d}t}\int_0^t x(\tau)h(t-\tau)\,\mathrm{d}\tau = \frac{\mathrm{d}}{\mathrm{d}t}\int_0^t x(t-\tau)h(\tau)\,\mathrm{d}\tau = \frac{\mathrm{d}}{\mathrm{d}t}[x(t)^* h(t)] \tag{15c}$$

In this equation, the upper and lower limits may also be extended to infinity.

In the field of measurement, convolution is of great importance for system identification (Davies, 1970). The autocorrelation function at the output of a system and the input are related by a double convolution (Woschni, 1988)

$$\psi_{yy}(\tau) = \int_0^\infty \int_0^\infty \psi_{xx}(\tau + \tau_1 - \tau_2)g(\tau_1)g(\tau_2)\,\mathrm{d}\tau_1\,\mathrm{d}\tau_2 \tag{16a}$$

If the autocorrelation function of the input $\psi_{xx}(\tau)$ and the cross-correlation function $\tau_{xy}(\tau)$ are measured, the weighting function of the system can be calculated, for which the following relation is valid (Davies, 1970; Woschni, 1988; Levine, 1996)

$$\psi_{xy}(\tau) = \int_0^\infty g(t)\psi_{xx}(\tau - t)\,\mathrm{d}t \tag{16b}$$

Deconvoluting (16b) gives the required pulse response function $g(t)$; the system may be regarded as being identified. Direct deconvolution techniques using (16b) can be difficult. Therefore, methods in the frequency domain were developed as shown in **Article 36, Systems in the Frequency Domain, Volume 1**. In the special case of white noise with an autocorrelation function $\psi_{xx}(\tau - t) = 2\pi S_0 \delta(\tau - t)$ the deconvolution degenerates to the equation

$$\psi_{xy}(\tau) = 2\pi S_0 g(\tau) \tag{16c}$$

This means that the weighting function corresponds directly to the cross-correlation function (Woschni, 1988).

1 FREQUENCY RESPONSE

(Note of clarification: Before this article is read, it is necessary to point out that in the literature s is often used instead of p and vice versa. λ is used for Eigen values as well as for p. G and H are often interchanged. There are differences in strict mathematical use, but engineers have found it acceptable to use them interchangeably and it is a matter of personal preference in these explanations.)

Using a sinusoidal input and taking both amplitudes of the output $\widehat{Y}$ normalized to the input $\widehat{X}$, and phase φ as a function of frequency ω follows the frequency response with

$$\text{amplitude characteristic is } |G(\mathrm{j}\omega)| = \frac{\widehat{Y}}{\widehat{X}} \tag{1a}$$

$$\varphi(\omega) \leq y, x \tag{1b}$$

In the complex presentation, the input $x = \widehat{X}\mathrm{e}^{\mathrm{j}\omega t}$ yields the output $y = \widehat{Y}\mathrm{e}^{\mathrm{j}(\omega t+\varphi)} = \widehat{Y}\mathrm{e}^{\mathrm{j}\varphi}\mathrm{e}^{\mathrm{j}\omega t}$, which means that the complex frequency response is

$$\frac{\widehat{Y}}{\widehat{X}}\mathrm{e}^{\mathrm{j}\varphi} = G(\mathrm{j}\omega) = |G(\mathrm{j}\omega)|\mathrm{e}^{\mathrm{j}\varphi(\omega)} \tag{1c}$$

This function is represented in the complex plane as a locus diagram. The complex frequency response may be split into a real and an imaginary part:

$$G(\mathrm{j}\omega) = P(\omega) + \mathrm{j}Q(\omega) \tag{1d}$$

with the relations

$$|G(\mathrm{j}\omega)| = \sqrt{[P^2(\omega) + Q^2(\omega)]} \tag{1e}$$

$$\varphi(\omega) = \arctan\left(\frac{Q(\omega)}{P(\omega)}\right) \tag{1f}$$

Figure 1 shows the representation of the frequency characteristics. If the differential equation is given, it is very convenient to obtain the frequency response by means of the terms

$$x^{(\mu)} = (\mathrm{j}\omega)^{\mu}\widehat{X}\mathrm{e}^{\mathrm{j}\omega t}; \quad y^{(r)} = (\mathrm{j}\omega)^{r}\widehat{Y}\mathrm{e}^{\mathrm{j}\varphi}\mathrm{e}^{\mathrm{j}\omega t} \tag{2a}$$

Substituting the differential equation, *see* **Article 35, Systems in the Time Domain, Volume 1**

$$T_n^n y^{(n)} + \cdots + T_1\dot{y} + y = G_0 x + \frac{b_1}{a_0}\dot{x} + \cdots + \frac{b_m}{a_0}x^{(m)} \tag{2b}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

ISBN: 0-470-02143-8.

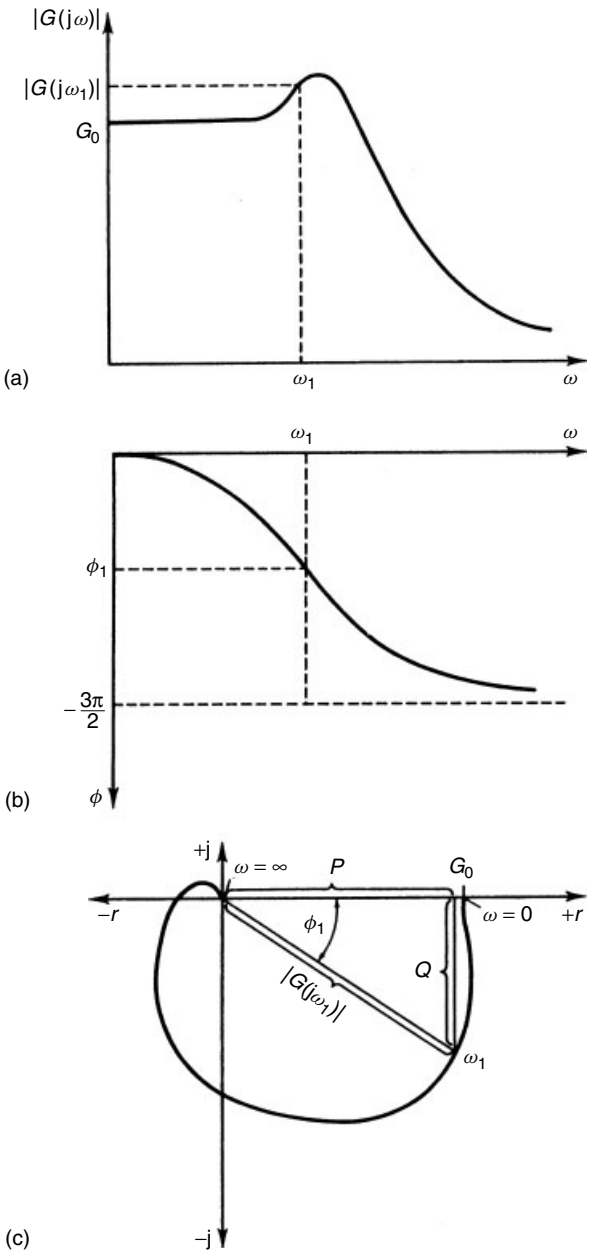

Figure 1. Graphical representation of frequency characteristics: (a) amplitude characteristic; (b) phase characteristic; and (c) locus diagram.

and solving the output–input relation leads to the complex frequency response

$$G(\mathrm{j}\omega) = \frac{\widehat{Y}\mathrm{e}^{\mathrm{j}\varphi}}{\widehat{X}} = \frac{G_0 + \mathrm{j}\omega\left(\frac{b_1}{a_0}\right) + \cdots + (\mathrm{j}\omega)^m\left(\frac{b_m}{a_0}\right)}{1 + \mathrm{j}\omega T_1 + \cdots + (\mathrm{j}\omega)^n T_n^n} \tag{2c}$$

This implies that substitution of nth-order differentiation by $(\mathrm{j}\omega)^n$ and nth-order integration by $(1/\mathrm{j}\omega)^n$ will yield the output–input relation.

The frequency response can be measured, by way of (1a, b), using a sinusoidal test signal. If the input is a stochastic signal with power density $S_{xx}(\omega)$, the output power density $S_{yy}(\omega)$ may be calculated according to Davies (1970) and Woschni (1988)

$$S_{yy}(\omega) = |G(\mathrm{j}\omega)|^2 S_{xx}(\omega) \tag{2d}$$

The double convolution in the time domain corresponds to a multiplication with $|G(\mathrm{j}\omega)|^2$ in the frequency domain (Woschni, 1988; Levine, 1996).

2 LOGARITHMIC CHARACTERISTICS AND BODE PLOT REPRESENTATION

Of great practical importance is the plotting of the amplitude characteristic in a double-logarithmic calibration graph and the phase characteristic with a linear φ-axis and a logarithmic ω-axis, known as *logarithmic frequency characteristics*. In order that a linear scale be used for the y-axis (Bode diagram), the amplitude is generally measured in decibel (dB) units,

$$20\log\left(\frac{\widehat{Y}}{\widehat{X}}\right) = 20\log|G(\mathrm{j}\omega)| \tag{3a}$$

The advantage of this method is illustrated in Figure 2. As treated in **Article 35, Systems in the Time Domain, Volume 1**, the overall behavior of series-connected systems is given by the multiplication of the frequency responses of each of these systems. Because of the logarithmic representation, the multiplication is simplified to a summation, which can easily be realized graphically.

For a system with first-order delay, used for approximation of more complicated systems, from the differential equation – *see* **Article 35, Systems in the Time Domain, Volume 1**.

$$T_1\dot{y} + y = x \tag{3b}$$

it follows that

$$G(\mathrm{j}\omega) = \frac{1}{1 + \mathrm{j}\omega T_1} \tag{3c}$$

$$|G(\mathrm{j}\omega)| = \frac{1}{\sqrt{1 + \omega^2 T_1^2}} \tag{3d}$$

$$\varphi(\omega) = -\arctan(\omega T_1) \tag{3e}$$

These frequency response functions are featured in Figure 3. From Figure 3(b) it can be seen that a critical

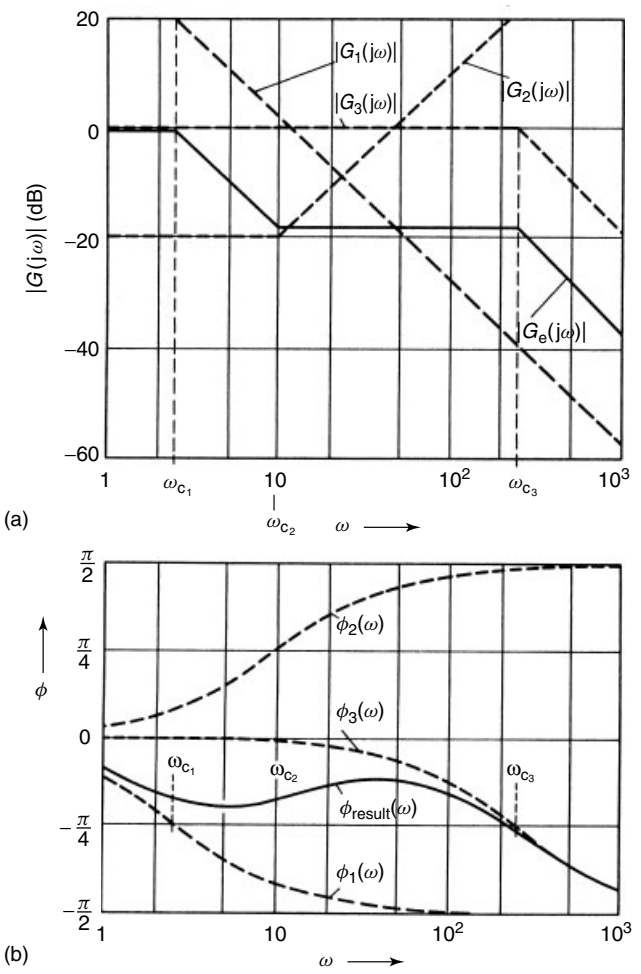

Figure 2. Graphical determination, through addition, of the frequency responses of series-connected systems (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd).

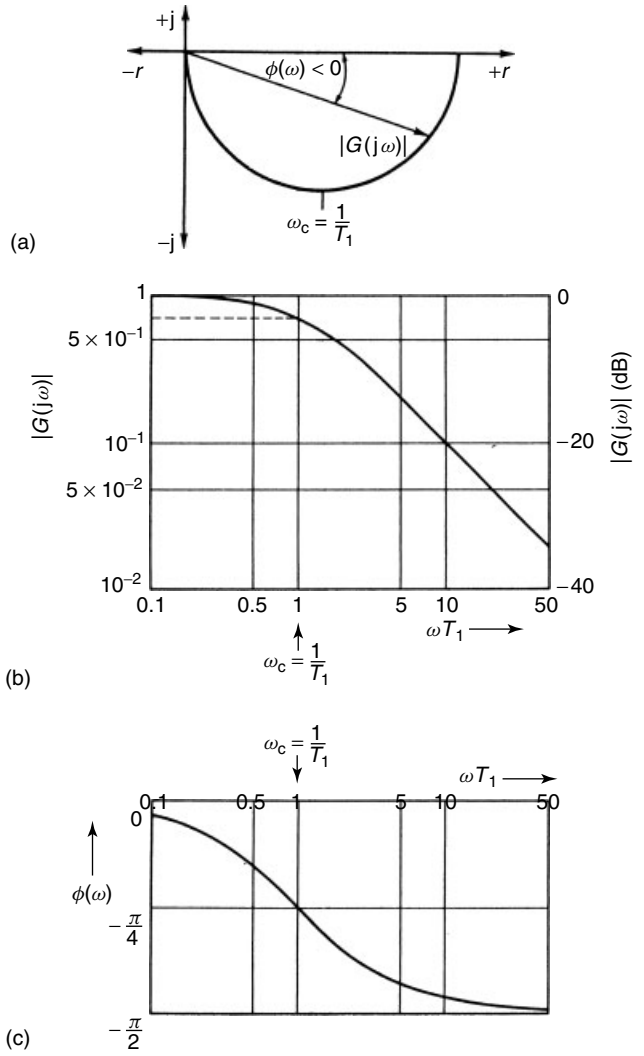

Figure 3. (a) Locus diagram; (b) amplitude characteristic and (c) phase characteristic for a first-order system.

frequency f_c (or ω_c) given by

$$2\pi f_c = \omega_c = \frac{1}{T_1} \tag{3f}$$

can be used to quickly generate approximations of the response behavior (Woschni, 2000).

Important examples of measurement system responses are discussed in **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**.

3 TRANSFER FUNCTION

A generalization of the complex frequency response arises if the frequency $j\omega$ is extended to the complex frequency

$$p = j\omega + \delta \tag{4a}$$

with the increased constant δ.

This complex frequency is the variable p (or s in some literatures) used with Laplace transformation (*see* **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**). In the physical sense, p means a harmonic oscillation with a exponentially increasing or decreasing amplitude (Woschni, 1988):

$$x = \hat{X}e^{pt} = \hat{X}e^{\delta t}e^{j\omega t} \tag{4b}$$

If s is represented in the p-plane, the left-hand side of this plane signifies stable solutions ($\delta < 0$) while the right-hand side leads to unstable solutions ($\delta > 0$).

This criterion is used for assessing the stability of systems as treated in **Article 38, Stability Issues, Volume 1**. The complex frequency p used instead of ω results in the transfer function $G(p)$ for the system described by (2c)

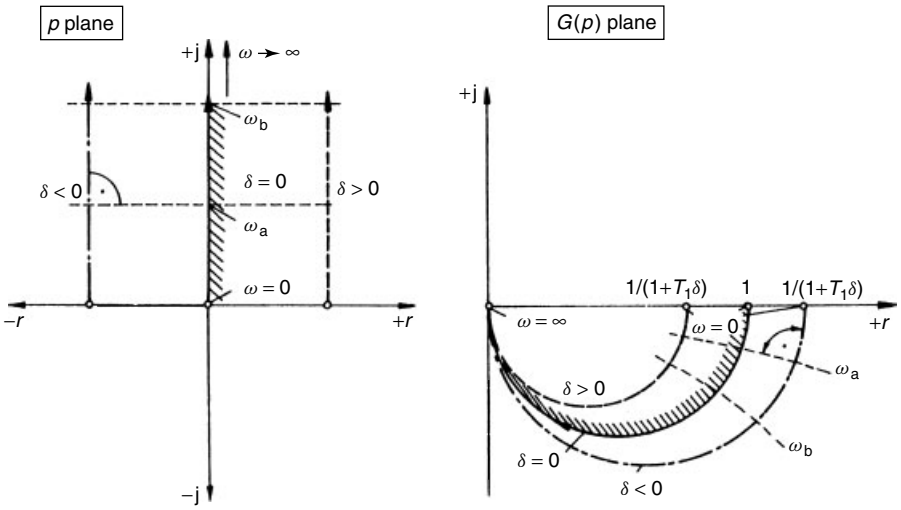

Figure 4. Representations of the transfer function for a first-order system.

with $b_0 = b_0/a_0$:

$$G(p) = \frac{\dfrac{b_0}{a_0} + p\dfrac{b_1}{a_0} + \cdots + p^m\dfrac{b_m}{a_0}}{1 + pT_1 + \cdots + p^n T_n^n} = \frac{\displaystyle\sum_{r=0}^{m} \frac{b_r}{a_0} p^r}{\displaystyle\sum_{\mu=0}^{n} T_\mu^\mu p^\mu} \tag{4c}$$

The $G(p)$ plane is a conformal mapping of the p-plane (Zadeh and Desoer, 1963; Woschni, 1988), which means that the side directions of the curves remain valid and small squares remain squares, as the next example shows. The system with first-order delay with the frequency responses (3c, d) has the transfer function

$$G(p) = \frac{1}{1 + pT_1} \tag{4d}$$

shown in Figure 4 with several values of δ. It can be observed that Figure 3 is a special case included in Figure 4.

4 POLES AND ZEROS AND ROOT LOCUS REPRESENTATION

By means of searching the zero points of both the numerator p_r^* and the divisor p_μ of the fraction (4c) one gains the equivalent product representation, the polynomial equation

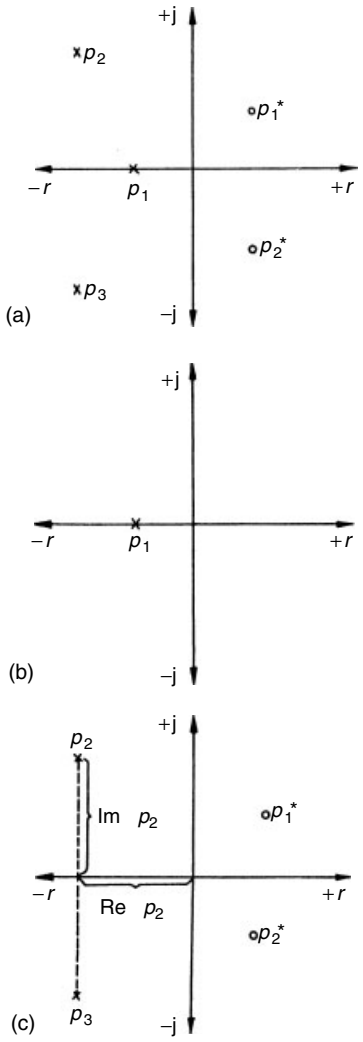

Figure 5. (a) Splitting up the pole-zero plane of a system; (b, c) into series-connected subsystems (x poles; 0 zeros).

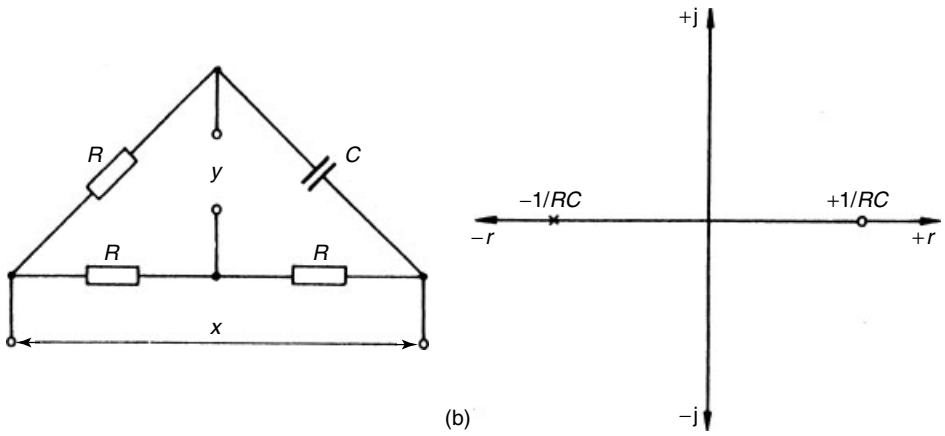

Figure 6. Phase-shift bridge: (a) circuit; and (b) pole-zero plane diagram.

alternative of (4c)

$$G(p) = c\frac{(p-p_1^*)(p-p_2^*)\ldots\ldots(p-p_m^*)}{(p-p_1)(p-p_2)\ldots\ldots(p-p_n)} = c\frac{\prod_{r=1}^{m}(p-p_r^*)}{\prod_{\mu=1}^{n}(p-p_\mu)} \tag{5a}$$

having the poles p_μ and the zeros p_r^* of the transfer function. Thus, the properties of a system are described completely, up to a constant c, by the position of poles and zeros, represented in the pole–zero plane (Figure 5). The poles agree with the Eigen values of the differential equation.

The frequency response can be calculated from the pole–zero plane by

$$G(\mathrm{j}\omega) = c\frac{\prod_{r=1}^{m}(\mathrm{j}\omega - p_r^*)}{\prod_{\mu=1}^{n}(\mathrm{j}\omega - p_\mu)} \tag{5b}$$

Figure 5 shows how, for series connections, the pole–zero representation of a complicated system can be split into a sum of simpler systems. Poles and zeros at the same point cancel each other; this feature called *compensation* is used for the correction of systems by means of additional series-connected correcting elements – *see* **Article 38, Stability Issues, Volume 1**). The position of the poles contains information as to whether the system is stable or not: existence of poles in the right half plane signifies instability, *see* **Article 38, Stability Issues, Volume 1**.

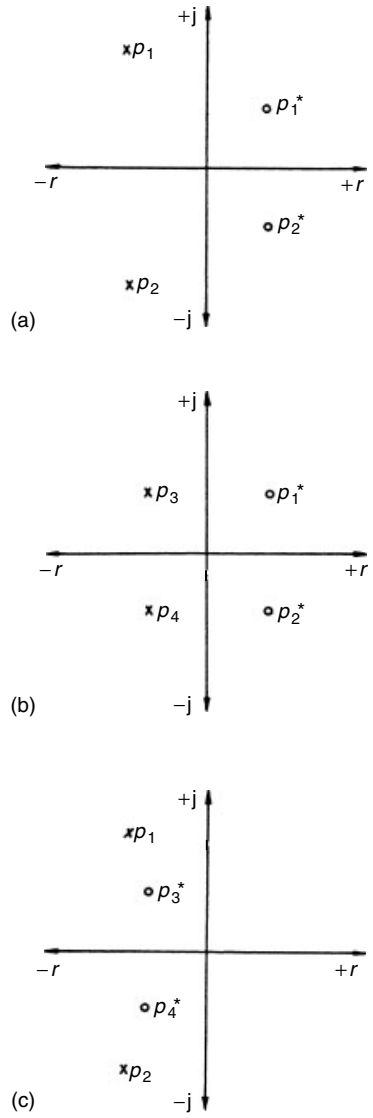

Figure 7. (a) System of Figure 5c; (b) all-pass system; and (c) minimal-phase system.

Of special interest in connection with stability problems is the path of the poles as a function of the parameters of systems. This method is called *root locus representation* and is the basis for system stability investigations (Levine, 1996).

5 TYPICAL EXAMPLE: PHASE-SHIFT BRIDGE

In measurement, the phase-shift bridge (Figure 6) is often used. The transfer function is

$$G(p) = \frac{1}{2}\frac{1 - pCR}{1 + pCR} \tag{6a}$$

and the pole and zero at

$$p_0 = -\frac{1}{RC};\ p_0^* = \frac{1}{RC} \tag{6b}$$

The pole–zero plane (Figure 6) shows a symmetrical position of pole and zero referred to as the imaginary axis. This configuration of poles has, typically, for all-pass circuits, a constant amplitude characteristic and a frequency-dependent phase characteristic as follows directly from (5b). All-pass systems play an important role in the correction of the phase characteristic (Woschni, 1988; Haykin, 2001).

Every system containing zeros in the right half plane can be split into an all-pass system and a so-called minimal-phase system without zeros in the right half plane, as shown in Figure 7 for the system represented in Figure 5c.

1 LAPLACE TRANSFORM IN GENERAL

In **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**, the relations between signals in the time and frequency domain are treated. In a similar way, the relations in systems may also be described.

The basic idea of the calculation of the time functions, that is, $g(t)$ or $h(t)$, is as follows. Both the spectral function $\widehat{X}(\mathrm{j}\omega)$ of the input and the frequency response of the system $G(\mathrm{j}\omega)$ or generalized $G(p)$ are given. It is then possible to derive the output caused by any of the several sinusoidal input spectral oscillations by multiplying the complex spectral density $\widehat{X}(\mathrm{j}\omega)$ with the frequency response and then applying the summation (integration) of all frequency components. This is valid because the superposition law applies for linear systems.

In system theory, the Laplace transform is preferred to the Fourier transform because it converges more quickly. It can be derived by substituting $\mathrm{j}\omega \rightarrow p$ in the Fourier transform equation (*see* **Article 27, Signals in the Frequency Domain, Volume 1**)

$$F(p) = \int_0^\infty f(t)\mathrm{e}^{-pt}\,\mathrm{d}t = L\{f(t)\} \tag{1a}$$

$$f(t) = \frac{1}{2\pi\mathrm{j}}\int_{c-\mathrm{j}\infty}^{c+\mathrm{j}\infty} F(p)\mathrm{e}^{pt}\,\mathrm{d}p = L^{-1}\{F(p)\} \tag{1b}$$

In system theory, this so-called one-sided Laplace transform is made use of; only the region $t \geq 0$ is of interest. For solving optical problems, the two-dimensional Laplace transform or Fourier transform is applied in the so-called optical transfer function (Goodman, 1968).

The convergence abscissa c in (1b) is chosen in such a way that the poles remain to the left of this abscissa. Owing to the residue theorem (Kaplan, 1962),

$$\int_{c-\mathrm{j}\infty}^{c+\mathrm{j}\infty} F(p)\mathrm{e}^{pt}\,\mathrm{d}p = 2\pi j \sum \mathrm{Re}\, s(p_r) \tag{2a}$$

and for a pole of nth order

$$\mathrm{Re}\, s(p_0) = \frac{1}{(n-1)!}\lim_{p\rightarrow p_0}\frac{\mathrm{d}^{n-1}}{\mathrm{d}p^{n-1}}[F(p)\mathrm{e}^{pt}(p-p_0)^n] \tag{2b}$$

Physical considerations lead to the following relationships between output and input (Woschni, 1988):

$$L\{y(t)\} = L\{x(t)\}G(p)$$
$$y(t) = L^{-1}\{L\{x(t)\}G(p)\} \tag{3a}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

This equation yields for the transfer function $G(p)$

$$G(p) = \frac{L\{y(t)\}}{L\{x(t)\}} = \frac{\widehat{Y}(p)}{\widehat{X}(p)} \tag{3b}$$

Using the Laplace transforms of the unit step $1/p$ and the Dirac function 1 (Table 1) provides, instead of (3b),

$$G(p) = \frac{L\{g(t)\}}{L\{\delta(t)\}} = L\{g(t)\} = \int_0^\infty g(t)\mathrm{e}^{-pt}\,\mathrm{d}t \tag{3c}$$

or

$$G(p) = \frac{L\{h(t)\}}{L\{w(t)\}} = pL\{h(t)\} = p\int_0^\infty h(t)\mathrm{e}^{-pt}\,\mathrm{d}t \tag{3d}$$

and for the calculation of the time functions

$$g(t) = L^{-1}\{G(p)\} = \frac{1}{2\pi\mathrm{j}}\int_{c-\mathrm{j}\infty}^{c+\mathrm{j}\infty} G(p)\mathrm{e}^{pt}\,\mathrm{d}p \tag{3e}$$

$$h(t) = L^{-1}\left\{\frac{G(p)}{p}\right\} = \frac{1}{2\pi\mathrm{j}}\int_{c-\mathrm{j}\infty}^{c+\mathrm{j}\infty} \frac{G(p)}{p}\mathrm{e}^{pt}\,\mathrm{d}p \tag{3f}$$

From (3a) it follows

$$\begin{aligned} y(t) &= L^{-1}\{L\{x(t)\}L\{g(t)\}\} \\ &= \int_0^t x(\tau)g(t-\tau)\,\mathrm{d}\tau = x(t) * g(t) \end{aligned} \tag{3g}$$

or

$$\begin{aligned} y(t) &= L^{-1}\{L\{x(t)\}pL\{h(t)\}\} \\ &= \frac{\mathrm{d}}{\mathrm{d}t}\int_0^t x(t)h(t-\tau)\,\mathrm{d}\tau \\ &= \frac{\mathrm{d}}{\mathrm{d}t}[x(t) * h(t)] \end{aligned} \tag{3h}$$

giving the convolution theorem of the Laplace transform (Table 2). Figure 1 demonstrates this fact. By means of these relations, the deconvolution problem may be solved (Davies, 1970; Woschni, 1988).

$$\begin{aligned} x(t) &= L^{-1}\left\{L\{y(t)\}\frac{1}{G(p)}\right\} \\ &= \int_0^t y(t)g^*(t-\tau)\,\mathrm{d}\tau = x(t) * g^*(t) \end{aligned} \tag{3i}$$

with

$$g^*(t) = L^{-1}\left\{\frac{1}{G(p)}\right\} \tag{3j}$$

Deconvolution often becomes extremely difficult because it is generally not possible to realize the inverse system functions. An alternative approach to the solution, by means of Fourier transforms, is often used (Davies 1970, Woschni 1988).

2 LAPLACE TRANSFORMS OF TYPICAL SIGNALS

In Table 1, typical signals including test signals as pulse, step, and ramp function are put together with the time function and the Laplace transform.

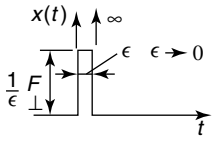
3 THEOREMS OF LAPLACE TRANSFORM

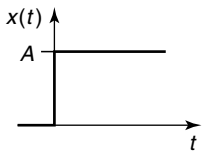
Table 2 shows theorems of Laplace transform. The initial values are often zero because systems are at rest before $t = 0$ and the input signal starts at $t = 0$. In this starting state, the differentiation theorem is very much easier as Table 2 demonstrates

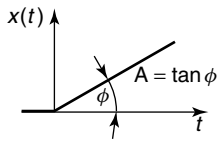
$$L\{f^{(n)}(t)\}\ p^n\ L\{f(t)\} \tag{4}$$

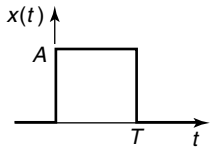
Using this result one gains easily, from the differential equation, the frequency response or transfer function; and vice versa as treated in detail in **Article 36, Systems in the Frequency Domain, Volume 1**.

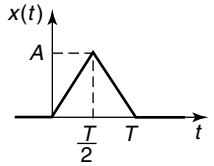
4 IMPORTANT CORRESPONDENCES OF LAPLACE TRANSFORM

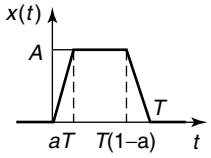












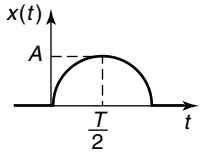


Table 3 contains important correspondences of the Laplace transform to be used to gain the transform of a given time function and vice versa. It is advantageous for it is possible to gain the transforms directly without solving the appropriate equations as shown in the next example.

5 AN IMPORTANT EXAMPLE

As an example, let us deal with a temperature sensor as shown in Figure 2. With the temperature of the environment δ_e and the temperature of the sensor δ_s, the volume V, the surface S, the specific density c, the specific heat or thermal equivalent χ and the heat-transfer coefficient α one obtains the differential equation

$$\begin{aligned} c\chi V\frac{\mathrm{d}\delta_\mathrm{s}}{\mathrm{d}t} + \alpha S(\delta_\mathrm{s} - \delta_\mathrm{e}) &= 0 \\ \frac{c\chi V}{\alpha S}\dot{\delta}_\mathrm{s} + \delta_\mathrm{s} &= \delta_\mathrm{e} \end{aligned} \tag{5a}$$

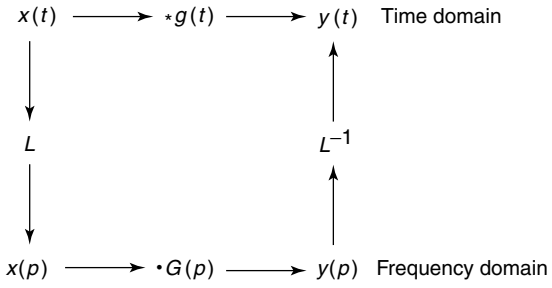

Figure 1. Convolution relationships.

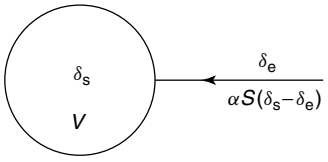

Figure 2. Temperature sensor.

Using (4) the transfer function is

$$G(p) = \frac{1}{1+pT} \text{ with } T = \frac{c\chi V}{\alpha S} \tag{5b}$$

The time functions are obtained using (3e, f)

$$g(t) = \frac{1}{2\pi\mathrm{j}}\int_{c-\mathrm{j}\omega}^{c+\mathrm{j}\omega}\frac{\mathrm{e}^{pt}}{1+pT}\,\mathrm{d}p \tag{5c}$$

$$h(t) = \frac{1}{2\pi\mathrm{j}}\int_{c-\mathrm{j}\omega}^{c+\mathrm{j}\omega}\frac{\mathrm{e}^{pt}}{p(1+pT)}pp \tag{5d}$$

and using the correspondences found in Table 3

$$g(t) = \frac{1}{T}\mathrm{e}^{-\frac{t}{T}} \tag{5e}$$

$$h(t) = 1 - \mathrm{e}^{-\frac{t}{T}} \tag{5f}$$

The time constant is then

$$T = c\chi\frac{V}{\alpha S} \tag{5g}$$

So it follows that the relation of $V/S =$ constant and has to be small for good dynamic behavior, which means

the diameter d of the sensor has to be so small as design conditions allow.

1 CONCEPT OF STABILITY

Let us deal, as an introduction, with an amplifier having amplification V as shown in Figure 1. If a part of $1/V$ of the output y is coupled back to the input x with the right phase (feedback), the amplifier will produce its own output y without there being an input. The system becomes unstable.

The system is stable if one of the following conditions is met:

1. The eigenvalues of the differential equation p_r exhibit a real part less than zero, that is

$$\mathrm{Re}(p_r) = \delta_r < 0 \tag{1a}$$

2. On the right-hand side of the pole-zero plot there are

no poles of the transfer function; (1b)

3. Decreasing eigenfunctions occur; this means that the weighting function $g(t)$ fulfills the condition

$$\lim_{c\to\infty} \int_0^c |g(t)|\,\mathrm{d}t \le M < \infty \tag{1c}$$

From examination of these stability conditions, certain stability criteria can be applied to test the situation to estimate its degree of stability, for instance, using the Hurwitz and Routh test.

If the following differential equation is given

$$a_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_0 y = b_0 x + \cdots + b_m x^{(m)}$$

then all coefficients a_r, and the determinants

$$\Delta_\mu = \begin{vmatrix} a_1 & a_0 & 0 & \dots & 0 \\ a_3 & a_2 & a_1 & a_0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ a_{2\mu-1} & a_{2\mu-2} & & \dots & a_\mu \end{vmatrix} \tag{1d}$$

have to be positive, that is, $a_r > 0$, $\Delta_\mu > 0$.

2 STABILITY CRITERIA

For practical applications, graphical methods based on the locus diagram representations are of value. The transfer function $G(p)$ consists of polynomials in the numerator $N(p)$ and the divisor $D(p)$:

$$G(p) = \frac{N(p)}{D(p)} \tag{2a}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

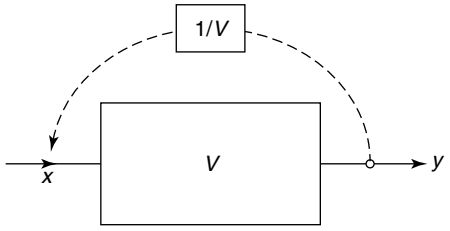

Figure 1. Amplifier with a feedback.

Application of the stability condition (1b) shows that the polynomial of the divisor $D(p)$ is not permitted to have zeros in the right-half plane including those lying upon the imaginary axis (2b) (stability limit).

For testing the stability of a given system, the divisor of the frequency response, that is, $D(\mathrm{j}\omega)$, is drawn on the complex plane (locus diagram) forming a closed curve by inclusion of negative frequencies. Because of the conformal mapping, the unstable field is always the one lying on the right-hand side of the locus curve drawn from $\omega = -\infty$ to $\omega = +\infty$ (see Figure 2). To test for stability, it is necessary to verify where the zero point is situated.

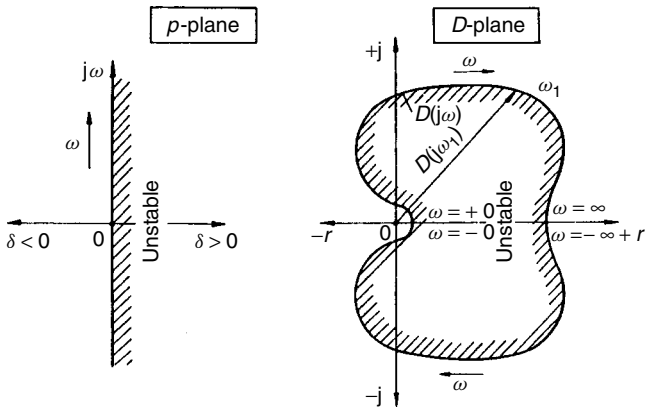

Figure 2. Locus diagram of the divisor $D(p)$.

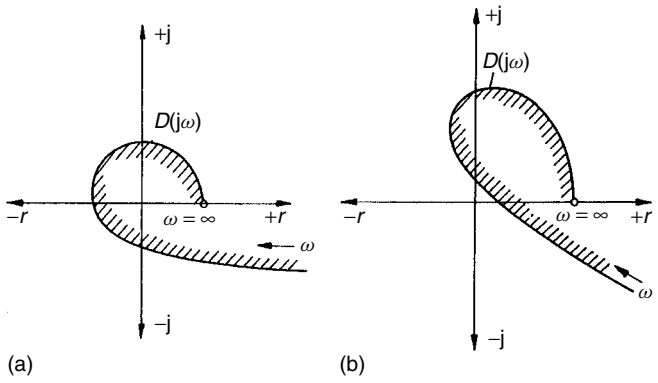

Figure 3. (a) Unstable system and (b) stable system.

If the zero point of the $D(p)$-plane remains left of the locus curve $D(\mathrm{j}\omega)$, passes from $\omega = -\infty$ to $\omega = +\infty$, the system is stable. If not, it is unstable (Figure 3) to some degree.

The procedure is also suitable for developing a statement on the stability margin (see Woschni, 1988; Zadeh and Desoer, 1963 and Section 4 of this article).

3 ROOT LOCUS REPRESENTATION

As described in (1b), the locus of the poles of the transfer function $G(p)$ facilitates the test of the stability of a system. The transfer function

$$G(p) = \frac{\dfrac{b_0}{a_0} + p\dfrac{b_1}{a_0} + \cdots + p^m\dfrac{b_m}{a_0}}{1 + pT_1 + \cdots p^n T_n^n} = \frac{\displaystyle\sum_{\nu=0}^{m}\frac{b_\nu}{a_0}p^\nu}{\displaystyle\sum_{\mu=0}^{n} T_\mu^\mu p^\mu} \tag{3a}$$

may be written in the form (Woschni, 1988; Levine, 1996), *see also* **Article 36, Systems in the Frequency Domain, Volume 1**

$$G(p) = c\frac{(p-p_1^*)(p-p_2^*)\ldots(p-p_m^*)}{(p-p_1)(p-p_2)\ldots(p-p_n)} = c\frac{\displaystyle\prod_{r=1}^{m}(p-p_r^*)}{\displaystyle\prod_{\mu=1}^{n}(p-p_\mu)} \tag{3b}$$

This means the roots of the divisor are the poles of $G(p)$ and thus they are responsible for stability. Stability means that there exist no poles in the right-hand side of the pole-zero plane (Figure 4).

Sampled-data systems with the sampling time T_S yields $z = \mathrm{e}^{pT_S}$, (Woschni, 1988; Levine, 1996)

$$G(z) = c\frac{(z-z_1^*)(z-z_2^*)\ldots(z-z_m^*)}{(z-z_1)(z-z_2)\ldots(z-z_n)} = c\frac{\displaystyle\prod_{\nu=1}^{m}(z-z_\nu^*)}{\displaystyle\prod_{\mu=1}^{n}(z-z_\mu)} \tag{3c}$$

Here, instead of the right-hand side of the pole-zero plane, as with (1b), the region outside the unit circle is the unstable one. So poles have now to be inside this circle to achieve stability as Figure 4 shows.

The main idea of the root locus representation is to allow movement of the poles by varying system parameters when investigating the stability. The method was introduced by Evans (1954) and is applied to find the critical

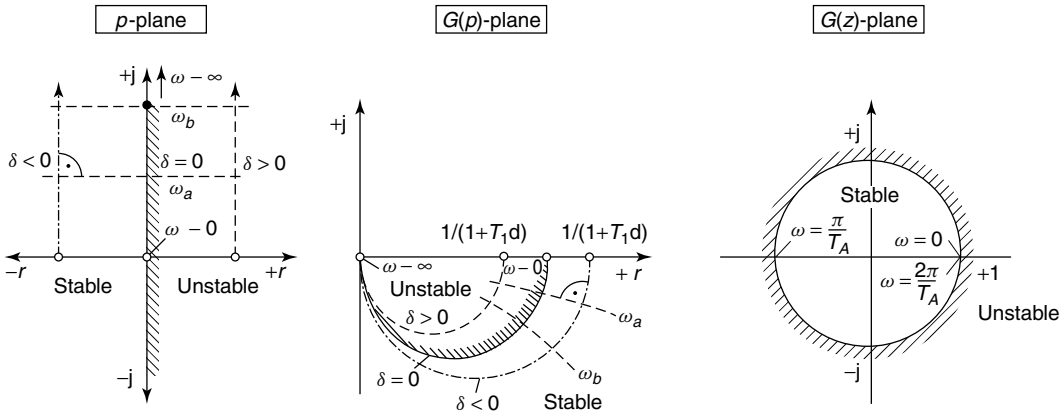

Figure 4. Mapping of the p-plane to the $G(p)$- and the $G(z)$-plane.

amplification V of closed-loop systems (automatic control systems) as dealt with in Section 4.

4 FEEDBACK AND FEED FORWARD AS AN IMPORTANT EXAMPLE

As an example of a commonly met system in instrument systems, consider the feedback system shown in Figure 5. For negative feedback (control situation), the frequency response is given by (*see* Section 3 of **Article 35, Systems in the Time Domain, Volume 1**)

$$G_e(j\omega) = \frac{G_1(j\omega)}{1 + G_1(j\omega)G_2(j\omega)} \tag{4a}$$

The $D(j\omega)$ function is

$$1 + G_1(j\omega)G_2(j\omega) \tag{4b}$$

Instead of testing this function, it is more convenient to verify that the open-loop frequency response

$$G_1(j\omega)G_2(j\omega) \tag{4c}$$

fulfills the condition related to the point '−1' as shown in Figure 6 (Nyquist diagram). The diagram illustrates that an increasing amplification V will take the system from a stable to an unstable state. This fact may be caused by nonlinearity and may lead to unstable oscillatory behavior, (see Section 3 of this article).

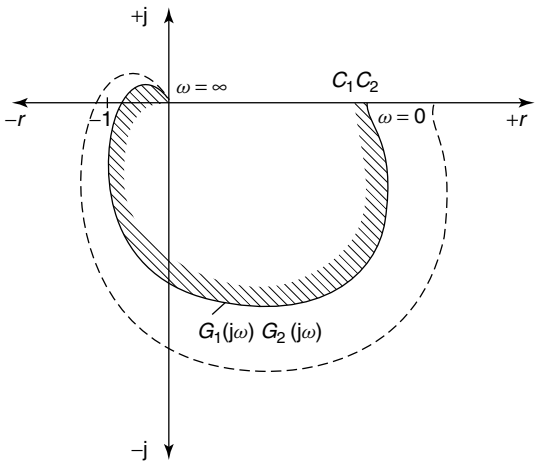

Figure 6. Testing stability of closed-loop systems (control).

A very important device is the operational amplifier shown in Figure 7.

Using (4b) the frequency response is with $|\underline{Z}_1| \ll |\underline{Z}_2|$ and $\underline{V} \to \infty$

$$\frac{\hat{Y}}{\hat{X}} = \underline{V}^* = \frac{\underline{V}}{1 + \dfrac{\underline{V}\,\underline{Z}_1}{\underline{Z}_1 + \underline{Z}_2}} = \frac{1}{\dfrac{1}{\underline{V}} + \dfrac{\underline{Z}_1}{\underline{Z}_2}} = \frac{\underline{Z}_2}{\underline{Z}_1} \tag{4d}$$

With $\underline{Z}_2 = R_2$ and $\underline{Z}_1 = 1/\mathrm{j}\omega C$ it is a differentiation network

$$\underline{V}^x = \mathrm{j}\omega C R_2 \tag{4e}$$

and with $\underline{Z}_2 = (1/\mathrm{j}\omega C)$ and $\underline{Z}_1 = R_1$ an integrator (Miller-integrator, bootstrap-generator)

$$\underline{V}^x = \frac{1}{\mathrm{j}\omega C R_1} \tag{4f}$$

Table 1 also compares structurally stable and unstable systems.

5 OPTIMIZATION OF SYSTEMS

Optimization is treated here specifically with respect to system theory. Both dynamic errors and errors caused by disturbances, for example, noise, are taken into consideration.

The behavior of measuring systems depends upon a number of parameters k_i, for example, time constants T_r, which, at least to a certain extent, may be freely selected. If the parameters of the system cannot be changed, an optimization can be effected by a following correction (also called *compensation*) system or by a correction system connected in opposition, the parameters of such a system being adjustable. In the commonly found microprocessor-based applications, the behavior of the system is set up by suitable programming.

The fundamental idea is shown for a one-dimensional problem in Figure 8. The difference between the output variables of the ideal optimum system (model) and the real system, with a following correction system, is formed and assessed according to the computing instruction defined by the optimization criterion. The parameters k_i of the correction system are set so that the real system resembles the optimum system as far as possible.

Distinction is made between static and dynamic optimization (Bellman, 1961) according to the definition of the performance criterion. If the system is dimensioned such that a performance function depending directly on the parameters

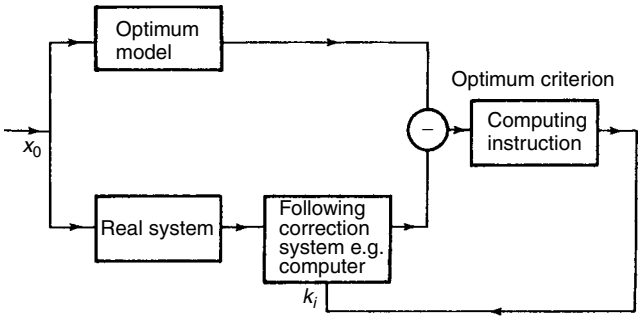

Figure 8. Principle of optimization.

k_i becomes optimum, we have a static optimization. In dynamic optimization, on the other hand, a process $x(t)$ is sought such that a performance function depending on a changing functional process assumes an extremal value.

The previous considerations imply that the central need of optimization is the creation of a suitable optimization criterion.

In most cases, the criterion of the mean-square error, as shown in Figure 9, is used. If $G_{\mathrm{real}}(\mathrm{j}\omega)G_{\mathrm{corr}}(\mathrm{j}\omega)$ is the frequency response of the system corrected by a following correction system $G_{\mathrm{corr}}(\mathrm{j}\omega)$ as shown in Figure 8, we obtain the mean-square error (Woschni, 1988)

$$\begin{aligned}\overline{\varepsilon^2} &= \int_0^\infty S_{xx}(\omega)|G_{\mathrm{id}}(\mathrm{j}\omega) - G_{\mathrm{real}}(\mathrm{j}\omega)G_{\mathrm{corr}}(\mathrm{j}\omega)|^2\,\mathrm{d}\omega \\ &\quad + \int_0^\infty S_{zz}(\omega)|G_{\mathrm{corr}}(\mathrm{j}\omega)|^2\,\mathrm{d}\omega \\ &= \overline{\rho^2} + P_z(5)\end{aligned}$$

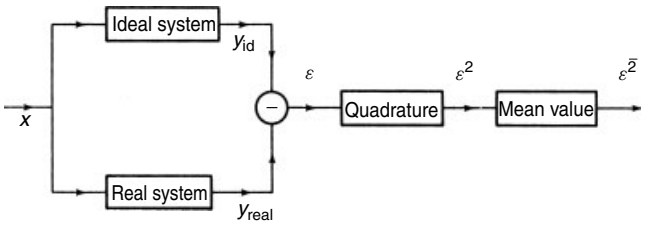

Figure 9. Mean-square error generation.

with the assumption having been made that the disturbances occur prior to the correction computer.

6 DECONVOLUTION

In **Article 35, Systems in the Time Domain, Volume 1**, the convolution integral is introduced to obtain the output $y(t)$ if the input $x(t)$ and the weighting function of the system $g(t)$ are known (Levine, 1996; Woschni, 1988).

$$y(t) = \int_0^t g(t)x(t-\tau)\,\mathrm{d}\tau \tag{6a}$$

The inverse problem is of great importance in measuring systems and is known as deconvolution. There the output signal $y(t)$ is measured with the input $x(t)$ or the wanted signal. The behavior of the measuring device, the weighting function $g(t)$, or the transfer function $G(p) = \mathbf{L}\{g(t)\}$ is known. System theory and Laplace transformation rules yields (Woschni, 1988; Levine, 1996)

$$x(t) = \int_0^t g^*(\tau)y(t-\tau)\,\mathrm{d}\tau \tag{6b}$$

With the weighting function $g^*(t)$ of the inverse system

$$g^*(t) = \mathbf{L}^{-1}\left\{\frac{1}{G(p)}\right\} \tag{6c}$$

As introduced in **Article 36, Systems in the Frequency Domain, Volume 1**, the transfer function of the measuring system $G(p)$ may be described by the pole-zero plane plot. Figure 10 shows this plane for a general nonminimal-phase system containing a minimal-phase system and an all-pass system. The inverse system $g^*(t)$ now has poles at the positions where the original system has zeros and vice versa.

Until there are no zero points of the original system in the right-half plane of the pole-zero plane (so-called minimal-phase system), it is possible to realize the inverse system. If the degree of the divisor is greater than the degree of the counter, this is possible as a limiting case. If the original system is a nonminimal-phase kind, the zero points of the all-pass in the right half of the pole-zero plane will be poles of the inverse system. This means that the system will be unstable and a realization of the deconvolution is not possible. In this case, it is only possible to fulfill the amplitude conditions of (6c) and to use an additional all-pass unit to gain a constant and increasing delay time.

7 TESTING OF SYSTEMS

Testing of systems is the task of system identification.

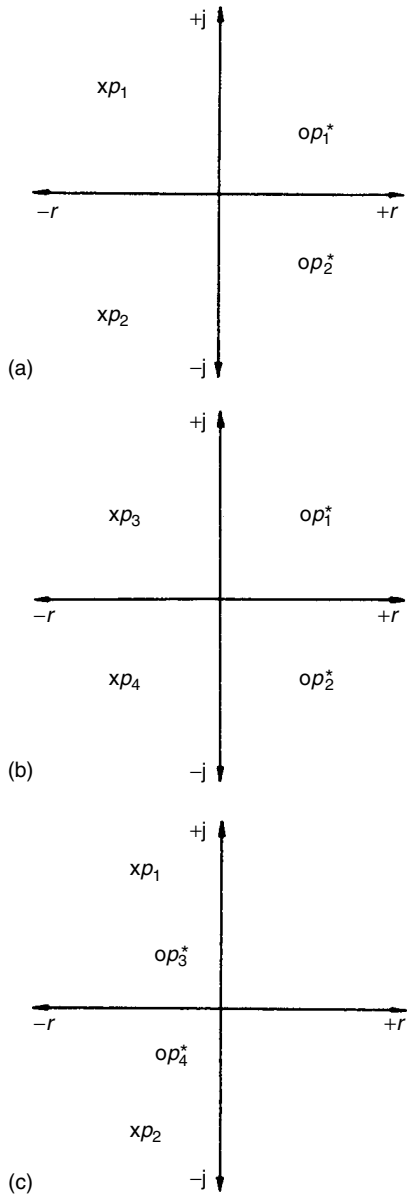

Figure 10. (a) Nonminimal-phase system (b) an all-pass system; and (c) a minimal-phase system.

Because of the relationships between performance in time and frequency domains, it is possible to calculate either of these functions if the other one is measured.

Often, it is the availability of test equipment that decides which of these characteristic functions is to be found. For instance, to test the frequency response of a temperature sensor, it is easier to rapidly change its environment (impulse stimulus giving a time domain response) than it is to apply cyclically varying temperature (frequency domain).

Testing of systems is performed by means of test signals produced by a test generator, recording the corresponding

Table 2. Survey of test signals.

Characteristic function	Input test signal	Output function	Characteristic values
Differential equation	Not specified	Not specified	Time constants T_r
In the frequency domain	Harmonic oscillation $x = \widehat{X}e^{j\omega t}$	Frequency response $G(j\omega)$; Transfer function $G(p)$	Critical frequency $f_c; \omega_c$
In the time domain	Unit step function $w(t)$ Unit pulse = Dirac delta function $\delta(t)$	Transient response $h(t)$ Weighting function $g(t)$	Transient time t_r, dead time t_d, delay time t_l, compensating time t_c, overshoot Δx_0
Stochastic functions	White noise $S(\omega) = \text{constant}$	Cross-correlation function $\psi_{xy}(\tau) \triangleq g(\tau)$	Transient time t_{tr} Correlation time t_{corr}

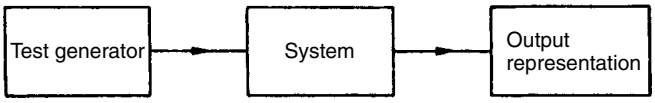

Figure 11. Testing of systems.

output signals as illustrated in Figure 11. Table 2 gives a survey of the test signals used, the output signals, and the characteristic values used for approximations. Today, the process of obtaining the characteristic functions is usually automated, making use of digitally programmable function generators that are controlled by microcomputers, to form the appropriate input signals.

In particular, the frequency response $G(j\omega)$ is obtained by measuring both phase angle and proportion of the amplitudes of output to a given sinusoidal input.

Before recording the true values, it is necessary to wait until the steady state solution appears, that is, $t > t_{tr} = 1/(2f_c)$.

If the measuring device itself has a nonideal frequency response $G_x(j\omega)$, $G_y(j\omega)$, the real frequency response $G(j\omega)$ may be calculated from the incorrect value $G^*(j\omega)$ by means of the relation (Woschni, 1972)

$$G(j\omega) = G^*(j\omega)\frac{G_x(j\omega)}{G_y(j\omega)} \tag{7a}$$

Other principles of calibration make use of comparison systems or reciprocity principles for systems with reversible operation (Woschni, 1972).

If the characteristic functions in the time domain, $g(t)$ of $h(t)$, are to be found, a problem arises in that the input signals are not the ideal ones, as shown in Figure 12 for a nonideal step function $w^*(t)$. Instead of the real transient response $h(t)$, $h^*(t)$ is used:

$$h^*(t) = \frac{d}{dt}\int_0^t w^*(\tau)h(t-\tau)\,d\tau \tag{7b}$$

By means of a deconvolution, it is possible to gain the real transient response where $w^*(t)$ is known (Woschni, 1972).

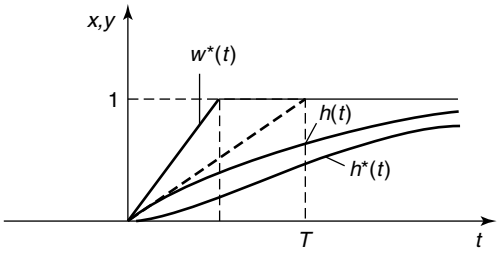

Figure 12. Testing with a nonideal step function $w^*(t)$.

In practice, it is usually sufficient that the rise time of the step function is smaller than one magnitude of the transient time of the system to be tested.

Of practical importance, especially for self-adaptive systems, are those methods of identification that use the noise as the input of a system (Davies, 1970). The weighting function $g(t)$ may be calculated by deconvoluting the relation

$$\psi_{xy}(\tau) = \int_0^\infty g(t)\psi_{xx}(t-\tau)\,dt \tag{7c}$$

with $\psi_{xx}(t)$ autocorrelation function of the input and $\psi_{xy}(t)$ cross-correlation function.

Because the deconvolution technique becomes difficult, methods in the frequency domain or special noise sources are used (Davies, 1970). Use of white noise yields

$$\psi_{xy}(\tau) = \text{constant} \times g(\tau) \tag{7d}$$

which means that the weighting function becomes a constant multiplied by the cross-correlation function (Woschni, 1988). For more details, including errors arising from use of a nonideal correlation function, and the reduction of errors see Davies (1970).

1 DEFINITION OF DATA AND ITS CHARACTERISTICS

Data in a measurement system is the raw form of what comes out of the measuring equipment. Measurement apparatus is applied to the phenomenon, which is observed and produces whatever representation of the observed phenomenon is consistent with the transformation effected by the instrument. A measurement system has two essential elements involved in the process of production of data; being the observed phenomenon and the measuring apparatus. Data is the result of the application of the apparatus to the phenomenon. The observed phenomenon has some state, which follows from the fact that there is some reality present, and that state is observed by means of the application of a standard instrument of a kind, sensitive to variations of some kind in the observed phenomenon.

The explanation above is necessarily abstract, because it intends to consider the broad range of possible scenarios, in which the phenomenon may be either a tangible attribute of tangible objects, such as mass, or some intangible attribute, such as intelligence. In any case, the instrument applied must be of a suitable kind to distinguish manifestations of the phenomenon in such a manner as to effect a mapping to a scale used for description of the phenomenon. This relationship is illustrated in Figure 1, which shows in symbolic form the relation of the observed phenomenon, X, which is an attribute of something, usually a tangible object, which may or may not itself be tangible. The measuring instrument transforms this to a parameter, Π, which is the data achieved by the measurement process. The transformation linking the phenomenon to the parameters is called Ψ, to symbolize that this transformation is a physical transformation.

The domain of the mapping, Ψ, is the possible value of the attribute manifestation in the observed, X; the range is the mapping of that domain into the data space of the possible parameter set, Π. A data set is produced when instruments are correctly applied to the observed. The data may take many forms but it is an image of the observed reduced to the dimensions detected by the instrument used. The image is 'flatter' than the observed because it could be investigated with respect to multiple attributes, but the image is the result of observation with respect to only a subset of the whole. This section is based on (Ferris 1997a, b, Section 8.3).

2 DEFINITION OF INFORMATION AND ITS CHARACTERISTICS

Information is a step up on data in complexity and value. Measurement data are the symbols representing the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

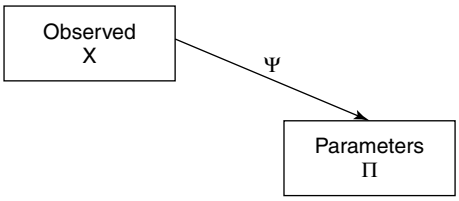

Figure 1. Illustration of the relation of the observed phenomenon, X, which is observed using a measurement instrument performing the transformation, Ψ, to produce the data, parameters, Π.

observations, whereas measurement information is the representation of the observation, which is embodied in the data (Crouch and Sydenham, 1994). Data is not information, but data contains information, which is the significance of the data, and is the vehicle for shifting information around. Depending on the representation scheme, the symbols may or may not appear to correspond with their significance. Information must be conveyed symbolically because significance cannot be directly transferred (Ayer, 1969; Jolley, 1973).

The distinction between data and information can be usefully drawn by considering the work done in quantification of 'information' in different disciplines. Let the measure of information developed by Shannon in communication theory be I_{Sh} (Shannon, 1964) and that developed by Dretske in philosophy be I_{Dr} (Dretske, 1981). In this analysis, I_{Sh} is found:

$$I_{Sh} = k \times \ln P_f \tag{1}$$

where $k \in \Re$ is a constant

P_f is the number of possible message forms

and I_{Dr} is found:

$$I_{Dr} = k \times \ln P_m \tag{2}$$

where $k \in \Re$ is a constant

P_m is the number of possible message meanings.

Both these measures of information quantity are important in measurement theory since instruments produce a representation of the observed in the form of parameter data, which must be communicated within the system, and information is carried by that data as a means of communicating something of substance about the observed.

I_{Sh} relates to the channel capacity required to convey the measurement data in a digital form. The number of possible message forms is the total number of possible different messages that could be conveyed using the number of digits in the message representation. The quantity of data I_{Sh} is dependant on such measurement system characteristics as the range and resolution of the instrument, which together define the number of states of the observed phenomenon that the measurement apparatus is capable of distinguishing. However, the representation of the data demands an integer number of bits, and so the minimum possible value of I_{Sh} is rounded up to the nearest integer above the number of resolvable states of the observed.

I_{Dr} pertains to the resolution of meaning effected by the message and so relates to the number of distinct cases that can be represented by the data in the system. The number of resolvable states of the observed is the number of possible meanings in the data received. Therefore, certainty of a particular state reduces the uncertainty about the state of the observed by defining which one of P_m possible states is present. The consequence is that I_{Dr} is as defined above.

The above discussion makes it clear that $I_{Sh} \geq I_{Dr}$. This is proved in Ferris (1997b, Th 3.3).

3 DEFINITION OF KNOWLEDGE AND ITS CHARACTERISTICS

Knowledge is a more complex and valuable entity than information, but is dependant on information. Information is not knowledge but is the foundation upon which knowledge is built. Information is transformed into knowledge when integrated with other information about the observed phenomenon, which enables the observer to increase understanding of the instance of the observed phenomenon through the observations that have been made.

The concept of knowledge is commonly associated with communication effected through natural language and this is a useful point to develop an understanding of knowledge in a measurement situation. Natural language communicates knowledge, that it has meaning, through the existence of many definitions, relating to words and the implications of grammatical constructions; conventions, relating to the interpretation of the combination of linguistic expression and context; and intention, relating to the purpose for which a particular speaker assembles a particular combination of words to assemble a means of communication of a thought (Burge, 1975). In a natural language communication situation, knowledge arises because the listener hears the discourse and interprets it in the light of the combination of the known definitions, conventions, and perceived intentions of the speaker.

To derive knowledge about the observed phenomenon is a common, and worthy, purpose of measurement activities. But, in the measurement situation, the data and the information that the data contains arises in a quite different situation than natural language. Measurement information arises

from nature, not intention, since measurement information is a statement of the state of a particular phenomenon at the time of observation (Butcharov, 1964). Therefore, interpretation of measurement information to produce knowledge of the observed is not affected by the factors used in interpretation of natural language, these being definitions, conventions, and intentions.

To obtain knowledge from measurement information requires that information existing because of the nature and structure of the world be assigned significance by the interpreter of the information. Situations, such as measurement, in which information exists independent of intention are fundamentally different than cases where information exists as a result of intention (Lewis, 1946; Brodbeck, 1968). Where information arises out of nature, the interpretive approach of perception, in which the information is recognized as containing evidence that the observed phenomenon is in a state evidencing one of some finite number of meaningful categories, is required. Perception is a process of recognizing that an observed phenomenon corresponds to a class of phenomenon that the perceiver knows and so the case observation is linked into a meaningful structure of knowledge of the world, and so the observed state of the observed become the basis of knowledge of the contextual significance of the state of the observed.

4 DEFINITION OF WISDOM AND ITS CHARACTERISTICS

Wisdom is the ability to judge the appropriateness of action and to behave in the correct manner in a situation. Wisdom has been recognized and valued since ancient times, having formed one of the traditional branches of philosophy. Some ancient philosophies were essentially embodiments of wisdom, with examples of this kind of writing found in Confucius and parts of the Old Testament, amongst other sources.

In measurement systems, wisdom relates to the taking of appropriate action on the basis of the observations made through the sensors. This occurs in two ways, the automatic feedback control system and systems in which measurements contribute to decisions.

In an automatic control system, illustrated in Figure 2, there is a controlled variable, the output, which is observed using a sensor. The signal produced by the sensor is used as an input to the primary system to adjust the output. The intention is to have a system in which the actual output approximates as closely as possible, at all times, the desired output.

In the case of a feedback control system, 'wisdom' is defined in the control loop design as the control input

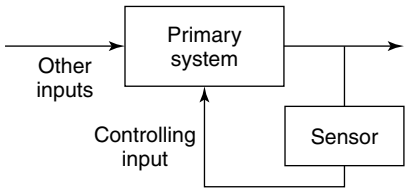

Figure 2. A generalized automatic feedback control system block diagram.

required to adjust the behavior of the primary system so that the output becomes the desired output. Determination of the control input is nontrivial because the control system is a dynamic system, which normally involves complicating factors such as time delays, with the result that a simplistic adjustment of the control input is liable to introduce significant problems such as overshoot, undershoot, or oscillation of the output relative to the desired output value.

In a measurement-based decision system, the contribution of the measurement system is to provide knowledge that classifies the observed phenomenon in a way that enables a decision to take appropriate action. The action may be taken by either a person or a machine. In a measurement-based decision system, the action taken is not a feedback control action of seeking to adjust the controlled output, but rather is an action of an apparently unrelated kind that is an appropriate action to take on the basis of the measurement observations. For example, in medicine, a patient may be measured in one way or multiple ways, resulting in knowledge of the state of the patient, embodied in a diagnosis. The action of wisdom, performed by the doctor, is a particular therapeutic maneuver, performed to correct the situation evidenced by the state of the patient, but not as a mechanistic adjustment of a control input that adjusts the observable output to lead to the conclusion that the patient's state is satisfactory.

5 RELATIONSHIP BETWEEN DATA, INFORMATION, KNOWLEDGE, AND WISDOM

Data is the lowest level of entity that is used in a system for processing matters of meaning concerning things. Data can be transformed into information when the data is organized into a form that distinguishes between resolvably different cases of the observed phenomenon. Knowledge is gained when information from one or more sources is integrated and analyzed to produce a coherent understanding of the matter of observation. Wisdom concerns the performance of appropriate action based on integration of various sources of knowledge. Wisdom normally involves analysis of items,

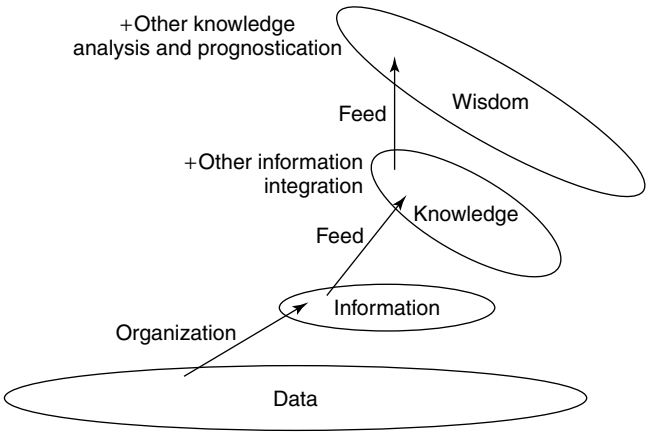

Figure 3. A pictorial representation of the relationship between data, information, knowledge, and wisdom.

probably many, of knowledge, and some kind of modeling of the situation in order to provide prognostication of the outcome resulting from various possible actions. The ideas of this paragraph are expressed in Figure 3.

Each of the elements, data, information, knowledge, and wisdom is a member in a hierarchy of both complexity, order, and value. The relative sizes of the elements in Figure 3 is also significant. Following the relation stated at the end of the Section 2 that discusses information, it is, in general, true that the quantity of information is less than or equal to the quantity of data in a measurement system. Knowledge, if quantified, would be less than or equal to the quantity of information because knowledge concerns categorization of the observation into meaningful categories of distinct. The quantity of wisdom is the smallest because there is always one best solution, although in many situations it may be unclear what the best solution is, and one rational and justifiable solution is selected from a small group of candidate actions instead.

The entities are situated in a stack of increasing order, because each entity is an expression of a more ordered arrangement of representation of the state of the observed phenomenon and the appropriate action arising from that state. The order is found in the fact that the entities each express the understanding of the observed phenomenon in greater simplicity of representation of the observed.

The complexity of representation decreases as one progresses upwards in the stack of elements. However, the complexity of the elements themselves increases as one advances up the stack because the simplicity of representation results from increased integration of various factors into the representation of the observed effected at each level.

In summary, a measurement process is used to collect data about the observed phenomenon; that data is organized as information about the observed and leads to the knowledge of the state of the observed phenomenon when integrated with other information about the observed; and the knowledge, when integrated with other knowledge about the observed and its context provides a basis for the exercise of wisdom.

1 HOW INFORMATION PROPAGATES FROM DISCOVERY

The world contains an infinite amount of latent information – that residing within systems, waiting to be established. The creation of available information begins with people who convert some of the latent information into a recordable form that suits the storage classification then in vogue. Figure 1 depicts how information passes around a circuit in which the information that is useful to measurement finds its way back to be the basis of the design of more measuring instruments, which in turn aids the flow of more information.

2 INFORMATION FLOW FROM SOURCES TO DEPOSITORIES

Figure 2 provides an appreciation of the flow of information through the many kinds and places where information may be found. Scholarship and experimental observation lead to latent information being made available; the first stage is termed *primary information*. This may occur as internal reports within organizations, in the personal records of workers, or in primary published literature. At times, books, often regarded as secondary sources, will contain primary material.

Within a few months of being established (weeks in some cases), primary information, of the publicly open kind, will often be published in primary journals where it is available through library services. Material published in primary journals is usually subject to expert refereeing that helps maintain, but cannot guarantee, the quality of reported material.

Primary information is also available in student theses (dissertations), patent specifications, and in some conference proceedings. A considerable part of it is held in company and defense secret locations where it is not openly available. It is also to be found in the proceedings of conferences, a source that may not be as well refereed as reputable primary journals; but it is usually available sooner.

There are no universal rules to regulate what is published, or where it is published. Primary information often also appears in part in the next class, the secondary outlets. Academic researchers work with the moral duty to publish their findings, but the same does not apply to many others. Because something cannot be located in open depositories is no guarantee that it has not been externalized from the latent state.

Primary information is, for a variety of reasons, not always presented in the form that is required, so it gets processed in many ways. It may need to be collected together to form a work on a common topic, or be reexpressed in a more acceptable form for others to make use of it. In this class are secondary journals, reviews, books, encyclopedias, dictionaries, videotapes, DVDs, CDROMs, the Internet, audiotapes, and films.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

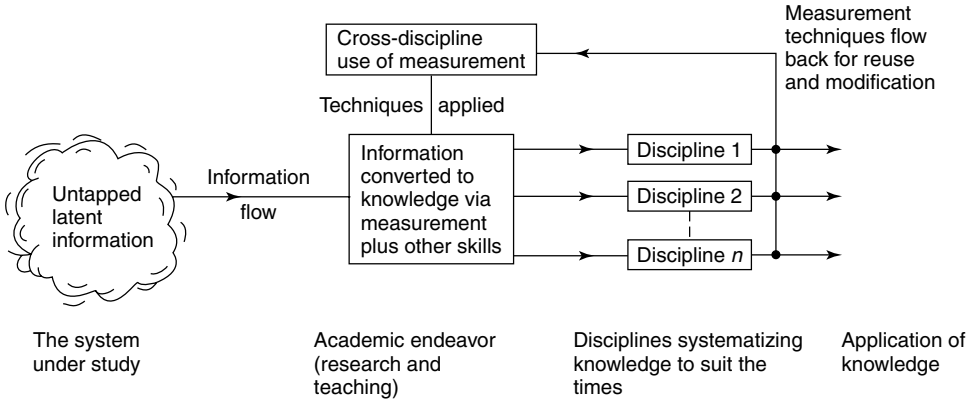

Figure 1. Extraction of latent information leads to new measuring instruments.

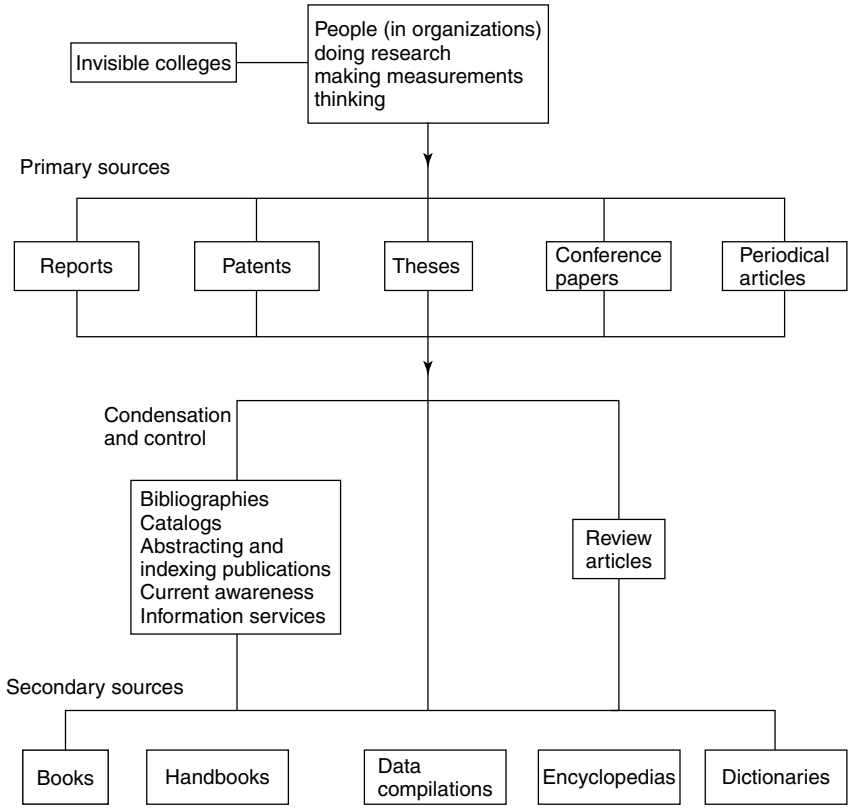

Figure 2. Flow of information through recorded, retrievable systems of documentation. (Reproduced from Melton (1978) with permission of Institute of Physics.)

Secondary information is usually easier to apply, for it distills the essence from the primary reports, leaving out the detail that does not stand the test of time or that is of little bearing to its use.

A major kind of published secondary source is that comprising the reference material that aids retrieval of primary material – bibliographies, abstracts, catalogues, information services.

Reviews and bibliographies are formed from secondary information but their construction, classification, and presentation can present a primary viewpoint, often being original in nature.

3 PROBLEMS OF SCALE

The rate at which information is published is almost incomprehensible. By 1900, the Royal Society in London had to abandon its attempts to catalog all of the scientific publications from 1800 to 1900 – the Author Index alone was

19 volumes in length! In 1974, an estimated 80 000 regular scientific and technical journals in a total of 150 000 of all kinds of journals were being published. Abstracting periodicals then numbered 1500, in a total of 3500. An estimate of that time suggested there were 300 000 books published in a year with over 3000 million books in print. By the end of the twentieth century, this increased exponentially to vast numbers. The rate is not slowing.

The diverse nature of measurement means that information needed could rest almost anywhere in the vast system of documentation, if it exists at all. Well-devised retrieval is essential to glean information in an efficient manner.

4 ENTER THE INTERNET

To provide a more reliable method of communication information, the United States created what has today become known as the Internet or simply the Web. This has grown over the past decade into a vast network of millions of computers that are all connected together via the servers of Internet Service Providers (ISP). The Web is now predominantly used by civilians all over the globe.

These computers offer information on a virtually infinite range of topics. To find the required information, the user makes use of search engines to mine down into the vast resource to select those instances that appear relevant. The user then opens them to see if they are what is needed; many are not, and much time can be wasted in seeking what is not there!

Search engines currently only allow users to locate material on topics of their choice by using symbol searches for words and strings in text files. Being developed, and more widely available soon, will assuredly be the facility to search images for contextual graphical constructs; this uses ontologies for topics, these being large sets of relevant rules about the structure and content of images of the supported domain. For example, the textile industry is adopting this method as a means to find patterns from large numbers of different designs now stored as images in computers. Software applications are available, which use this method for searching images. The development of the ontologies needed is a costly business. A typical ontology will contain over 100 000 rules.

The availability of the Internet can be likened in the time span of man to the epoch when the printing press of the 1400s made information available to many more people of that time. Then, recorded information was only available to a privileged few in painstakingly produced single copies of books of the monks, and in the art of religions such as stained glass windows and paintings.

The Internet has made information available to just about every person on the Earth at a comparatively affordable cost and in almost any geographical location.

On the surface it would seem that the Internet gives its millions of subscribers all they need to know for free. Searches will indeed often discover considerable material on a topic of one's choice. The reality is, however, that the freely available information may not have the veracity required, its time stamp is not always clear, and it rarely provides a sufficient depth of knowledge to allow serious decisions to be taken from it.

Publishers of the traditional technical books have placed considerable emphasis on offering book material online via their highly developed Web sites. These sources of knowledge can be relied upon better and do give organized material that is refereed and recorded in a highly professional and concentrated manner. To provide this service, they must charge fees by subscription or, along the way, as a 'pay as you use' service.

Benefits of having information stored in the electronic, or e-file form, as compared to the traditional hard copy form, are many:

- Access is to any part of it with immensely faster find times for specific knowledge than by using books.
- Hugely larger sets of information can be made available at virtually any location.
- Parts can be selected and reused to form new sets of knowledge (where this is permitted).
- Upgrading the information is a matter of editing files; no reprinting of all of the information with its changes is needed.
- Foundational knowledge will become clear and settle down to allow expansion from sound foundations and not be rejigged for each new edition of a book.

Measurementor, www.measurementor.com, Sydenham (2004), is an example of this form of information delivery. Some of its statistics illustrate the problem that will be faced by those needing up-to-date and definitive knowledge.

Creating the basic knowledge base listing for it showed that the sound set of information needed by a measurement system designer would involve over 4000 one-page items and that even this set of information could only serve satisfactorily as an entry gateway to their fuller needs. It has been estimated by this writer that at least 1000 books would be needed to provide a deep library of information for a profession. All of the titles could not be economically created by one publishing source alone. Internet and gateway products, like Measurementor, can provide this degree of access, for it allows thousands of commercial providers to offer material that sits in their specialty area.

Several Web sites give useful information on measuring systems. They are useful but too often only get the user acquainted with the topics. They also are not coordinated with respect to their information, nor structured to any scheme that stands much scrutiny.

GlobalSpec, http://www.globalspec.com/, claimed to be the world's largest database of technical products and services, provides rapid location and access to a vast number of items – 9000 suppliers catalogues, 850 000 product families and 45 million parts. Many are supported with explanations given in its tutorials and application notes of its Technical Library. The aim of the service is to sell products and services to users on behalf of its clients.

The Sensors magazine Web site http://www.sensorsmag.com/ provides a Literature Showcase for many companies and gives access to the past articles of the Sensors magazine. Search facilities are provided to assist in finding material.

Many manufacturers of measuring systems and instruments offer information assistance via their own Web site. An example of the upper end of this type of information support is that of National Instruments http://www.ni.com/. In their offerings is a service called 'Instrupedia' – a short encyclopedia of measurement that will be found to be useful at times.

The impact of the Internet is already clearly evident. It seems reasonable to suggest that within the next decade, e-sources of information will become routinely linked to parts of all people's lives, especially in support of their professional duties. Already the law and medical professions have taken up Internet use to give their practitioners rapid and full access to their particular bodies of knowledge. Others will follow as the cost of time and time taken to locate information becomes a major cost factor in such areas as teaching, design, and procurement fields.

1 TERMINOLOGY USED IN MEASUREMENT

Information retrieval by browsing through original material makes use of many recognition features – words, illustrations, mathematical formulas – but this method is invariably too slow for searching the bulk of the literature.

Realistic retrieval procedures are almost exclusively based on the principle of tracing linguistic terms used by authors in their titles, abstracts, and index keys. Consequently, the choice of terms written into abstracts and used in searching is of paramount importance.

The diversity and uncoordinated multiplicity of the sources of generation (and regeneration!) of instrument concepts has brought with it a highly varied and inconsistent nomenclature. Indeed, some terms used have multiple meanings. It is only in recent times that standardization of terms has begun to be accepted; they are not, as yet, widely used nor broadly developed. Data bases relevant to measurement knowledge are discussed in **Article 42, Information Databases of Relevance to Measurement, Volume 1**.

The wide and often incorrect use of synonymous terms makes literature retrieval difficult. Apparently obvious terms often lead nowhere – metrology, measurement, sensor, and instrumentation in particular; they are too commonly used. The name *instrument science*, for example, might be indexed using at least 10 alternatives, such as measurement systems, measurement physics or measurement science, and so on. The fundamental term *metrology* also has at least two different meanings and it often gets confused with 'meteorology'.

Terms describing the activity of the process of measurement exist in great abundance. Figure 1 lists some of these. It is easy to see how many different terms are used for describing the same thing.

2 LIST OF KEY TERMS RELEVANT TO MEASUREMENT

Measurement, in many specific disciplines, has its own name. Figure 2 lists a compilation of these. Thus, the literature of measurement is spread over the whole body of knowledge. Use of a large-size dictionary usually gives little assistance in separating them, for it is their technical

relate to the activity of measurement these being contained in the thesaurus of the INSPEC™ database.

4 CLASSES OF PUBLICATIONS RELEVANT TO MEASUREMENT

Consider now the necessary classification of a measurement classification from the author's and reader's viewpoints. It is found that numerous possibilities exist for deciding the key list of index terms.

In general, authors contributing to measurement align more with their field of application or discipline than with sources publishing fundamentals of measurement science. Often, they see the instrument content as insignificant and not worth abstracting in their report. Many facets of a report might not be cited in the few keywords used.

The reality is that the report on a topic including measurement, although given several descriptors, should only be published in one journal. Ethics suggest this is the correct policy, but there is a case for multiple releases in different types of publications so that the contribution can be found by those who need it, as they approach the material from different perspectives.

As an example, consider a hypothetical report containing, as part only, the calibration of a novel, laser-based, alignment system used, by the XYZ Company, to test the military load-carrying capacity of an historic concrete bridge while the bridge is conveying a mobile nuclear reactor. Just where the report should be published is an open question.

A report can be placed into an outlet that emphasizes, with an example of each, its

- principle used (Hall effect)
- philosophical thinking (impact on the philosophy of science and technology)
- application area (manufacturing)
- device (SQUID)
- technology (MEMS)
- theory (sensitivity analysis)
- proprietary aspect (XYZ new product)
- fashionable topic (fuzzy systems)
- industry (user survey), and so on.

Many primary journals publish measurement contributions. Those more obviously dedicated to measurement are many. Figure 4 gives a list of measurement-related journals that could be chosen for publication of the above report. It also gives the rationale for the choice of each.

Other aspects might be that it relates to include transportation, power generation, environmental issues, civil engineering, environmental safety, and many more.

Authors should pay attention to the need to prepare several papers on a major topic, each on its key aspects and for a different readership.

5 LIBRARY CLASSIFICATION SCHEMES

Now consider classification from the viewpoint of location in a library collection. The location of book literature is identified in a library by the classification code-numbering

Example: Calibration of a novel, laser-based, alignment system used, by the XYZ Company, to test the military load-carrying capacityof an historic concrete bridge while the bridge is conveying a mobile nuclear reactor.

Class basis chosen	Example of typical journal for publication
Physical principle used (interferometer)	Applied Optics
Discipline based on a device used (laser)	Laser Focus
Contemporary nature (novel and timely)	New Scientist
Military relevance	Classified report of a military organization
Discipline of use (surveying)	Photogrammetric Engineering
Parameter of measurement (measurand is related to strain)	Journal of Strain Analysis
Measurement principle used (angle measuring interferometer)	Measurement Science and Technology
Constructional material used (concrete)	Magazine of Concrete Research
Standardization (calibration)	Newsletter of National Conference of Standards Laboratories
Design implications	Journal of Elasticity
Testing	International Journal of Non-destructive Testing
Instrumentation detail	Instrumentation and Control Systems
Engineering heritage	Transactions of the Newcomen Society
Trade journal	XYZ Affairs (hypothetical name)

Figure 4. Classes and example journals in which an instrument might be reported.

scheme used. Placement and retrieval are based on an allocated code number to each title, not by the use of a set of key terms, as is the case in computer retrieval of journal literature abstract information.

Several schemes of library location classification are in use. Predominant systems in use are

1. Dewey Decimal Classification;
2. Library of Congress (LC);
3. Universal Decimal Classification (UDC).

Other schemes used are local subject code allotment and even author order, but only in some cases. Subject retrieval by that alone is virtually impossible in this last case. Electronic catalogs have made it easier to find material, for they can search in words in the title, extended keywords, and abstract where used.

Each of the established systems has its prime-listing directory – such as the Dewey Decimal Classification and Relative Index.

The UDC system is fundamentally supported by an extensive set of British Standards Institution standards documents, which enable great detail in subject identification. For instance, one code number is specifically for the cards used to print weight in automatic weighing machines! In practice, some libraries using the UDC system make use of a much abridged version.

UDC and Dewey are somewhat alike, but not identical. The LC system is quite different in code allocations. Equivalence between LC and Dewey codes is published.

The diverse and ubiquitous nature of measurement often makes classification of such material a difficult decision. It is publishers who assign a class call code to a book, that being part of their publishing support – but those that assign them are seldom experts on measurement literature. Most acquisition librarians will make use of this call number, for they also will not be expert enough to challenge the one allocated.

It is, therefore, quite possible for a book to be placed in one of many alternatives – it is not unheard of for a second edition of a book to be coded differently than the first!

6 LIST OF DEWEY CLASSIFICATION CODES WHERE MEASUREMENT MATERIAL IS LOCATED

The lack of structure of the knowledge of measurement science is reflected in library holdings: material will be found diffused throughout many classes. An impression of the situation is obtained by the study of the selected list of subjects and code numbers given in Figure 5 that is taken from the Dewey Classification. Overall, the system contains over 30 000 named code numbers of which at least some 700 are measurement related.

For most effective searching, the full classification would need consulting – a matter of many days of work! Library catalogs will have an alphabetical subject index in their entries but this will seldom provide the detail sought. The wide choice of measurement topics requires searching on the basis of a detailed study of the handbook of the classification system – but even then a book might not be in the class to which a user thinks it should be allocated.

It is appropriate here to explain the development of the Dewey Decimal System, for this has a strong bearing on current day problems with its use in class engineering and technology titles.

The Dewey system was devised in the late nineteenth century when technical publishing was in its infancy. Its structure is a reminder of who did the intellectual thinking at that time. Its construction did not cater to the subsequent explosion of technical knowledge. For this reason, subjects that often began as quite a reasonable and small subset of knowledge have had to be allocated a relatively extended code length, thus going deep into the numbering system.

For that reason, already long code numbers had to be greatly extended to cope with what are now major subsets of knowledge. For example, the 620.0–629.0 series was devoted to engineering and allied operations. This required electrical measurements to have a long call number of 621.381043.

All this contrasts with the nineteenth-century awareness of time measurement that allocated the code 529.78 to that topic. It can be seen that length of the call number is not an indicator of depth of specialist topics.

Many aspects of modern measurement are not placed in the Dewey Decimal Classification where they could now be expected to be in a library. For example, telegraphy (384.1) is placed in the Social Science 300's group. Holography (774) appears in the Arts 700's group along with games theory at 795.01. Computing has all but taken over class 1.0, originally assigned to knowledge.

In some, but not all, groups, there is a specific code for relevant instrumentation for that application. An example is that of flow properties and their measurement (532.053). This is not at all standard practice – many principles or application areas of measurement do not possess such a specific measurement aspect call number.

Occasionally, to add yet more difficulty, a new volume of the classification index itself is published. This requires some changes to codes (deletion, placement elsewhere, new code numbers). This produces only minor changes in the location of titles in the established libraries as it generally affects only books cataloged after that event.

Dewey Decimal code	Classification volume entry
001.422	Statistical method (formerly 311.2)
001.51	Communication theory
001.53	Cybernetics
001.533	Self-organizing systems
001.6	Data processing
003	Systems
016	Bibliographies and catalogs of specific disciplines and subjects. Note: Other codes used such as —.0 of notation
119	Number and quantity
120	Knowledge, cause, purpose, man
121	Epistemology
152	Physiological and experimental psychology
169	Analogy
330	Economics
339.3	Measures of national income
364.12	Criminal investigation (Detection)
368.011	Rates and rate making (Insurance)
371.26	Educational tests and measurements
378.16	Educational measurement and student placement
384.1	Telegraphy
384.9	Visual signaling
389	Metrology and standardization
501	Philosophy and theory
502.8	Techniques, apparatus, equipment materials
511.43	Error theory
512.7	Number theory
515.42	Theory of measure and integration
519.52	Theory of sampling
519.86	Quality control and other statistical adjustments
522.2–522.5	Instruments (astronomy)
526.3	Geodetic surveying
529.75	Time systems and standards
530.16	Measurement theory
530.7	Instrumentation (for measurement, control, recording)
530.8	Physical units, dimensions, constants
531.382	Elastic constants and their measurement
532.053	Flow properties and their measurement
534.4	Measurements, analysis and synthesis of sound
535.33	Optical instruments (see also specific functions class) Microscopes formerly 578.1
536.5	Temperature (536.51–536.54 Measurement)
539.77	Detection and measurement of particles and radioactivity
542.3	Measuring apparatus (laboratory-chemistry)
543.07	Instrumentation (chemistry)
544	Qualitative analysis
545	Quantitative analysis
548.1	Geometrical crystallography
551.4	Geomorphology (.4607 is Deep sea surveys and exploration)
573.6	Anthropometry
574.028	(no key title given but biological instrumentation here see 610.28)
578.4	Use of microscopes
591.18	Movements senses, control mechanisms (Zoology)
610.28	Medical instrumentation (see also 574.028)
611.8	Nervous system and sense organs
612.8	Neurophysiology and sensory physiology (extensive sub grouping)
614.7	Environmental sanitation and comfort (614.71–614.77 cover pollution but no specific class for measurements)
615.19018	Assay methods (pharmacy)
616.07	Pathology (includes diagnoses and prognoses)
617.05	Surgery by instrument and technique
617.752	Optical work

Figure 5. Sample list from the likely Dewey Decimal codes that relate to measurement.

Dewey Decimal code	Classification volume entry
617.89	Audiology
617.9178	Surgical instruments, apparatus, material
620.0042	Engineering analysis, synthesis, design
620.0044	Testing and measurement (engineering)
620.1127	Non-destructive testing of materials (subgroups on radiographic, tracer, ultrasonic, magnetic methods)
620.32	Measurements (of mechanical vibration)
620.72	Systems analysis, synthesis, design
621.313	Generating machinery and converters (includes maintenance and testing)
621.37	Electrical testing and measurement
621.372	Units and standards of measurement
621.373	Recording meters
621.374	Measurement of electric quantities (various subgroups exist)
621.379	Measurement of non-electrical quantities
621.381043	Measurements (electronic)
621.38137	Testing measurements standardization (Classifier instructed to place measurements in group for application)
621.381548	Testing and measuring devices and their use (Electronic)
621.383	Specific instruments and apparatus of wire telegraphy
621.38417	Measurements and standardization (radio)
621.3843	Specific instruments and apparatus of radio telegraphy
621.3887	Measurements and standardization (television)
621.3895	Underwater devices (subgroups include hydrophics and Sonar)
621.4831	Reactor physics (includes testing of physical phenomena occurring within reactors)
621.4835	Operation, control, safety measures
621.756	Inspection technology (in factory operations engineering)
621.902	Machine tools (including numerical control and other automation techniques)
621.994	Measuring tools
622.15	Geophysical exploration (several subgroups)
622.8	Mine health and safety
623.71	Intelligence and reconnaissance topography (military engineering)
623.819	Design tests (nautical)
623.863	Nautical instruments
624.1513	Soil mechanics (includes tests)
624.17720–624.1779	Specific structural elements (includes strength tests)
625.794	Traffic control equipment
627.81	General principles (Dams and reservoirs) (includes surveying)
628.177	Measurement of consumption (sanitary engineering)
629.045	Navigation (celestial in 527)
629.1345–629.1346	Aircraft tests, measurements, standards, maintenance, repair (see subgroups)
629.135	Aircraft instrumentation and systems (many subgroups)
629.273	Panel instrumentation (vehicles)
629.4775	Control of temperature, humidity, air supply and pressure
634.9285	Mensuration (forestry)
637.127	Quality and purity determinations (cows milk)
640.73	Consumer education (includes guides to quality and value of products and services)
657.48	Analytical (Financial accounting) (Measurement of profitability, of financial strength, of income, of liquidity, of flow of funds)
658.28	Equipment for safety and comfort (includes noise control)
658.516	Standardization (equipment, procedures, in general management)
658.562	Standards and specifications (form, size, dimensions, quality, materials, performance, including standardization formerly in 658.16)
658.568	Inspection (includes statistical methods of quality control)
658.834	Consumer research (studies of consumer preferences, attitudes, motivations, behaviour)

Figure 5. (*Continued*).

Dewey Decimal code	Classification volume entry
660.283	Process equipment (chemical instruments, apparatus, machinery)
662.622	Properties, tests, analysis (of coal)
664.07	Tests, analysis, quality controls (food—for texture, taste, odor, colour, contaminants)
665.0288	Tests analyses, quality controls (oils, fats waxes, greases)
666.13	Tests, analyses, quality controls (ceramics)
669.95	Metallography
674.13	Properties and their tests (lumber)
675.29	Properties, tests, quality controls (leather, fur)
676.121	Properties, tests, quality controls (Pulp)
676.27	Properties, tests, quality controls (paper and paper products)
681	Precision instruments and other devices (several groups)
697.9315	Psychrometrics
697.9322	Temperature controls
771.37	Focusing and exposure apparatus
774	Holography
781.91	Musical instruments
788.971	Mechanical and electrical reproducers
913.0310285	Interpretation of remains (includes dating, use of data processing in ancient studies)

1 COMMONLY USED INFORMATION SOURCES FOR MEASUREMENT

There exist some, but not many, Internet-based services that provide valuable information on measuring systems as their main line of support. Major organizations that offer lists, guides, and relevant databases, INSPEC, National Conference of Standards Laboratories International (NCSL) and National Institute for Science and Technology (NIST), are covered in later sections.

Global Quality Services www.GlobalQualityServices.com offers a search engine in the field of metrology. It indexes a collection of Web sites in the field of metrology.

IMEKO (*International Measurement Confederation*) http://www.imeko.org is a nongovernmental federation of 34 national member organizations individually concerned with the advancement of measurement technology. Its objectives are the promotion of international interchange of scientific and technical information in the field of measurement and instrumentation and the enhancement of international cooperation among scientists and engineers from research and industry. It was founded in 1958. It offers information on the many meetings of its Technical Committees but does not provide detailed database information about measurement.

NI (*National Instruments*), http://www.ni.com provides a range of support services. One information service offered is a database of some 2000 instrument solutions; another is its Instrupedia, an Encyclopedia of Instrumentation provided on CD-ROM. The glossary part is provided online.

Ei COMPENDEX http://edina.ac.uk/compendex is a comprehensive interdisciplinary engineering information database having over six million summaries of journal articles and conference proceedings and 220 000 new additions every year.

It uses thesaurus-style indexing. Citations are arranged by subject and numbered sequentially; abstracts are provided. Each entry is indexed by article title, author name, and affiliation, journal or proceeding source, date of publication, and page length. Access to this database is via personal or shared accounts. It covers mechanical, civil, environmental, electrical, structural, process, materials science, solid-state physics and superconductivity, bioengineering, energy, chemical, optics, air and water pollution, solid-waste management, hazardous waste, road transportation, transportation safety, manufacturing, quality control, and engineering management issues. Thus, while it does not have a category for measurement, considerable content will be found on that topic by careful searching.

GIDEP (*Government-Industry Data Exchange Program*) http://www.gidep.corona.navy.mil is a cooperative activity between government and industry participants seeking

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

to reduce expenditures of resources by sharing technical information essential during the research, design, development, production, and operational phases of the life cycle of systems, facilities, and equipment. Its content contains metrology data, such as material constants. Utilization of GIDEP data can materially improve the total quality and reliability of systems and components during the acquisition and logistics phases of the life cycle, and reduce costs in the development and manufacture of complex systems and equipment. Again, it is not set up to support measurement as such but can be useful.

ISI® (*Science Citation Index*) http://www.isinet.com/isi/products/citation/sci provides access to current and retrospective bibliographic information, author abstracts, and cited references found in 3700 of the world's leading scholarly science and technical journals covering more than a hundred disciplines. The Science Citation Index Expanded™ format and the online version, SciSearch®, cover more than 5800 journals.

BIOSIS http://www.biosis.org has the objective of facilitating understanding of the living world by helping researchers, educators, students, and others in accessing information relevant to the life sciences. It is an entire life sciences file corresponding to Biological Abstracts (BA) and Bio Research Index (BioI). It includes, from 1969, biomedical material and is sourced from over 9000 serials.

Biology Browser www.biologybrowser.org is an interactive portal designed for the life sciences community. It creates a dynamic environment that connects users with valuable information through interactive discussion forums, quality-controlled Web links, science news, and other free resources.

CHEMCON http://www.chemcon.net is a global network of chemical conferences in the field of chemical control regulations.

CDI http://www.virtualref.com Comprehensive Dissertation Index (not to be confused with another CDI, the Center for Defense Information) contains all dissertations at academic doctoral level granted in the United States and in over 125 other-country institutions. It covers from 1861 and grows at over 500 citations a month. Since 1976, coverage has been expanded to include European institutions, and later other institutions worldwide – but their coverage is rather patchy.

IFI CLAIMS http://www.ificlaims.com is a 45-year old, multifaceted, database holding data on US patents. It is offered as being a trusted and comprehensive source of US patent information.

CPI Conference Papers http://library.dialog.com has provided, since 1973, a Conference Papers Index (CPI) that contains over 800 000 entries of papers given at over 1500 major conferences. It provides citations to sessions presented at major scientific meetings around the world. Subject emphasis since 1995 has been in the life sciences, environmental sciences, and the aquatic sciences, while older material also covers physics, engineering, and materials science. Information is derived from final programs, abstracts booklets, and published proceedings, as well as from questionnaire responses.

ENVIROLINE http://library.dialog.com covers the world's environment related information. It provides indexing and abstracting coverage of more than 1000 international primary and secondary publications reporting on all aspects of the environment. These publications highlight such fields as management, technology, planning, law, political science, economics, geology, biology, and chemistry as they relate to environmental issues. It corresponds to the print material *Environment Abstracts*.

GEOARCHIVE http://library.dialog.com is a comprehensive database covering all types of information sources in geosciences, hydrosciences, and the environmental sciences. The criteria for inclusion in GeoArchive are that the source should be publicly available and have relevant information content, even if the reference is to a small news item in a magazine. It provides, from 1969, international coverage of over 5000 serials, books from over 2000 publishers, geological maps, and doctoral dissertations. It is indexed using *Geosaurus*, the hierarchical thesaurus that classifies references by subject, geography, and stratigraphy. It includes an alphabetical index of around 30 000 terms available from the producer. The printed publications *Geotitles, Hydrotitles, Geoscience Documentation*, and the *Bibliography of Economic Geology* are derived from GeoArchive.

ISMEC Mechanical Engineering Abstracts http://www.cas.org/ONLINE/DBSS/ismecss.html is a bibliographic database (from 1973) containing in-depth coverage of worldwide literature on mechanical engineering, engineering management, and production engineering. Theoretical perspectives and applications for current research results are included. Records contain bibliographic information, controlled and uncontrolled terms, and abstracts. A specific topic area is Measurement and Control.

NTIS (*National Technical Information Service*) http://www.ntis.gov is the central source for US government scientific, technical, and business information. It leads to titles on research and development activities published by over 200 US Federal Agencies. Audiovisual materials, computer data-files, and software are included.

WPI (*World Patent Index*) http://www.derwent.com files (partially, since 1963) patent specifications issued by the major industrial nations. It corresponds to CPI and WPI and grows at over 250 000 new inventions per year.

These few examples illustrate the various kinds of services that are available. Many may need to be searched

to locate measurement information; there seems to be no easier method than to patiently work through them.

2 INSPEC ABSTRACTING SERVICE

INSPEC http://www.iee.org/Publish/INSPEC is produced by the Institution of Electrical Engineers. It is a major English-language bibliographic information service providing access to the world's scientific and technical literature in physics, electrical engineering, electronics, communications, control engineering, computers and computing, and information technology. The INSPEC database was formed in 1969, being based on the *Science Abstracts* service provided by the Institution of Electrical Engineers since 1898. It provides Current Awareness, New Product Information, Technological Forecasting, Competitive Intelligence, and Patent-Related Searching. Over 3400 scientific and technical journals and some 2000 conference proceedings, as well as numerous books, reports, and dissertations are scanned each year for relevant articles to abstract and index for inclusion in the Database. It contains over 7 million bibliographic records and is growing at the rate of 350 000 records each year. It also publishes an INSPEC Thesaurus of terms that contains over 10 000 terms, of which at least 800 are relevant to a search for an instrument-related subject. As they are diffused throughout the whole set, considerable time is needed to properly choose suitable key terms. For an explanation of the difficulties of finding measuring systems literature *see* **Article 41, Terminology and Classification of Measurement Systems, Volume 1**.

3 NCSLI SERVICES

NCSLI (National Conference of Standards Laboratories, International) http://www.ncsli.org was established in 1961 as a professional association for individuals engaged in all spheres of international measurement science. It provides real-time professional career support and advancement opportunities and sponsors an annual technical Annual Workshop & Symposium. Topics covered by the site include implementing national and international standards, achieving laboratory accreditation, new measurement technology, advances in measurement disciplines, laboratory management procedures and skills, equipment management, workforce training, and new instrumentation. In particular http://www.ncsli.org/resources/index.cfm is an internal location for some useful resources. These include an Acronym and Abbreviation Glossary, Procedures Database, Training Information Directory and NCSLI Archives.

4 NATIONAL LABORATORIES

Technological countries have at least one of these carrying the responsibility for developing and maintaining the prime physical standards. They additionally offer staff expertise through consultancies and by participation in industry clubs.

The National Physical Laboratory (NPL), UK, http://www.npl.co.uk is an example. Their bibliography of staff publications can be useful at times but this site does not appear to offer lists and guides, as does the next of the NIST.

5 NIST SERVICES

The National Institute for Science and Technology, NIST, US – formerly the National Bureau of Standards (NBS) – http://www.nist.gov offers a vast array of pull-up information services. One of regular value is a guide to the use of SI units.

6 IMEKO BOOK SURVEY

The practical problems of establishing the existence of book material on measurement science and technology were recognized in 1978 by the Higher Education Committee (TC-1) of the International Measurement Confederation (IMEKO).

It was decided that the Committee should establish a list of titles for free distribution to member nations of IMEKO, and any other interested user. The bibliography was completed in 1980 (Sydenham, 1980).

Initially it was thought that the list would be quite short and that key articles in the serial literature could also be included. Entries were to be for works in the four official IMEKO languages – English, French, German, and Russian.

It was soon established that computer searching, at that time, was not productive for book location. The best approach was found to be to select entries from a decade collection of publishers' catalogs and promotional mailings, from committee members' personal book collections, and from visits to the catalogs of libraries that were closely related to measurement interests.

It was found that individual contributor's book lists rarely overlapped each other, yet each person was convinced theirs was in touch with the bulk of the related book literature. The final list includes over 800 titles up to that date. Books related to, but not directly concerned with, measurement and instrumentation (such as control theory, systems design) were not included. It is, unfortunately not yet available in electronic form.

Sections of the listing (by author only), cover

1. Fundamental concepts (theory of measurement for instance);
2. Units, standards, calibration;
3. Measurement uncertainty, results processing, errors;
4. Instrumentation practice (in 10 groups);
5. Instrument system design, construction, and evaluation;
6. Education and training;
7. Miscellaneous (mainly historical).

An entry is included only once in the listing.

The problems of deciding what are significant papers in the journal literature was addressed and found to be too problematic to produce. The truly vast quantity of papers available was realized when the first 18 instrument-related terms (of a possible 650 from the INSPEC thesaurus!) were combined with the term 'review' and tested on a short file length of INSPEC. It produced over 800 abstracts, most of which appeared to be valid entries for a bibliography. Clearly, the user must go direct to the databases to generate citations, sorting them online to yield those of individual relevance.

7 PERSONAL LISTS

Browsing, current awareness services, and other sources such as reprint requests and conference attendance, provide the individual with a steady influx of quite specific information. When the number of entries reaches a few hundred, it becomes necessary to use a computer database to record them. For this to be useful, it in turn requires ordered storage.

Traditional personal methods involving card indexes have given way to the use of personal computers, especially to the application of relational databases. Setting up citation references for general use is not easy for some 100 attributes are needed to define the paper and book reference in all of the ways required. Publishers ask for so many variations that it is not easy to accommodate them in a simple database. ENDNOTES is a database set up for processing bibliographies. There is no doubt that making satisfactory records of citation lists needs diligence and care to detail as the sources are found.

The tediousness of rekeying reference items into the required form could well do with increased use of standard formats for bibliographic entries.

Users with personal lists are encouraged to mount them in an enduring Web site and maybe then advise Measure-Mentor of that location for inclusion in its link.

1 UNITS

All measurement is made in terms of comparison with a like quantity. If we live in isolation, the latter quantity may be anything that we choose. However, we might lose the latter and if we wish to communicate the result with ourselves or with other people possibly in another place at a later date, then it is obvious that it is useful, even essential, that we all use the same reference quantity or can relate our more transient reference quantity to it. Thus, one might well use one's foot or a convenient stick when spacing plants in the garden, but would convert the spacing to meter if one were writing a book on planting.

The general arrangements by which this agreement is obtained are illustrated in Figure 1. The SI or Systéme International des Unités (Table 1) has been set up to achieve this universality and all dimensioned measurements may be related to the units of this system.

The English language has some 80 000 words, but with measurement we try to have the minimum possible 'vocabulary'. Initially, it was intended that all SI measurements would be expressed in terms of six basic units but it was decided that a seventh should be added in order to take account of the needs of chemistry and related fields (Table 2).

Many of our measurements are expressed in terms of jawbreaking combinations of these basic units. It soon became apparent that it was impracticable to have a 'measurement vocabulary' of only seven base units and the derived units were also agreed, the number of these being kept to a minimum (Table 3).

The current International Vocabulary on Metrology (VIM) defines a unit as 'a scalar quantity defined and adopted by convention, with which other quantities of the same kind are compared in order to express their magnitudes relative to that quantity'.

The following notes are added:

1. Units are designated by conventionally assigned names and symbols.
2. Units of quantities of the same dimension may be designated by the same name and symbol even when the quantities are not of the same kind. For example, the joule per kelvin, J/K, is the name and symbol of both a unit of heat capacity and a unit of entropy.
3. Units of dimensionless quantities are numbers. In some cases, these numbers are given special names, for example, radian and steradian.
4. If there is a risk of confusion, the term 'unit of measurement' should be used.

Units that are named after people take the lowercase for the name of the SI unit and the uppercase for the symbol; thus the ampere, symbol A, is the SI base unit of electric current.

1.1 SI conventions

The value of a quantity Q is given by the product of the numerical value of Q, $\{Q\}$ and the unit or units of Q, $[Q]$, thus:

$$Q = \{Q\} \times [Q] \tag{1}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

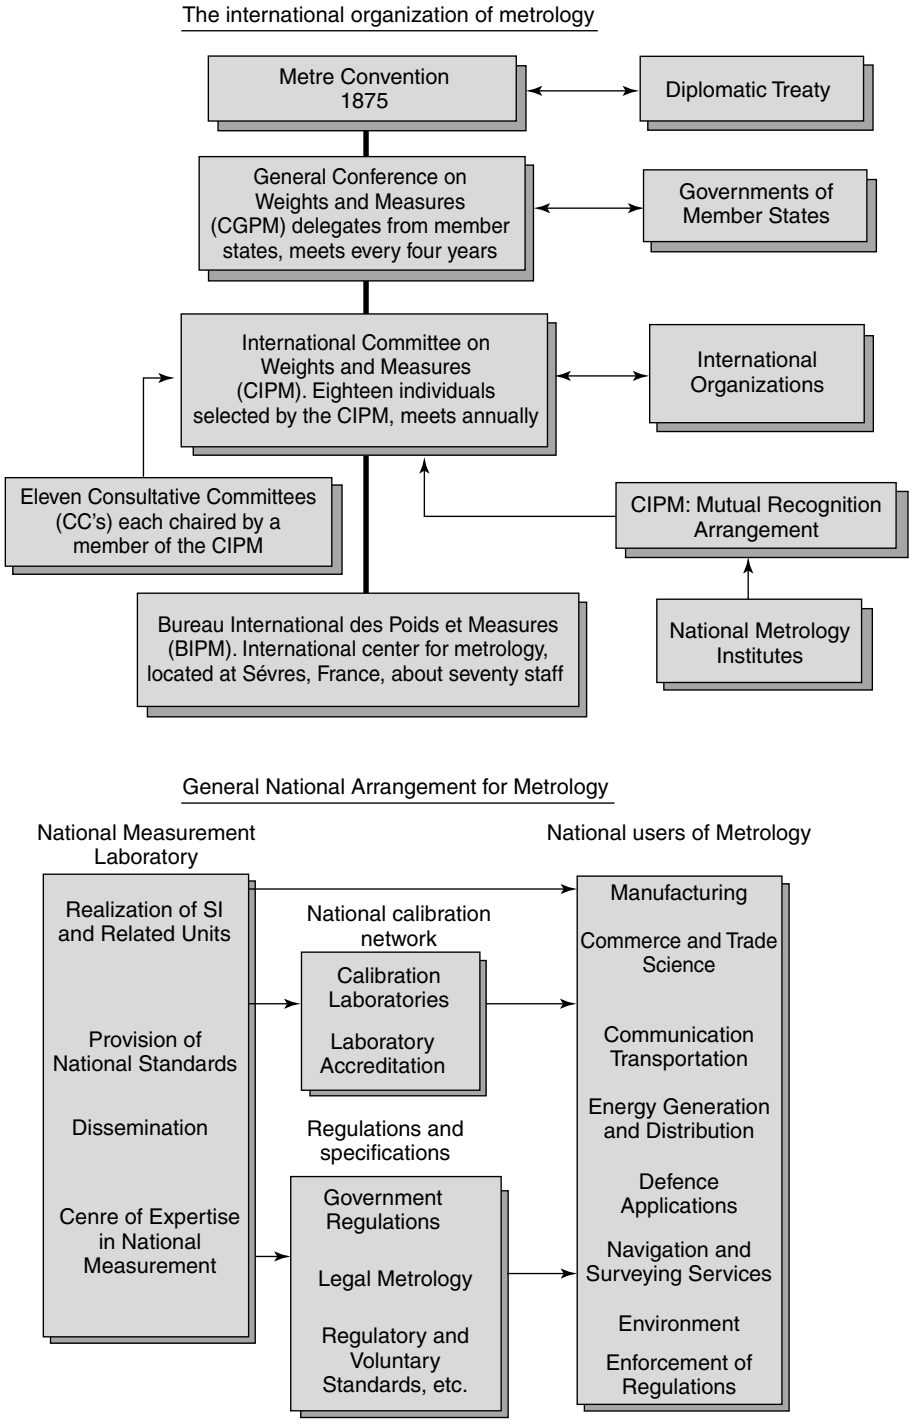

Figure 1. The international organization of metrology.

The convention is that italic font is used for the symbols for quantities, and upright Roman font for units.

1.2 Coherence

The agreed derived units had to satisfy the criterion that whatever correctly dimensioned combination of base and derived values was used, the numerical value remained the same. This excluded popular units such as the liter, degree, minute, hour, day, and so on. However, certain units such as these were in such widespread use that it was agreed that certain noncoherent units could be used alongside the SI units.

Table 1. The composition of the International System of Units (SI) and prefixes: 2002.

Type of unit	Number
SI base units	7
SI named derived units	21
Named SI prefixes	20
Experimentally determined[a]	3
Units outside the SI (day, minute, etc.) (off system units)[a]	10

[a]Units approved for use alongside the SI.

Table 2. The SI base units.

Base quantity	SI base unit name	Symbol
length	metre (meter in USA)	m
mass	kilogram	kg
time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
amount of substance	mole	mol
luminous substance	candela	cd

1.3 The SI prefixes

The 11th General Conference on Weights and Measures (CGPM) authorized certain prefixes to be used in association with SI units. The initial list has since been extended to that given in Table 4. Any of these may be attached to any SI unit but they must not be cascaded. For example, 10^{-6} kg = 1 mg (1 milligram), but not 1 μkg.

1.4 Non-SI units (i) accepted for use, (ii) values determined experimentally, and (iii) used currently (temporarily) with the International System

The International Committee on Weights and Measures (CIPM) (1969) recognized that users would wish to employ the SI together with units that are not part of it but are important and widely used, listed three categories of non-SI units: units to be maintained; to be tolerated temporarily; and to be avoided. In 1996 the CIPM agreed on a new classification of non-SI units: units accepted for use with the SI, Table 5; and units accepted for use with the SI whose values are obtained experimentally, Table 6.

Table 5 lists non-SI units that are accepted for use with the SI. It includes units that are in continuous everyday use, in particular, the traditional units of time and of angle, together with a few other units, which have assumed increasing technical importance.

It has proved useful to have some experimentally derived units in fairly common use as well, and these are shown

Table 3. The SI derived units with special names.

Quantity	Name	Symbol	Expression in terms of:	
			Other units	SI base units
angle	radian	r		$m \times m^{-1}$
solid angle	steradian	sr		$m^2 \times m^{-2}$
frequency	hertz	Hz		s^{-1}
force	newton	N		$m \times kg \times s^{-2}$
pressure, stress	pascal	P	$N\ m^{-2}$	$m^{-1} \times kg \times s^{-2}$
energy, work, quantity of heat	joule	J		$m^2 \times kg \times s^{-2}$
power, radiant flux	watt	W		$m^2 \times kg \times s^{-3}$
electric charge, quantity of electricity	coulomb	C		$s \times A$
electric potential, potential difference, electromotive force	volt	V	W/A	$m^2 \times kg \times s^{-3} \times A^{-1}$
capacitance	farad	F	C/V	$m^{-2} \times kg^{-1} \times s^4 \times A^2$
electric resistance	ohm	Ω	V/A	$m^2 \times kg \times s^{-3} \times A^{-2}$
electric conductance	siemens	S	$A \times V$	$m^{-2} \times kg^{-1} \times s^3 \times A^2$
magnetic flux	weber	Wb	$V \times s$	$m^2 \times kg \times s^{-2} \times A^{-1}$
magnetic flux density	tesla	T	Wb/m^2	$kg \times s^{-2} \times A^{-1}$
inductance	henry	H	Wb/A	$m^2 \times kg \times s^{-2} \times A^{-2}$
Celsius temperature	degree Celsius	°C		K
luminous flux	lumen	lm	$cd \times sr$	$cd \times m^2 \times m^{-2} = cd$
illuminance	lux	lx	$m^{-2} \times cd \times r$	$m^{-2} \times cd$
activity (referred to a radionuclide)	becquerel	Bq		s^{-1}
absorbed dose, specific energy (imparted), karma dose equivalent, ambient dose equivalent, directional dose equivalent, personal dose equivalent, organ equivalent dose	gray	Gy		$m^2 s^{-1}$
catalytic activity	katal	kat		$s^{-1} \times mol$

Table 4. The range of SI prefixes.

Factor	Name	Symbol	Factor	Name	Symbol
10^{24}	yotta	Y	10^{-1}	deci	d
10^{21}	zetta	Z	10^{-2}	cento	c
10^{18}	exa	E	10^{-3}	milli	m
10^{15}	peta	P	10^{-6}	micro	μ
10^{12}	tera	T	10^{-9}	nano	n
10^{9}	giga	G	10^{-12}	pico	p
10^{6}	mega	M	10^{-15}	femto	f
10^{3}	kilo	k	10^{-18}	atto	a
10^{2}	hecto	h	10^{-21}	zepto	z
10^{1}	deca	da	10^{-24}	yocto	y

Table 5. Non-SI units accepted for use with the International System.

Name	Symbol	Value in SI units
minute	min	$1\,\text{min} = 60\,\text{s}$
hour	h	$1\,\text{h} = 60\,\text{min} = 86\,400\,\text{s}$
day	d	$1\,\text{d} = 24\,\text{h} = 86\,400\,\text{s}$
degree	°	$1^\circ = (\pi/60)\,\text{rad}$
minute	′	$1' = (1/60)^\circ\pi$
second	″	$1'' = (1/60)' = (\pi/6400)\,\text{rad}$
liter	l, L	$1\,\text{L} = 1\,\text{dm}^3 = 10^{-3}\,\text{m}^3$
metric ton	t	$1\,\text{t} = 10^3\,\text{kg}$
neper	Np	$1\,\text{Np} = 1$
bel	B	$1\,\text{B} = (1/2)\ln 10\,\text{Np}$

Note: Other units which are currently approved for use alongside the SI in order to satisfy the needs of commercial, legal and specialized scientific use include: nautical mile (knot), are (a), hectare (ha), bar (bar), angstrom (Å), and barn (b).

Table 6. Non-SI units accepted for use with the International System, whose values are obtained experimentally.

Name	Symbol	Value in SI units
electronvolt	eV	$1\,\text{eV} = 1.60217653(14) \times 10^{-19}\,\text{J}$
unified atomic mass unit	u	$1\,\text{u} = 1.66053886(28) \times 10^{-27}\,\text{kg}$
astronomical unit	ua	$1\,\text{ua} = 1.49597870691(30) \times 10^{11}\,\text{m}$

Note: The latest CODATA values may be obtained from the National Institute for Science and Technology (NIST) and International Bureau of Weights and Measures (BIPM) Websites: http://physlab.nist.gov/cuu/Constants/Citations/Search.html, http://www.ibipm..fr/enus/, or http://physics.nist.gov/cuu/Constants/Table/allascii.txt

in Table 6. The electron volt is probably the most frequently encountered of these via its extensive use in measuring X-ray energies. The unified mass unit is particularly important in chemistry and serves as the reference quantity for atomic weights and atomic masses. The astronomical unit serves as the basic length reference unit in astronomy, particularly within the solar system, and larger scale units such as the parsec are subsequently related to it.

2 THE DEFINITIONS OF THE SI BASE UNITS

The definitions of the SI units are carefully framed to reflect the increasingly stringent requirements of modern science and technology. Although the names and symbols for the SI units are intended to be constant, the definitions are modified in the light of progress in order to increase the stability and invariance of the SI. Each time that the definition is changed care is taken to see that the new unit lies within the reproducibility of the old. The definitions of the SI units were originally derived from concepts related to properties of the earth and these were soon transferred to artifact units such as the prototype meter and kilogram. One can readily imagine that the reproducibility of the meter was ultimately limited by the width of the engraved markings as well as by the stability of the platinum–iridium bar.

2.1 Unit of length (meter, symbol m)

The meter is the length of the path traveled by light in a time interval of 1/299 792 458 of a second.

2.2 Unit of mass (kilogram, symbol kg)

The kilogram is the unit of mass. It is equal to the mass of the international prototype of the kilogram.

2.3 Unit of time (second, symbol s)

The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom.

2.4 Unit of electric current (ampere, symbol A)

The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible cross section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per metre of length.

2.5 Unit of thermodynamic temperature (kelvin, symbol K)

The Kelvin, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

Because of the way that thermodynamic scales used to be defined, it remains common practice to express a thermodynamic temperature T, in terms of the difference from the reference temperature $T_o = 273.15$, the ice point. This temperature is called the Celsius temperature, symbol t, and is defined by the equation

$$t = T - T_o \tag{2}$$

The numerical value of a Celsius temperature, expressed in degrees Celsius, is given by

$$\frac{t}{^\circ\mathrm{C}} = \frac{T}{\mathrm{K}} - 273.15 \tag{3}$$

2.6 Unit of amount of substance (mole, symbol mol)

The definition of the mole comprises two parts:

1. The mole is the amount of substance of a system, which contains as many elementary entities as there are atoms in 0.012 kg of carbon 12; its symbol is the 'mol'.
2. When the mole is used, the elementary entities must be specified and they may be atoms, ions, electrons, other particles, or specified groups of such particles.

In this definition, it is understood that unbound atoms of carbon, at rest and in their ground state are referred to.

2.7 Unit of luminous intensity (candela, symbol cd)

The candela is the luminous intensity, in a given direction, of a source that has emitted monochromatic radiation of frequency 540 1012 Hz and has a radiant intensity in that direction of 1/683 watt per steradian.

3 TRACEABILITY

Traceability to the SI units involved is the desired characteristic of any measurement. Thus, if one measures a length with a cheap plastic ruler, one often finds that the lengths so measured will differ from those made with a steel ruler because the markings on the plastic ruler are not quite at the correct separations. One should always assume, as a matter of routine, that all other measuring equipment, analog or digital, electronic or mechanical, and so on, may similarly be in error at some level of accuracy (including nonlinearities). Thus, one's local measurement units will almost certainly differ slightly from the correct SI values. Of course, even the national and international representations of the units will be slightly in error.

It follows from this that all measurements must be made with devices that have been calibrated in some way against nationally or internationally maintained SI standard representations of the SI units, or other agreed and known units to the appropriate degree of accuracy. This has given rise to the concept of traceability. The current official definition of traceability is given in the International Vocabulary on Metrology as follows:

> The property of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons having a stated uncertainty.

4 OTHER UNIT SYSTEMS

There are other unit systems in common use. These have a fixed relationship with the SI, such as the cgs and fps systems, although the size and spelling between the British and the US versions of the derived units in the latter (for example, the US gallon and the Imperial gallon) may well differ.

There are other systems that are useful for scientific purposes whose relationship with the SI must be determined experimentally. Notable examples of these are the System of Astronomical units and the atomic system of units, the system of natural units, the Planck units, and so on. These systems are based on the fundamental physical constants. The accuracy of our knowledge of these has been rapidly

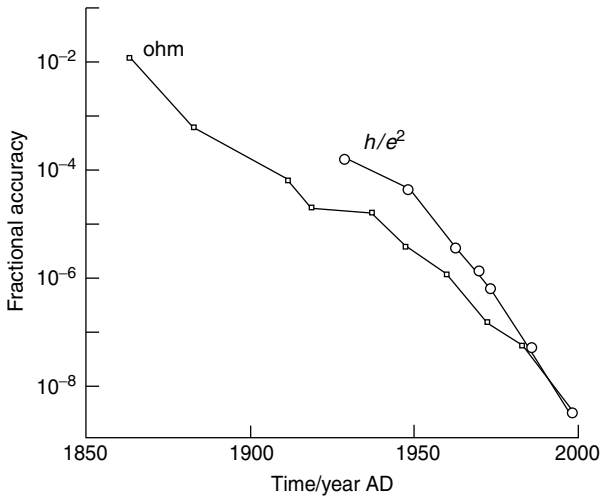

Figure 2. Illustrating how the accuracy of the fine structure constant and/or h/e^2 caught up with that of the realization of the ohm: the ohm may now be maintained in terms of an internationally agreed value for the Klitzing constant.

catching up with the accuracy with which the SI unit(s) may be realized. See, for example, Figure 2.

1 INTRODUCTION

The term standard has many definitions. The Oxford English dictionary defines *standard* as '**noun 1** a level of quality or attainment. **2** a required or agreed level of quality or attainment. **3** something used as a measure, norm, or model in comparative evaluations. **adjective 1** used or accepted as normal or average. **2** (of a size, measure, etc.) regularly used or produced'.

The measurement standards, on the other hand, are those devices, artifacts, procedures, instrument, systems, protocols, or processes that are used to define measurement units and on which all echelon measurements depend on the fundamental physical standards.

From the above definitions, the word 'standard' implies comparative evaluations, which can be physical quantities and/or processes and procedures. Consequently, there are several kinds of standards. In addition to the *fundamental physical measurement standards*, there are standards of *practice or protocols* that can be defined as documents describing the operations and processes to achieve unified results.

This article largely deals with the *practice and protocol* standards, which can loosely be termed as *published standards*.

Both physical and published measurement and metrology standards play a fundamental role in shaping the efficiency of domestic and global economies. Published standards are important as the documents that provide textual and illustrative information on what and how measurements should be done, and how they are done.

They are necessary for worldwide progress in trade liberalization, research and development activities, interpenetration of different technological sectors, and also for ensuring consistency in emerging technologies. Consequently, because of the national and international implications, there are many institutions that are responsible to investigate, develop, determine, and maintain the relevant standards to support worldwide scientific and industrial activities.

However, national and international authorities are subject to various internal and external forces, differences of expertise opinions, and commercial interests during the development of the standards that may not always end up with the ideal situations. This, unfortunately, may result in a confusing number of standards with different versions and interpretations for a specific artifact or measurement. In addition, publications grow over time as new technological developments take place, and the standards authorities and procedures change.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

In this article, an introductory explanation on the nature, scope, and generation of the published standards is given with some examples.

The process of developing the published standards is explained, and guidance is given on how to go about finding the relevant standards for a specific application. After having read this article, the reader should be able to appreciate the importance of the standards in the design and application of measuring systems and should have some informed idea on the selection of most applicable standards for his/her needs.

2 PUBLISHED STANDARDS

Published standards are documents describing the operations and processes that must be performed to achieve a particular task. The National Standards Policy Advisory Committee (http://www.nist.gov) describes a standard as 'a prescribed set of rules, conditions, or requirements concerning definitions of terms: classification of components; specification of materials, performance, or operations; delineation of procedures; or measurement of quantity and quality in describing materials, products, systems, services, or practices'.

It is important to realize that measurement standards are developed by various national and international bodies, sometimes operating totally independently; hence there may be different versions for the same subject. Examples of national and international standards bodies are the International Organization of Standardization (ISO), the International Electrotechnical Commission (IEC), the American National Standards Institute (ANSI), and so on. These organizations have multiple internal departments, committees, subcommittees, and working groups to support their activities.

Common to all organizations, in the initial stages of developing published standards, general terminology, vocabulary, and definitions concerning standardization and related activities are determined. This acts as an agent to develop a mutual understanding amongst the members, groups, and concerned parties at individual, governmental and nongovernmental levels. The aim is that these standards are prepared in such a manner that they can be understood, used, and referred to easily. To stimulate this, standards organizations have strict guidelines to assist technical groups and committees in drafting and producing the standards.

The typical preparation of a standard includes two main stages:

- *Preliminary work* that includes overall analysis, identification of target groups, determination of subject delimitation, finding the relevant sources, determining the affecting concepts, choosing the languages, working out the schedules, and so on.
- *Working procedure* that includes collecting and recording terminological data, establishing the term list, determining the concept fields and concept systems, formulating definitions, establishing and structuring the entries, order of entries, indexes, graphic representation, bibliography, and so on.

Given that standards on a specific topic exist, determining the relevant one for a specific application can be tackled by adopting a top-down approach. That is, the standards can be classified under general headings, such as the following

- generalities, terminology, standardization, documentation
- mathematics, natural sciences
- environmental, health protection, safety
- metrology and measurements
- mechanical systems and components
- health care and related technology
- electrical, electronics, telecommunications engineering
- road vehicles, railways, aircraft and space vehicle engineering
- civil engineering
- domestic and commercial equipment, entertainment, sports
- mining, metallurgy, petroleum and related technologies

and others.

Each general standard contains many discipline-based standards. For example, metrology and measurement standards may have the following

- metrology and measurement including measuring instruments, preferred numbers, standard measures, general aspects of reference materials, and so on
- measurement of volume, mass, density, viscosity
- measurement of time, velocity, acceleration, angular velocity
- acoustics and acoustic measurements
- optics and optical measurements
- thermodynamics and temperature measurements
- electricity, magnetism, electrical, and magnetic measurements
- radiation measurements

and others.

Discipline-based standards contain specific standards. For example, electrical, and magnetic measurements may comprise the following

- electrical engineering in general including voltages, general electrical terminology, electrical documentation, electrical tables, safety, fire-hazard testing
- electromagnetic compatibility

- insulating materials and fluids
- galvanic cells and batteries
- power transmission and distribution networks
- resistors, inductors, capacitors, semiconductor devices
- integrated circuits, microelectronics, logic, and analog microstructures
- radio-communications, mobile services, integrated services digital network (ISDN)
- fiber optic communications, telecontrol, telemetering
- television and radio broadcasting

and others.

These specific standards can further be divided into individual standards. Consider electromagnetic compatibility (EMC) as an example, which may have the following standards:

- electromagnetic compatibility in general
- emission
- immunity, and so on.

Application areas of specific standards may differ greatly. Continuing with the EMC, there are standards for the following

- wheelchairs and motorized scooters
- robots
- earth moving machinery
- space systems
- agricultural and forestry machinery
- lifts, escalators, conveyors, road vehicles, and so on.

More information on EMC measurement will be provided in the examples; see Section 8.

3 STANDARDS ORGANIZATIONS RELEVANT TO MEASUREMENT

Standards are formulated by standards development organizations (SDOs). These organizations can be government agencies, professional societies, international or regional organizations, private companies, or trade associations.

World standard organizations can be categorized in four major groups as national, international, consortium, and industry organizations, as illustrated in Figure 1.

Each organization has various branches that are responsible for a particular area. As an example, Figure 2 illustrates some important branches of the American National Standards Institute.

A list of some of the national and international organizations concerned with published measurement standards are given in Table 1.

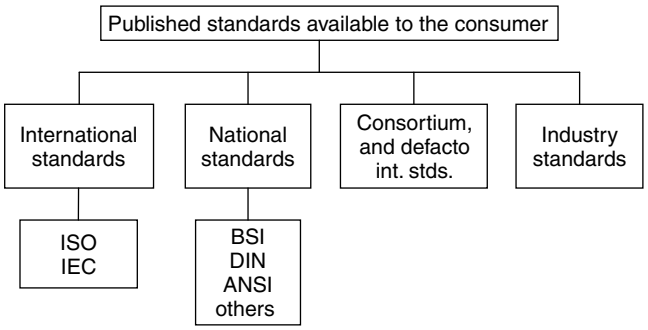

Figure 1. World standards organizations.

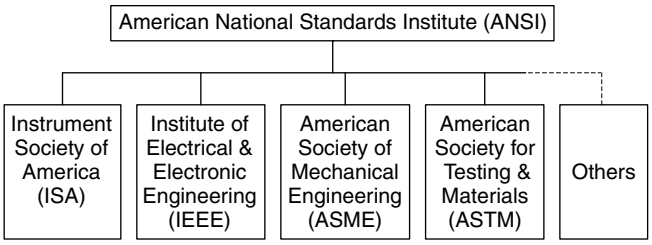

Figure 2. Branches of American National Standards Institute.

Each organization has several specialist groups that encompass a broad range of scientific disciplines, such as electromagnetic, temperature, chemical, mechanical, radiation, optic standards, and so on.

4 LINKS BETWEEN STANDARDS ORGANIZATIONS

Standards are important for scientific, research and development activities and for international trade; consequently, there are continuous links and cooperation between national, regional, and international organizations as listed in Table 1.

For example, in the case of ISO, there are many affiliated standards organizations.

Affiliated organizations largely represent countries as

1. *full members* that are entitled to participate and exercise full voting rights on any technical committee and policy committee of ISO;
2. *correspondent members* that do not take an active part in the technical and policy development work, but are entitled to be kept fully informed about their work of interest; and
3. *subscriber members* that represent the countries with small economies.

Table 1. List of some of the national and international standard organizations.

Acronym	Organization name and web address
ANSI	American National Standards Institute (http://www.ansi.org/)
AFNOR	Association française de normalization (http://www.afnor.fr/)
BSI	British Standards Institution (http://www.bsi-global.com/)
CEI	Comitato Elettrotecnico Italiano (http://www.ceiuni.it/)
CEN	Comité Européen de Normalisation (http://www.cenorm.be/)
CENELEC	Comité Européen de Normalisation Electrotechnique (http://www.cenelec.be/)
CSSN	China Standards Information Center (http://www.cssn.net.cn/)
DIN	Deutsches Institut für Normung (http://www2.din.de/)
IBN	The Belgian Institution for Standardization (http://www.ibn.be/)
IEC	International Electrotechnical Commission (http://www.iec.ch/)
ISO	International Organization for Standardization (http://www.iso.org/)
JISC	Japan Industrial Standards Committee (http://www.jisc.go.jp/)
KATS	Korean Agency for Technology and Standards (http://www.ats.go.kr/)
NIST	American National Standards and Technology (http://www.standards.com.au/)
ON	Austrian Standards Institute (http://www.on-norm.at/)
SAA	Standards Australia (http://www.standards.com.au/)
SCC	Standards Council of Canada (http://www.scc.ca/)
SII	The Standards Institution of Israel (http://www.sii.org.il/)
SNZ	Standards New Zealand (http://www.standards.co.nz/)
TSE	Türk Standardlari Enstitüsü (http://www.tse.org.tr/)

The membership fees of the subscriber members are reduced but they are allowed to be represented in some committees.

Currently, the ISO has about 96 full member countries including Australia, Germany, France, UK, and USA; 36 correspondent members; and 14 subscriber members. More information on this can be found in the ISO website (http://www.iso.org).

Apart from the international organizations that are made up with many voting and nonvoting members, numerous organizations maintain links between standard institutions and organizations. Examples of some of these organizations are as follows:

- *The Asia-Pacific Legal Metrology Forum* (APLMF) is a grouping of legal metrology authorities in the Asia-Pacific Economic Cooperation (APEC) economies and other economies on the Pacific Rim. The objective of this forum is the development of legal metrology and the promotion of free and open trade in the region through the harmonization and removal of technical or administrative barriers.
- *Bureau International des Poids et Mesures* (BIPM) that ensures worldwide uniformity of measurements and their traceability to the International System of Units (SI).
- *World Trade Organization* (WTO), an international agency whose purpose is to help trade flow as smoothly as possible in a system based on rules, to settle trade disputes between governments, and to organize trade negotiation.

Once a published standard is developed by an organization, depending on its applicability that standard may be adapted by other organizations after some modifications.

In addition, many standards organizations collaborate as consortiums to develop and implement particular standards, as in the case of field-bus systems – *see* **Article 172, Field-bus Systems, Volume 3** – for industrial digital information transmission applications.

5 DEVELOPMENT OF PUBLISHED STANDARDS

Standards development organizations (SDOs) undertake the task of producing relevant standards in their expertise areas. There are many different national and international SDOs, for example, in the electrical engineering field, some of the organizations in the USA are as follows:

- Department of Energy(DOE)
- Electronic Industries Association (EIA)
- International Electrochemical Commission (IEC)
- Institute of Electrical and Electronic Engineers Standards Association (IEEE)
- National Electrical Manufacturers Association (NEMA)
- National Institute of Standards and Technology (NIST).

Similar arrangements apply for other disciplines.

At the individual organization level, they have different ways of developing published standards depending on their

structures and sizes. Here, the ISO will be given as a typical standards body; more information can be found on the ISO website (http://www.iso.org/) and on the websites of many other organizations. The ISO operates with the following committees and groups:

- *Policy development committees* that are established by the General Assembly to draft policies. The committees are open to all full member and correspondent members, and they directly report to the council. Policy development committees have several branches such as CASCO (Committee on conformity assessment), COPOLCO (Committee on consumer policy), and so on.
- *Council* that operates the ISO. It consists of 18 elected representatives of full members and some permanent officers.
- *Council standing committees* that advise the Council on policy and strategic matters and raise any related issues.
- *Technical management board* that examines proposals, monitors the work of technical committees, and establishes and dissolves technical advisory groups.
- *Technical advisory groups* (TAGs) that advise the Board on basic, sectoral and cross-sectoral coordination, coherent planning, and the needs for new work. TAG 4 is responsible for metrology matters.
- *Technical committees* that are responsible for a particular area such as TC 12 for quantities, units, symbols, conversion factors; TC 108 for mechanical vibration and shock; and so on.
- *Ad hoc advisory groups* that recommend standardizations.

The standards to be internationalized can be brought to the attention of the ISO from a country or industry or business through one or more of the member organizations.

Members propose the new work item to the ISO as a whole. If accepted, the work item is assigned to an existing technical committee.

Technical committees are composed of experts appointed from industrial, technical, and business sectors. These experts may be joined by others with relevant knowledge, such as representatives of government agencies, testing laboratories, consumer associations, environmentalists, and so on. Generally, experts are chosen from the national delegations nominated by the member institutes of the countries concerned.

The ISO rules state that member institutions are expected to take account of the views of a broad range of interested parties and other stakeholders so that acceptance of the proposal becomes a consolidated and national consensus.

National delegations of experts of a technical committee meet to discuss and debate a new or amended standard until a consensus is reached on a draft agreement. The draft agreement is then circulated as a Draft International Standard (DIS) to ISO's members for comments and balloting.

Members are responsible for providing public-review procedures for making draft standards known and available to interested parties as well as to the general public. Once the feedback is received from members, the draft standard is formulated in its final form to be voted by the members.

If voting is in favor, the document, with eventual modifications, is circulated to the ISO members as a Final Draft International Standard (FDIS). If that vote is positive again, the document is then published as an International Standard.

Similar processes take place in other organizations, for example, in the case of International Electrotechnical Commission (IEC), there are seven stages to develop a full standard document (http://www.iec.org/):

1. Proposal Stage – New work item proposal (NP)
2. Preparatory Stage – Working draft(s) (WD)
3. Committee Stage – Committee drafts (CD)
4. Inquiry Stage – Inquiry draft (DIS, CDV)
5. Approval Stage (FDIS – Final draft international standard)
6. Publication Stage (IEC)
7. If an FDIS fails, the Technical Report 2 (TR2) is published and revised after 2 years.

TR2 status means publication of work is still under technical development, or where for any other reason there is a future but not an immediate possibility of agreement, on an International Standard.

6 OBTAINING STANDARDS

There are several hundred thousand standards and technical regulations in the world containing special requirements for a particular country or region. Finding information on the specific standards can be a very difficult task.

Nevertheless, once the relevant standard is identified for a particular application, the standards can be obtained in paper or electronic forms from various sources. The institutions of the country where the standards are applied can supply all the relevant information. Alternatively, one can purchase the standard directly from the issuing body or through private suppliers. Most of the universities, institutions of higher learning, and public libraries keep the current and the most-used standards. If the standards are not available in a particular library, it is possible to get them through the interlibrary loan services.

Nowadays, the standards can be purchased online from standards institution or other providers using their catalogues. Some of the web sites that provide full-text standards are given below, but the list is not exhaustive.

- ETSI, European Telecommunications Standards Institute, offers direct access to publicly available ETSI telecommunications standards (http://www.etsi.org/).
- IAEA, International Atomic Energy Agency, offers most recent IAEA publications online (http://www.iaea.org/).
- !IEEE Xplore!, Institute of Electrical and Electronics Engineers, offers standards for members (http://ieeexplore.ieee.org/).
- NISO, National Information Standards Organization, offers free full-text access to NISO information standards (http://www.niso.org/).
- ANS, American National Standards Institute, offers a range of standards for purchasing (http://www.ansi.org/).
- Global Engineering Documents offers national and international standards (http://global.ihs.com/)
- HIS, Information Handling Services, offers most engineering standards (http://www.ihs.com/).
- WSSN, World Standards Services Networks, offers national and international standards (http://www.wssn.net/).
- NSSN, National Standards Services Networks, offers national and international standards (http://www.nssn.org/).

As an example, the WSSN is a network of publicly accessible Web servers of standards organizations around the world. This server contains links to national, regional, and international standardization bodies. It also provides access to other national and international organizations that develop standards in their specialized subject areas.

If web browsers are selected to find standards, search can be made by keyword entry, such as EMC, temperature, noise, and so on; or by standard number, such as TP1, AB4, and so on; or by complete title or portion of a title, such as motors and generators, electrical equipment, and so on; or by date if the publication dates are known.

7 USE OF STANDARDS IN SUPPORT OF DESIGN AND OPERATION

Standards in measurement and metrology largely define guidelines for testing methodology, accuracy, and reporting criteria for consistency and accuracy. From guidelines, the necessary instrumentation, procedures, and control processes can be determined and used appropriately for the design, construction, operation, maintenance, installations, safety, and other related areas.

Use of standards in the design and operations offer many advantages:

- improves the communication between designers and operators
- provides practical application of expert knowledge
- represents accumulated experience, thus avoiding ground-up starts
- enhances operability and interoperability, thus ensuring compatibility
- sets a benchmark for global applications
- sets the recognized level of quality
- increases market access and user acceptance
- improves communication between peers in industry and other concerned parties
- provides immediate access to technical resources
- provides an understanding on the future trends
- provides consistency in products
- provides traceability
- facilitates interchangeability of products and quality assurance
- ensures safety
- facilitates migration of products for integrated systems.

Because of the advantages listed above, standards are used for many purposes, such as the following:

1. To identify and plan the measurement activities. Once the data is collected, it is processed in a prescribed manner so that it can be easily understood by other parties.
2. To select appropriate instruments and experimental setups to yield credible and reliable results.
3. To design new products and improve the existing ones.
4. To comply with the consumer/customer expectations.
5. To meet the legal requirements and counteract possible challenges, and so on.

As mentioned earlier, one problem with using standards is that there may be too many of them for a particular application; hence selection of the appropriate one may be difficult. Usually, customers require the use of a particular standard that suits his/her requirement within that country. In the case of international applications, the recommended ones by the standards authorities need to be selected and complied with.

8 EXAMPLE OF DEVELOPMENT OF A PUBLISHED STANDARD

In this section, electromagnetic compatibility (EMC) will be given as an example of the types of standards and the selection of the appropriate ones.

Electromagnetic radiation is a form of energy that can propagate through a medium. It can be generated intentionally or unintentionally that can interface with electronic systems, instruments, and other working equipment, thus degrading their performance.

This electromagnetic interference (EMI) may be generated by almost all electrically operating devices. Owing to increase in man-made EMI generated around the globe, allowable limits as well as measurement techniques on the radio frequency (RF) noise have been set at national and international levels.

The Federal Communication Commission (FCC), International Electrotechnical Commission (IEC), and the military are some of the bodies setting standards on the EMI.

In the USA, the FCC and military are two regulating bodies governing the EMC standards.

In Europe, each country has its own EMC governing body as well as its own standards. Recently, European countries adopted the IEC 1000 as the common EMI/EMC standard.

The frequency spectrum over which EMI can be generated spans from DC to γ-rays (10^{21} Hz) and beyond. The spectrum for use in EMC mainly covers from a few Hertz to 40 GHz. Lower frequencies are a main concern for the biological, while higher frequencies cause serious concern for communications, instruments, most electronic devices, and military applications.

Supposing that we want to do an EMC test and we are beginners on the subject, we will face typical information briefly listed in Table 2.

Table 2. A brief list of standards concerning EMC.

EN 50065-1:2001	Signaling on low-voltage electrical installations
EN 55015:2001	Radio disturbance of electrical lighting and similar equipment
EN 55020:2002	Immunity of broadcast receivers and associated equipment
EN 50083-2:2001	Cabled networks for television, sound signals, interactive services
EN 5009022:1997	Home and building electronic systems
EN 60669-2-1:2000	Switches for household and similar fixed electrical installations
EN 501304:1996	Alarm systems
EN 50148:1996	Electronic taximeters
EN 50199:1998	EMC – Arc welding equipment
EN 50227:1999	Control circuit devices and switching elements
EN 50263:2000	EMC – Measuring relays and protection equipment
EN 50270:1999	Electrical apparatus for combustible gases, toxic gases, or oxygen
EN 55011:2000	Industrial, scientific, and medical RF equipment
EN 55014-1:2001	Household appliances, electric tools, and similar apparatus
EN 60204-31:1998	Safety of machinery
EN 604391:1999	Low-voltage switch gear and control gear assemblies
EN 60945:2002	Maritime navigation and radio communication equipment
EN 60947-5-1:1998	Low-voltage switch gear and control gear
EN 61000-6-4:2001	Generic – Emission standard for industrial environments
EN 611312:2000	Programmable controllers
AS/NZS 3652:1998	Arc welding equipment
AS/NZS 4251:1999	EMC – Residential, commercial, and light industry
AS/NZS 4251: 1999	EMC – Industrial environments
AS 62040.2	Uninterruptible power systems
CSA C108:1977	Electromagnetic interference measuring instrument
CSA-C108.6-M91	Industrial, scientific, and medical RF equipment
IEEE 299:1997	Measuring the effectiveness of the shielding enclosure
IEEE 475:2000	Measurement for field-disturbance sensors, 300 MHz to 40 GHz
IEEE C37.100:1992	Definitions for power switchgear
ISO 7637-1:2002	Road vehicles
ISO 13766:1999	Earth-moving machinery
MIL-HDBK-1857	Grounding, bonding, and shielding design practices
MIL-HDBK-241B	Design guide for EMI reduction in power supplies
MIL-STD-469B	Radar engineering interface requirements
MIL-STD-1541A	EMC requirements for space systems
SAE ARP 958D	EMI measurement antennas – Standard calibration method

This list in Table 2 is by no means exhaustive. In fact, we can find over 500 entries on the subject. However, we can see in the list that some of the standards are duplicated, probably originating from the same source. We also notice that standards organizations specialize in some areas, which mostly concerns their area of expertise.

9 SUMMARY OF BENEFITS OF PUBLISHED STANDARDS

Both physical and published measurement and metrology standards are important in shaping the efficiency of domestic and global economies. They are necessary for worldwide progress in trade liberalization, research and development activities, interpenetration of different technological sectors, and also for ensuring consistency in emerging technologies.

Many national and international standards organizations are maintained by governments and private enterprises.

Many standards exist because of the diversity of organizations and accumulation of the documented material over time. However, a user can select the appropriate standards for a particular application easily by carefully identifying the area of concern.

The use of standards in design and applications offer many advantages such as providing expert knowledge, setting level of quality and consistency, ensuring safety, and so on.

1 DEFINITION OF CALIBRATION

Calibration of instruments and processes is essential for checking their performances against known standards. This provides consistency in readings and reduces errors, thus validating the measurements universally. The calibration procedure involves comparison of the instrument against primary or secondary standards. In some cases, it may be sufficient to calibrate a device against another one with a known accuracy. After the calibration of a device or a process, future operation is considered to be error bound for a given period of time under similar operational conditions.

The process of calibration is carried out in a hierarchical order. At the highest level, the primary reference standard is assigned a value by direct comparison with the reference base of SI units. The primary standards are designated and widely acknowledged as having the highest metrological quantities that have values without reference to other standards of the same quantity. In the second level, the secondary reference standards are calibrated by comparing with primary standards of the same quantity using a high precision comparator and making appropriate corrections. In the third level, working standards are routinely used to calibrate instruments and processes against the secondary reference standards or their representatives. More is provided about physical standards in **Article 43, Units, Volume 1**.

The most important element in calibration is the relationship between a single measurement and the reference base for the unit of measurement: the reference base is the prime source of authority. The base units of measurement are the Le Systeme International d'Unites (SI) units maintained in the Bureau International des Poids et Mesures, Paris. These are kilogram for mass, meter for length, second for time, candela for luminous intensity, kelvin for thermodynamics, ampere for current, and mole for amount of substance. Other reference bases such as newton for force, hertz for frequency, and so on, are derived from the base units and maintained by national standards.

Recently, with the wide applications of digital systems, many intelligent instruments can make self-calibrations – **Article 160, Smart Sensor System Features, Volume 3**. In these cases, postmeasurement corrections are made and the magnitudes of various errors are stored in the memory to be recalled and used in the laboratory and field applications. A new trend is that certain calibrations can be conducted over the Internet by entering the appropriate Websites of manufacturers or calibration authorities – *see* **Article 47, Internet Calibration, Volume 1**.

The Oxford English Dictionary defines the term calibrate as '**1** mark (a gauge or instrument) with a standard scale of readings. **2** compare the readings of (an instrument) with

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

those of a standard. **3** adjust (experimental results) to take external factors into account or to allow comparison with other data.'

Calibration can be defined as 'a set of operations to establish the relationship between values of quantities indicated by measuring instruments and systems under specified conditions.'

Therefore, calibration is a process that assigns values to the response of an instrument relative to reference standards or to a designated measurement process. Calibration aims to eliminate or reduce bias in the measurement system relative to the reference base in accordance to a specific algorithm. The bias may be introduced by the instrument itself and remain constant independent of the direction of measurement. Alternatively, bias may be caused by linear drift over the time of measurement.

Some of the important definitions related to calibration are as follows

Calibration procedure: 'A documented, verified, and validated process that describes a set of operations in accordance to a given method.'

Calibration provider: 'Laboratory or facility including personnel that performs calibration in an established location.'

Errors: 'Result of a measurement minus the true value of the measurand.'

Reference standard: 'Measurement standard having the highest metrological quality available in an organization.'

Uncertainty of measurement: 'Dispersion of values that can be attributed to the measurand.'

In accordance with the above definitions, a calibration can serve two main purposes:

1. If the instrument reads in the same units as the reference standards, the purpose of calibration is to eliminate biases and minimize the instrumental errors.
2. If the instrument reads in different units than the reference standards, the calibration serves the purpose of converting the instrument readings to the units of interest.

In both cases, most calibrations are likely to have uncertainties.

Since most calibrations are likely to have uncertainties in the calibrated values, they need appropriate evaluations.

Uncertainties can be evaluated as type A evaluations and type B evaluations. The type A evaluation applies to both random error and bias and uses statistical techniques. Type B evaluations can apply to both random error and bias too, but the calculation of the uncertainty component is not based on a statistical analysis of data but on factors such as experience, scientific judgment, scant data, use of different laboratories, and so on. The ISO guidelines, such as ISO 11095, give guidance on how to assess, correct, and calculate uncertainties.

2 BENEFITS OF CALIBRATION

Calibration is a process of testing and comparing the errors of measurement instruments and processes with accepted standards in order to detect and correct variations in performance. Therefore, calibration assures that devices and processes meet expected performance specifications within universally acceptable levels and accuracy. Hence, calibration has the following benefits:

- It determines whether measurements made before the calibration were valid.
- It gives confidence that the future measurements will be accurate.
- It assures consistency and compatibility with those made elsewhere.
- It leads to repeatability and reproducibility assessments of the instruments and processes.
- It provides confidence that products meet their specifications, thus reducing legal liability – *see* **Article 25, Introduction to Signals in Physical Systems, Volume 1**.
- Without calibration, the product quality may be poor, thus opening up legal challenges and high failure rates of the products, thus increasing costs.
- It increases efficiency by ensuring that measurements are correct.
- In the process industry, calibration of devices assures that the processes are well controlled and that the products meet expected specifications.
- It leads to documentation of performance of instruments and processes to meet quality standards such as ISO 9000, ISO 1400, and QS-9000.
- Frequent calibrations can provide a graphical view of the equipment uncertainty over time, thus leading to reliability of performance. This gives in-service life analysis; hence, depreciation and replacements can be predicted in an informed manner.
- Measurements made within international standards promotes global acceptance, thus increasing competitiveness.
- It helps convenient implementation of related regulations and legislation that govern the use of equipment in a particular application.
- As the technology changes, the regulations and legislation of test and measuring instruments change continually, and calibration helps compliance validity of measurements and processes under changing conditions.

- In some cases, calibration can be used as a gain; the value multiplied by some input can produce a scaled output.

3 CALIBRATION PERSONNEL

The calibration is conducted by the use of appropriate devices representing the reference standards that are deployed by trained personnel. Appropriate devices are kept as secondary standards and working standards by national authorities and companies themselves. The calibration process involves set rules, regulations, and processes.

During the calibration, the calibrating personnel make the following assumptions:

1. Handling procedures are consistent.
2. Test item and reference standard respond in the same manner in the test environment.
3. Random errors associated with the measurement are independent.
4. Multiple measurements form a distribution curve with the same standard deviation.
5. The test item and reference standards are stable during the measurement.
6. The bias of the test item and reference standard are the same, and hence it can be eliminated by taking the difference between the two readings.
7. Once the calibrations are carried out, ideally the difference is zero or can be explained by appropriate charts and statistical relationships.
8. Calibration is repeatable, yielding the same results.

Skilled calibration personnel are essential to the precision of the calibration. Calibration personnel may need to have appropriate clothing (static free clothing, gloves, face masks, etc.) for safety as well as to avoid the possibility of contamination. Although fully trained and experienced, it is possible for different operators to produce measurements differing in signs and magnitudes. To overcome this problem, measurements by different operators can be plotted and compared. Another solution may be to maintain separate calibration curves by the same operator. This may not be a problem in automated calibrations.

4 CALIBRATION LABORATORY PRACTICE

Calibration is conducted by organizations that perform tests and or calibrations in permanent, temporary, or remote locations. These organizations may have several laboratories (called *calibration laboratories*) for calibrating different instruments and processes.

Some organizations cover a broad spectrum of technologies within a wide variety of industries such as communication, defense, medical, aerospace, automotive, and chemical industries.

Laboratories are accredited by authorities in accordance with guidelines such as the ISO Guide 58.

Accreditation is a formal recognition that a particular laboratory is competent to conduct specific tests and/or calibrations.

Calibration of an instrument is intended to eliminate or reduce bias in its readings over a continuous range of values. For this purpose, a reference standard with known values is measured by the instrument and the functional relationship between the values of the standards and the corresponding measurements is established.

A successful calibration procedure requires the following basic steps:

- selection of an appropriate reference standard with known values covering the range of interest;
- application of the instrument or the reference standard;
- conducting calibration curves (i.e. least-squares fit) to establish the relationship between the measured and known values of the reference standard;
- correction of measurements using calibration curves;
- preparation of the appropriate documentation of the calibration procedure, results, analysis, and interpretation of results for the client.

Once a procedure is adapted, the calibration relies on the instrument continuing to respond consistently and in the same way during the calibrations. If the system drifts or takes unpredictable deviations, the calibrated values may not be easily corrected for bias and errors, thus degrading the accuracy of the measurements.

During the calibration process, the readings of the test item are compared with the reference standards such that values can be assigned on the basis of the known values of the reference standard. The reference standards can be: resistors, length standards, voltage standards, and so on.

However, in many situations, it may be impossible to achieve a perfect calibration because of instrument and measurement biases, and uncontrollable random errors. Mathematically: Ideal value = Measured value + Bias + Error

Similarly, a reference value may be subject to bias and error: Ideal reference value = Reference value + Bias + Error

This leads to a deficiency in the calibration: Deficiency = Ideal measured value − Ideal reference value

Owing to randomness of errors, this deficiency may not be zero; therefore, the calibration measurements have to be repeated many times. Then, the statistical techniques can be applied to work out the calibration curves, average readings, and standard deviations.

The process of collecting data for creating the calibration curve is critical to the success of the calibration program. As a rule of thumb, a minimum of five reference standards is required for a linear calibration curve and ten reference standards are sufficient for more complicated calibration models.

Nowadays, most calibrations are conducted using computers to capture and analyze data. Once the results are obtained, software packages can assist in analyzing the information. Most packages use the method of least squares for estimating the coefficients. Some of the packages are capable of performing a weighted fit if the errors of the measurements are not constant over the calibration interval. The software tools provide information such as the coefficients of a calibration curve, standard deviations, residual standard deviation of the fit, and goodness of the fit.

Calibrations of instruments and processes can be made under static or dynamic conditions. If the calibrated variable has multiple inputs and outputs, the input is varied in increments, in increasing and decreasing directions, over a specified range.

The observed output then becomes a function of that single input. For better results, this procedure may be repeated by varying the input, thus developing a family of relationships between the inputs and outputs.

In multivariable situations, the input/output relationship usually demonstrates statistical characteristics. From these characteristics, appropriate calibration curves can be obtained, and statistical techniques can be applied for analysis.

5 PHYSICAL FEATURES TO BE CALIBRATED

The physical features to be calibrated depend on the characteristics of the measuring instrument or process under test.

Calibration is applied in a diverse range of measurement instrument and processes. Some examples follow.

Flow calibration: There are many devices and facilities available for the measurement of liquid, air, or solid flow – *see* **Article 190, Calibration and Standards in Flow Measurement, Volume 3**. Once the method of measurement is determined by an appropriate flowmeter set up, static or dynamic calibrations can be carried out. In the case of static-gravimetric liquid flow, a calibration facility may include a reservoir, a pumping system, a pipeline, flowmeter under test located on the pipeline, collection system, computers and interface, supporting software, and so on. The calibration of flow of fluid through the meter can be determined by collecting the prescribed mass of steady fluid flowing over a measured time interval.

Sensor calibration: Sensors may have to be calibrated after having their data integrated with a signal conditioning system. This process for calibrating the processing part of the system requires injection of a known input signal into the sensor. By observing the output, a correct output scale can be configured for that particular application. If the sensor is used for time varying inputs, the dynamic calibration becomes necessary. In most cases, transient behavior of sensor top step response may be sufficient to assess the dynamic response of the sensor.

Calibration of food products: As food contains many chemical substances, the calibration of devices becomes complex. In the case of honey, for example, the following parameters need to be identified by calibrated instruments and processes: fructose, glucose, turanose, maltose, moisture level, acidity, and so on.

Calibration of images: Calibration is one of the first steps in image processing. For example, astronomical images are calibrated to eliminate the effect of cameras, light pollution, and distortions. Various methods are used to ensure calibrated images by eliminating thermal, readout, and other effects. For thermal effects, the cameras are cooled below certain temperatures and dark frames are used to compensate the noise generated by camera electronics.

6 LABELS USED IN CALIBRATION

Calibration labels are important as they supply information on the efficiency and applicability of instruments. They indicate parameters of instrument, tolerances, and special conditions of use. Calibration labels need to conform to the requirements of ISO/IEC 17025 General Requirements for the Competence of Testing and Calibration Laboratories. ISO 17025 requires the following

- All measurement equipments shall be securely and durably labeled.
- The labels should clearly indicate the name of the calibration laboratory, date of calibration, due date, usage equivalent, and the authorized officer.
- Information on the label must be legible and durable under reasonable use and storage conditions.

- When it is impractical to affix a label directly on an item, the label may be affixed to the instrument container.
- Temperature-resistant seals may be used when necessary.
- Functional labels should contain reference standards.

As an example, labels on radioactivity-measuring instruments contain information on calibration parameters, applicable dose levels, type of radioactivity detected, source used, and so on, as illustrated in Figure 1.

Meters with multiple probes have additional labels for each additional probe containing information such as the following

- date last calibrated and call date
- probe or sensor type
- information on organization and personnel who conducted the calibration
- range of measurement and correction factors for each range
- efficiency of the instrument, and so on.

Calibration labels must be durable and legible. They are made from various materials such as metal plates, soft adhesive aluminum, vinyl overlays, or transparent adhesive tapes. In the case of metal plates and adhesive aluminum, information and markings may be permanently indented for durability. Calibration labels may have the following information:

- calibrate before use
- not calibrated
- obsolete
- do not use
- does not conform
- indication only
- information only
- out of calibration
- reference only
- uncalibrated instrument
- user-calibrated instrument, and so on.

7 MEASUREMENT ASSURANCE PLANNING (MAPS)

Measurement Assurance Planning (MAP) is a group of activities designed for critical evaluation of a group of measurements. The term was generated by the National aeronautics and Space Administration (NASA) and National Institute of Standards and Technology (NIST) for describing the calibration of instruments for their Earth Observing System (EOS) programs. The concept is applied to calibration of EOS satellite, ground-based and airborne instruments where it consists of a series of carefully designed activities in space explorations and measurements.

However, the idea of MAPs has been adapted by many other organizations as a guideline for good practices in measurement and calibration activities under various names such as Volt MAP, Mass MAP, Accelerometer MAP, and so on.

NASA applies MAPs to achieve accurate, precise, and consistent long-term series of radiometric measurement data form multiple instruments and multiple platforms to advance scientific understanding of the earth as a system. It is identified that the success of the project depends on proper calibration of all instruments against a set of recognized physical standards and careful characterization of the instrument performance at the system level.

Other important points would be adhering to good measurement practices and established protocols, intercomparing measurements wherever possible, and establishing traceability for all instruments to the common scale of physical quantities maintained at the national standards laboratories.

8 COSTS OF CALIBRATION

A successful calibration process requires hardware and software, special equipment, and manpower, hence the costs are variable depending intensity of use of these variables. The cost of calibration depends on what is calibrated and who is calibrating by it.

In simple cases where a one-off instrument is involved, cost can be lower than one hundred dollars, but complex cases can cost thousands of dollars.

Calibration cost depends on whether the calibration is carried out on the premises of calibrating laboratories or on the factory floor being outsourced to third parties.

Certification by ISO 10012-1, ISO 9001, MIL-STD 45662A, and MIL-HDBK-52B requires calibration for measuring equipment. In many situations, such as weighting systems calibration, it is a statutory requirement.

One of the major factors for cost is the frequency of calibration of an instrument. Most calibration systems issue

a validity period during which the instrument can be used without concern for major errors and uncertainties. Some organizations use finely worked out methods for determining calibration intervals, while others use conservative calibration intervals barely able to meet the legal demands.

The perception exists that calibration cost can be reduced if the interval can be stretched legitimately. The use of uncalibrated instruments in an organization can be costly as it may affect the product quality and quality of downstream operations.

Standards such as MIL-STD 45662A suggest good calibration intervals. As a rule of thumb, 85 to 95% of all instruments returned for calibration meet the calibration limits. The calibration limits are determined by probability charts of age of instruments and their failure data.

Usually, an instrument must be calibrated if the failure rate increases or functionality deteriorates when compared to other standard instruments.

It is possible that a planned calibration costs, say, $200 as opposed to an unexpected failure costing thousands of dollars. In this respect, a number of different mathematical techniques, such as the Weibull statistics and renewal equations, can be employed to analyze the costs. There are different software tools (e.g. visualSMITH, Calibration Manager, etc.) available for cost analysis and for determining calibration intervals.

9 TRENDS IN CALIBRATIONS AND CASE STUDIES

With the availability of advancing technology, the classical calibration process is changing on at least three fronts, these being the following:

1. electronic calibration
2. e-calibration using Internet and communication techniques
3. intelligent and self-calibrating instruments and sensors.

These techniques are now explained with some examples.

Electronic calibration: Many modern instruments offer features for closed-case calibrations so that electronic calibration can be employed. Electronic calibration is a single connection and one- or two-port calibration technique without disturbing the components inside the case. Once the calibrating equipment, for example, computer, is linked with the device under calibration, appropriate software generates the necessary calibration information. Errors due to gains and offsets of the instrument are corrected mathematically within the instrument processor to obtain the correct measured values. Analog corrections can also be made via the adjustment of the parameters of the digital-to-analog converters. Corrected calibration constants are kept within the nonvolatile memory for permanent use.

As an example of this method, the Agilent™ electronic calibration modules 8719, 8720, and 8722 microwave network analyzers provide a broad frequency range of calibrations from 10 MHz to 67 GHz (http://we.home.agilent.com/USeng/nav/). Similarly, Fluke™ offers electronic calibration facilities for multifunction process, pressure, and temperature instruments (http://www.fluke.com/calibrators/cal.asp).

Remote calibration: A new trend of calibration is emerging in the form of Internet calibration. Undoubtedly, the use of Internet is likely to expand the calibration capabilities without the transportation of equipment from one place to another. Internet calibration technique is supported by web-accessible test procedures and appropriate hardware and software.

As examples of Internet calibration, Fluke™, UK, offers calibration systems for the Fluke 4950 multifunctional instruments (http://www.npl.co.uk/npl/news/press/pr16-2000.html).

Anritsu™ is active in investigating the possibilities of Internet-based calibration using portable OTDR MW9076 (http://www.electronicstalk.com/news/anr/anr163.html). The OTDR is controlled via the Internet with the aid of appropriate software. The software can be controlled through a PC via modem, mobile telephone access, or PCI cards.

Similar efforts are made by NIST to realize Internet-based calibrations particularly aimed for radiation processing industry – see also the work of NPL in UK, as described in **Article 47, Internet Calibration, Volume 1**.

In some cases, calibration algorithms and production automation know-how are available online by combining standard low-cost integrated circuits and Internet access. Online calibration is supported by appropriate software that includes the mathematical models of the interface electronics and optimizes calibration on the basis of this model.

Self-calibrating instruments and sensors: Nowadays, many smart sensors are available in the marketplace, including digital programmable calibration features, as shown in Figure 2. Particularly, sensors complying with IEEE 1451.4 standards provide comprehensive transducer electronic datasheets (TEDs) that contain configuration, scaling, and calibration information necessary to make measurement through mixed mode interface.

Many smart sensors – *see* **Article 160, Smart Sensor System Features, Volume 3** – are capable of calibrating themselves, scaling the incoming data, computing statistics, and communicating with other digital systems on the

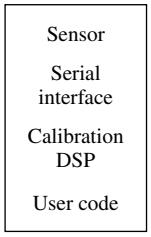

Figure 2. Main features of self-calibrating smart sensors.

network. Most commercially available software permits calibration of smart sensors and upload the new parameters directly to the sensor's circuitry.

In an application of smart sensors (the Atmos™ SSP14 Sensor Signal Processor family) (http://www.sensorsmag.com/isensors/dec00/34/main.shtml), each smart sensor has a memory that is programmed at the factory with a set of default zero and span curves defining the relationships with the physical phenomenon. These default curves represent average sensor output adjusted for the most accurate response at room temperature. Each time calibration is done, the appropriate zero or span curve is adjusted in the vicinity of the calibration.

10 LITERATURE ON CALIBRATION

Literature on calibration is available from various sources. These are:

1. *Manufacturers*: They supply comprehensive information about calibration requirements of their products.
2. *Regulating authorities and standards institutions*: These supply information on calibration requirements of instruments and devices. Calibration can be statutory, particularly where health and safety is important.
3. *Calibration services*: These provide information on calibration processes.
4. *Organizations*: They provide rules and regulations for their equipments for assurance planning.
5. *Books*: These provide information on calibration issues and processes. Details of some of these books can be found in the bibliography.

Many nations and organizations maintain laboratories with the capability of primary functions of calibrating instruments and field measuring systems that are used in everyday operations. Examples of these laboratories are: Standards Council of Canada (SCC), National Institute of Standards and Technology (NIST), National Association of Testing Authorities (NATA) of Australia and the British Calibration Services (BCS), and Australian Standard (AS).

Some important information on calibration can be found in ISO, IEC, IEEE, and national standards publications. Some of these publications are briefly explained below.

ISO 17025 is an international standard for calibration and testing laboratories. It requires labs to demonstrate that they operate a quality system covering processes, documentation, and quality management. The laboratories need to generate technically valid results accounting for the equipment procedures and personnel. Information on ISO 1705 can be found in many books or ISO publications (http://www.fasor.com/iso25/)

BS EN ISO 9000:2000 is a family of standards for international quality management. These standards are globally accepted and applied by many organizations. (www.iso.ch/iso/en/iso9000-14000/)

The military standards MIL-STD-45662A are standards that describe the requirements for creating and maintaining calibration systems for measurement and testing. They are available at http://store.mil-standards.com/.

1 PHYSICAL FEATURES TO BE CALIBRATED

Calibration is the process of giving a measuring system traceable accuracy. The general topic of calibration is covered in **Article 45, Calibration Process, Volume 1**. This article deals with how to determine and set the interval between calibrations.

There exist many physical features of a measuring instrument that may need calibration. Often, the manufacturer's original test certificate will indicate which parameters will need periodic calibration and give a recommendation for what interval to use. The following list provides a checklist of some of the many possible error sources that may need quantifying:

1. zero setting;
2. full-scale value;
3. error of nonlinearity;
4. gain or transduction coefficient;
5. effect of external influence parameters (temperature, relative humidity, atmospheric pressure, magnetic fields, vibration, radio frequency interference, ambient illumination level, and more);
6. power supply variations and noise on supply;
7. response to pulsations on measurand;
8. frequency response;
9. step response and other inputs;
10. maximum safe voltage levels;
11. leakage resistance to ground;
12. level of operation of a protective device;
13. general inspection of instrument integrity;
14. battery voltages;
15. transmission and reflectance levels in optical systems.

Before a new instrument is commissioned, it is first necessary to establish a suitable calibration plan. The instrument should be calibrated before use and proper records created. The group that is responsible will be required to maintain a record system. Often a history card is used, on which is recorded all required technical details about the instrument including calibration information. A calibration procedure should be established in writing and be used each time the item is calibrated.

Where automatic testing equipment (ATE) is used, the system will generally produce a calibration printout, which can act as the certified calibration document. Clearly, the data displayed is selected to suit the need.

It is often convenient to hold a copy of the calibration certificate with the instrument but in such cases the original should still be filed elsewhere in a secure location. In the event of severe damage to the instrument, or its complete loss, the certificate will then be most useful to help phase-in a replacement.

2 CALIBRATION LABELS

Many different reasons exist for requiring one or more of the many physical parameters listed above to be calibrated. A guide of the types of calibration labels that are in use was published in the *NCSL Newsletter* of July 1978, this being the summary of a study organized by one of the Regional Groups of the NCSL membership. The following list is extracted from that report:

1. standards calibration.
2. calibration: manufacturer's specifications.
3. calibration: limited specifications.
4. calibration: facility specification.
5. calibration: limited facility specification.
6. not usable for acceptance testing.
7. cross-check.
8. operational check.
9. calibration not required.
10. preventive maintenance.
11. calibrate before use.
12. inactive or do not use.
13. reject.
14. reference or primary standard.
15. transfer standard.
16. working standard.

The list was compiled from government, military, and private users. It was thought during that meeting that, in many cases, simplification of labeling systems might be possible.

Associated with every calibration is the cost of making a new calibration, and the cost resulting because of not having done it when it needed to be done. The first cost is relatively easy to decide. It depends upon the instrument complexity, ease of adjustment, degree of automation, calibration procedure, ability of staff, and less obvious factors such as cost of loss of production while it is being calibrated, loan or spares holdings needed to reduce such loss of production, transport costs, and costs of the associated paperwork. Clearly, the cost of making a calibration far exceeds the staff time of those involved. A balance must be made between keeping costs low by employing less calibrations and the risk of waiting too long.

Costing the effect of using an instrument that might be (or might not be!) out of calibration is the intangible factor. Overcalibration is often considered to be – see Gebhart (1980) – the safe path, but in the interests of preserving maximum financial efficiency as well as, perhaps, maximum instrument integrity, it is usually necessary to seek a suitable calibration interval along with guiding rules, which will decide when, in the future, the instrument should be calibrated.

Obviously, the interval will depend upon the equipment's characteristics and the purpose of the instrument. In nuclear power stations, the torque wrenches used to tighten critical nuts, such as those that hold on the reactor vessel top, are recalibrated after a dozen or so pulls: for each nut and its associated pull, there is an individual record of the circumstance. At the other end of the scale is the multimeter of the servicing electrician that may not need to be calibrated after the initial build unless the instrument becomes damaged.

Statements on calibration interval are not easily found. Useful sources could be NCSL (1996), Dietrich (1997), Morris (1998).

3 CALIBRATION INTERVAL ASSESSMENT

A priority problem faced by calibration facilities is establishing suitable calibration intervals to be used. At present, it does not appear that there will ever be developed a system that guarantees minimum cost of calibration and zero loss through not having recalibrated an instrument in time. It is necessary to build up information about an instrument as its life passes, making intelligent informed estimates of need that are gained from this experience and by study of what others have done beforehand. The essential state to target for is an adequate state of satisfaction that a responsible decision has been made and that undue risks are not taken.

To assist those without such experience, the following information is extracted from various issues of the *NCSL Newsletter*:

A suitable paper that describes how a very large organization handles the problem – the US Army – is provided in Westmoreland (1980).

The bibliography of the June 1977 *Newsletter* issue is specifically concerned with calibration interval topics.

During early 1978, the NCSL Calibration Systems Management Committee conducted a US survey on this subject. Their findings are published in the July 1978 issue. It contains the following outline of how a typical member laboratory characterizes its calibration interval system:

1. Initial intervals are established on the basis of the recommendation of others, usually the manufacturer of the instrument.
2. All instruments with the same function (e.g. DMMs, scopes, etc.) are calibrated on the same interval.
3. Intervals are adjusted (lengthened or shortened) periodically (about twice a year) based on analysis of data for the manufacturer and model number group of instruments.

4. Major test systems are either calibrated as a system, or individual instruments within the system are removed and calibrated separately.
5. A maximum interval (between one and two years) is imposed, but there is no minimum interval.
6. The interval system is intended to provide either at least 85% or at least 95% in tolerance of instruments at recalibration.

An update of the NCSL work has been published, but is out of print, NCSL (1996). As ISO9000 is so widely used to assist quality operations, Morris (1998) may be of use.

4 TYPES OF CALIBRATION INTERVAL

Calibration intervals are often initially based upon one of two procedures, these being 'recall after a given calendar time period' or, the less favored method being based on 'instrument usage time'. These are discussed in Greb (1973). Once established, the period is varied in accordance with experience. The impact of the smart instrument generation containing self-calibration of a kind adds a new dimension to the task.

The recall periods of a large number of commercial instrument products were surveyed and reported in the May 1976 issue, the topic being followed up in Gebhart (1980).

It is not easy to provide any simple rule to adopt. Recall for calibration periods vary from 1 to 36 months, varying considerably from user to user for the same product. Some instruments have a calibration period as little as only 10 days.

It might be considered that the better the quality of an instrument the longer can be the calibration interval. Quality in this case is defined to be a factor of recalibration interval. An extensive study (Greb, 1976a,b) provides detailed comment on whether such simplistic assumptions are correct. The results of the study are expressed in terms of the intolerance rates (ITR) that occur.

On the quality of precision instrumentation, in the more general sense of the term, the reader is referred to Moss (1978), in which is summarized the experience of the Aerospace and Guidance Metrology Center, US, about the acceptance of new equipment from industry. It is stated there that a considerable amount of incoming equipment was rejected – 21% over one period involving 62 contracts. Of those failing to meet specifications, 43% were adjustable to specification but many were either condemned or returned for other, less serious, reasons. The author states that some improvement was evident at the time of study but that 1 in 6 complex facilities did not comply and 1 in 10 needed action beyond adjustment. These findings would probably not surprise many purchasers of instrumentation. A similar situation appears to still exist.

5 CALIBRATION OF AUTOMATIC TEST EQUIPMENT (ATE)

Where the number of instruments and degree of variation and type arises and the number of calibrations is high, a case may exist where automation of many of the test processes becomes economically viable. Remembering that calibration and testing work is an overhead cost, it is usually necessary to produce a cost-benefit analysis, which can clearly show that there is an economic case to support introduction of automated test equipment (ATE). A case study (Pearson 1980) provides one group's experience of getting started. The topic of calibration in testing is given some content in O'Connor (2001).

1 USE OF INTERNET TO CONDUCT CALIBRATION

Regular instrument calibration is an essential part of today's quality driven measurement environment, and a traceable link to a national or international standard should be present. Achieving traceability requires a laboratory to periodically send their standards to be calibrated at a National Measurement Institute (NMI), acquiring a certificate and correction values. The standards are measured under carefully controlled conditions at the NMI, but there is no guarantee that these conditions will be reproduced when the standards are used at the remote laboratory. Furthermore, in some cases, the value of the standards can be affected by transport leading to an uncertainty component, which is difficult to assess.

The downtime experienced by laboratories fulfilling calibration schedules can be extremely disruptive and costly while the equipment is sent away. On the equipment's return, system checks, paperwork, and the update of soft or hard calibration figures compounds the delays. Implementation of remote calibrations using the Internet as a data transmission medium has emerged as a solution to all of the transportation, environmental, downtime, and cost issues present in current calibration schemes. Additional benefits emerge in the dissemination of measurement techniques and good practice equally to all laboratories using an Internet service.

The use of the Internet to assist in metrology has taken a number of forms. In the simplest case, the Internet acts as a means of exchanging information between two remote sites with human operators at each end using video or interactive links (Filipski, 1999).

The second stage of development was remote monitoring of sensors (Lee and Schneeman, 1999 and O'Dowd *et al*., 1997).

However, services are emerging that are truly remote calibrations. These allow a laboratory to log on to a site, perform an accredited measurement and create a full uncertainty evaluation instantly (Dudley and Ridler, 2000, 2001).

Services that offer online standard or instrument calibration have become known as *Internet Calibration Services* or iCals.

2 TYPE OF MEASURAND SUITED TO INTERNET CALIBRATION

Clearly, Internet calibration is not applicable to all metrology areas, because physical constraints or human interaction are essential for some measurements.

However, measurements that rely on a standard issue instrument, on artifact, or are distinctive in the software developed as part of the calibration process, are open to Internet implementation. The implementation of remote calibration via the Internet varies considerably with each

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

measurement example but some general rules are that the system must have one of the following:

- Stable calibration artifact with easily verified performance check.
- Easily transported measurement artifact from which the calibration is derived.
- Unique software for calibration and uncertainty calculation.

3 PROCEDURES FOR CARRYING OUT AN INTERNET CALIBRATION

A laboratory undertaking an Internet-based calibration observes a number of advantages during the measurement process compared to a conventional method. Once a computer has been connected to the measurement system, typically through GPIB (General Purpose Interface Bus) or RS-232 ports, the laboratory only needs to log on to their calibration service provider.

Once connected to the system, the measurement system, standards, and instrumentation are known by the iCal service. It instructs the operator, in the correct order, to perform the measurements.

Effectively, the iCal system provides the operator with a soft procedure to perform the measurements assuming, of course, the operator is skilled and has been accredited with using the system.

Once the measurement procedure is completed, the iCal system generates the required final data with uncertainties ascertained from the measured and database information, providing the operator with a certificate if applicable.

During the measurement process, there is potential for the iCal system to provide measurement assistance screens with video or procedural details for specific parts of the process. In no way does an iCal system 'de-skill' the calibration operator; instead, it provides the maximum assistance to ensure an accurate and efficient calibration.

In addition, the iCal service provides the administration with any measurement procedural changes through new international standards and ensures all groups are following common guidelines. Finally, data warehousing and historical records are automatically kept on the iCal service Web site and can be accessed and checked with minimal demands on the service users.

4 EXAMPLE OF AN INTERNET CALIBRATION SERVICE

The first true iCal service was developed by the UK's National Physical Laboratory (NPL), (Dudley and Ridler, 2000, 2001). It combines the technology of remote monitoring, remote control, and NMI calibration techniques for application in a microwave frequency measurement system called *vector network analysers* (VNA).

VNAs provide a swept frequency measurement of the transmission and reflection coefficients for an electrical network. Calibration is performed using instrument firmware and a set of standard devices, all of which are assumed to be ideal and are available as standard items from the VNA manufacture.

Correction of the measurement data to that of the NMI comes via precision verification artifacts, air-spaced transmission lines, attenuators and terminations, whose properties change little over time. An external computer, running a specially designed code, controls the calibration and evaluates the uncertainty in measurement. The extension of control across the Internet is ideal for this particular system.

A calibration procedure under non-Internet conditions requires the client to send the calibration laboratory their precision verification artifacts for periodic calibration. The NMI returns the verification device plus certificate and correction data, Figure 1(a). The client must then implement their measurements using the verification information and introduce their own uncertainty budget. It should be noted that typically a 1 to 18 GHz calibration for a VNA results in several thousand correction values being generated. The majority of VNA firmware does not allow inclusion of these correction values and a client will usually have to resort to creation of proprietary control software or use a spreadsheet to correct measured data using the calibration information.

The Internet version, while not removing the need for physical movement between sites of the instrument's standard reference, does simplify the process, Figure 1(b).

When the NMI receives the client standard, all correction factors are stored in an online database. The standard is returned, but now all a client needs to do to measure a device with traceability is to connect their control PC to the service Web pages.

While online, the client enters the required measurement parameters and is offered options based on the knowledge the NMI has about the client's equipment. From this point, the entire measurement process is controlled by NMI and the need for clients to assess their own uncertainty budget is removed.

There exists great potential for many new applications of Internet calibration and metrology. Applications are being investigated in the medical and optical networks markets. The optical communications network provides a method of a real standard transfer for wavelength measurements.

If telecommunications networks were all-optical – they are presently a combination of optical and electrical – it would be possible for an NMI to distribute a wavelength

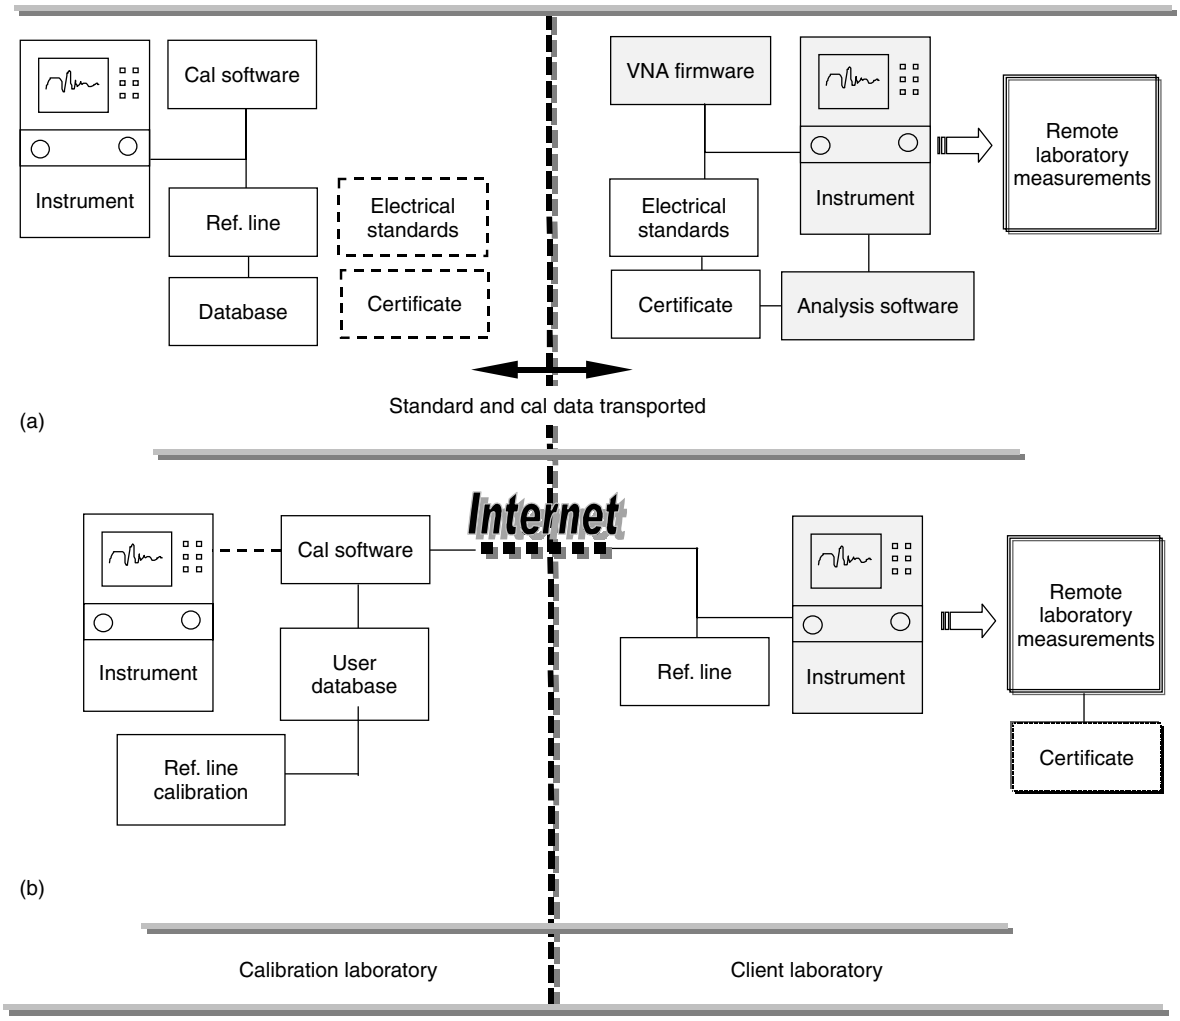

Figure 1. (a) Basic components of Internet calibration system: artifacts, instrument and control firmware, producing a certificate for the remote laboratories' artifacts. (b) The Internet system removes the need for traveling verification artifacts by allowing direct access to the calibration software and client historical database.

standard into the network creating a 'real' international standard artifact.

Other possibilities such as frequency, noise, and possibly time stamping could be placed on the back of the wavelength standard for added value. Futher information is found on http://www.internetcalibrations.com.

48: Common Sources of Errors in Measurement Systems

Dietrich Hofmann
Steinbeis Transfer Centre for Quality Assurance & Quality Measurement, Jena, Germany

1 Definition of Errors in Measurement Systems 289
2 How Errors Arise in Measurement Systems 290
3 Terms Used to Describe Errors 290
4 Types of Errors in Defined Classes 290
5 List of Error Sources in Measurements 292
6 Standards on Error Description 292
7 Uncertainties of Measurements 293
8 Glossary of Terms for Errors and Uncertainties 294
Reference 294

1 DEFINITION OF ERRORS IN MEASUREMENT SYSTEMS

A number of crucial definitions are first needed to ensure clarity of discussion. These are as follows.

Measurement error is defined as the difference between the distorted information and the undistorted information about a measured product, expressed in its measurands. In short, an error is defined as real (untrue, wrong, false, no go) value at the output of a measurement system minus ideal (true, good, right, go) value at the input of a measurement system according to (1):

$$\Delta x = x_r - x_i \tag{1}$$

where Δx is the error of measurement, x_r is the real untrue measurement value, and x_i is the ideal true measurement value.

A *measurement* is an experimental process to acquire new knowledge about a product.
A measurement is the realization of planned actions for the quantitative comparison of a measurand with a unit.
A *measurand* is the physical quantity that is to be measured. Generally, a measurand is the input of a measurement system.
Measuring is a process for ascertaining or determining the quantity of a product by application of some object of known size or capacity, or by comparison with some fixed unit – see www.iso.ch/9000e/2000rev_8e.htm.
A *product* is the result of a process after ISO 9000:2000, point 3.4.2 – see http://www.iso.ch.
Four generic product categories exist as follows: service, software, hardware, processed material.
Many products comprise elements belonging to different generic product categories. Whether the product is then called service, software, hardware, or processed material depends on the dominant element. A *process* is a set of interrelated or interacting activities that transform inputs into outputs (ISO 9000:2000, point 3.4.1) – see http://www.iso.ch. Inputs to a process are generally outputs to other processes.
A *measurement process* is a set of operations used to determine the value of a quantity (ISO 9000:2000, point 3.10.2) – see http://www.iso.ch.
Measuring equipment is the measuring instrument, software, measurement standard, reference material or auxiliary apparatus, or a combination, necessary to realize a measurement process (ISO 9000:2000, point 3.10.4) – see http://www.iso.ch.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

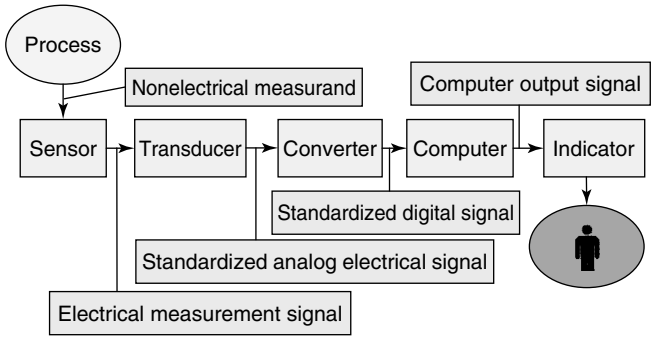

Figure 1. Measurement chain.

A *measurement system* or measuring system is the totality of all measuring equipments and auxiliary means to obtain a measuring result.
A *measurement signal* is the quantity in a measuring instrument or measuring equipment, which is unequivocally related to the measurand.
A *measuring chain* (Figure 1) is the structure of elements of a measuring equipment or measuring system, which channels the transfer of a measurement signal from the input of the measurand to the output of the measured value.
A *measured value* is a value that is unequivocally related to the measurand at the output of a measuring chain.

2 HOW ERRORS ARISE IN MEASUREMENT SYSTEMS

A measurement under ideal conditions has no errors. Real measurement results, however, will always contain measurement errors of varying magnitudes. A systematic (clearly defined process) and systemic (all encompassing) approach is needed to identify every source of error that can arise in a given measuring system. It is then necessary to decide their magnitude and impact on the prevailing operational conditions.

Measurement system errors can only be defined in relation to the solution of a real specific measurement task.

If the errors of measurement systems given in technical documentation are specified, then one has to decide how that information relates to which

- measurand
- input
- elements of the measurement system
- auxiliary means
- measurement method
- output
- kind of reading
- environmental conditions.

If the measurement system has the general structure given in Figure 1, the following errors may appear for a general measurement task:

- input error
- sensor error
- signal transmission error 1
- transducer error
- signal transmission error 2
- converter error
- signal transmission error 3
- computer error
- signal transmission error 4
- indication error.

3 TERMS USED TO DESCRIBE ERRORS

Globalization of the economy is strongly driving international standardization and accreditation programs, for example, ISO 9000 and ISO 17025, are the means of assuring quality control of components fabricated throughout the world.

Accrediting organizations such as American Association for Laboratory Accreditation (A2LA) experienced double digit annual growth in the past decade, particularly in the dimensional metrology field (classified under mechanical).

Most of these standards and accreditation programs require traceable measurements and hence measurement uncertainty statements – see www.mel.nist.gov/proj/sfnmi.htm.

Recent developments in metrology use

- the International System of Units (SI),
- the Guide to the Expression of Uncertainty in Measurement (GUM), and
- the International Vocabulary of Basic and General Terms in Metrology (VIM),

as a starting point for the application of terms to describe errors in the frame of uncertainties (see Figure 2).

4 TYPES OF ERRORS IN DEFINED CLASSES

Systematic error (bias) is a permanent deflection in the same direction from the true value. It can be corrected. Bias and long-term variability are controlled by monitoring measurements against a check standard over time.

Random error is a short-term scattering of values around a mean value. It cannot be corrected on an individual measurement basis. Random errors are expressed by statistical methods.

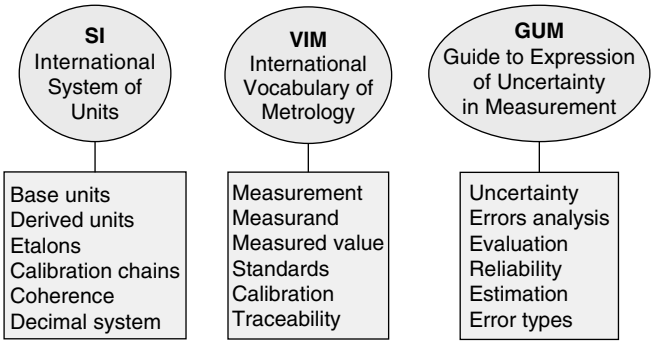

Figure 2. Main tasks of SI (http://physics.nist.gov/cuu/units), VIM (http://www.abnt.org.br/ISO_DGuide_99999(E).pdf), and GUM (http://www.gum.dk/home.html).

A fundamental source for theory and application of statistical methods is the NIST/SEMATECH Engineering Statistics Handbook (*NIST/SEMATECH e-Handbook of Statistical Method* – see http://www.itl.nist.gov/div898/handbook/, 26.03.2003).

It describes, and uses in detail, the so-called EDA method. Exploratory data analysis (EDA) is an approach for data analysis that employs a variety of techniques (mostly graphical) to

1. maximize insight into a data set,
2. uncover underlying structure,
3. extract important variables,
4. detect outliers and anomalies,
5. test underlying assumptions,
6. develop parsimonious models, and
7. determine optimal factor settings.

Most EDA techniques are graphical in nature with a few quantitative techniques included. The reason for the heavy reliance on graphics is that graphics gives the analysts unparalleled power to reveal the structural secrets of data and to be always ready to gain some new, often unsuspected, insight into the measured data in combination with the inherent pattern-recognition capabilities of man – see http://www.itl.nist.gov/div898/handbook/eda/section1/eda11.htm.

Most of the graphical techniques outlined in Figure 3 are demonstrated in the case studies given in the above-mentioned Web site.

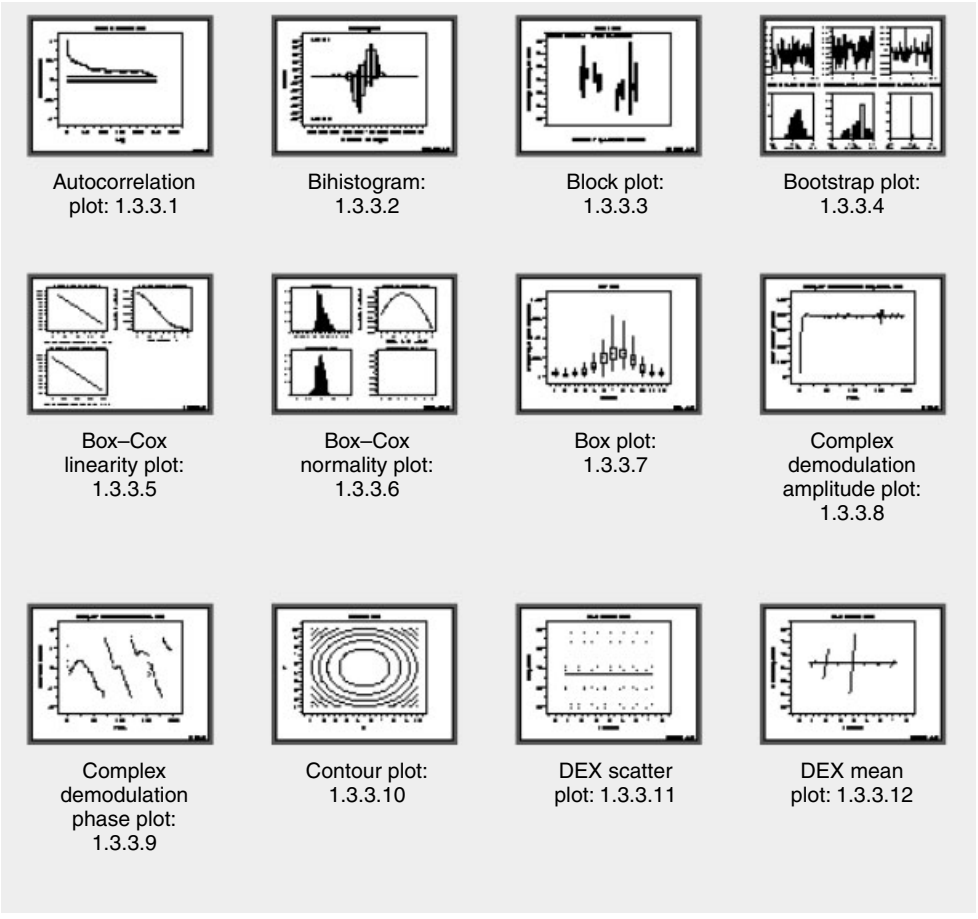

Figure 3. Graphical techniques in alphabetical order (excerpt) (http://www.itl.nist.gov/div898/handbook/eda/section3/eda33.htm).

5 LIST OF ERROR SOURCES IN MEASUREMENTS

Systematic errors or bias are repeatable errors existing with the specified source; these can be adjusted out or compensated for.

The terms 'bias' and 'systematic error' have the same meaning. Bias is defined in the International Vocabulary of Metrology, VIM, as the difference between the measurement result and its unknown 'true value'. It can often be estimated and/or eliminated by calibration to a reference standard – see http://www.itl.nist.gov/div898/handbook/mpc/section7/mpc7.htm#VIM.

To investigate sources of systematic errors, a general checklist of error sources in measurement should be used, which has been collected by specialists working in the field concerned. The main sources are

5.1 Lack of gauge resolution

Resolution better called (but rarely done so) *discrimination* is the ability of the measurement system to detect and faithfully indicate small enough changes in the characteristic of the measurement result – see http://www.itl.nist.gov/div898/handbook/mpc/section4/mpc451.htm.

5.2 Lack of linearity

A test of linearity starts by establishing a plot of the measured values versus corresponding values of the reference standards. This obtains an indication of whether or not the points fall on a straight line with slope equal to 1, which indicates linearity (proportional variation) – see http://www.itl.nist.gov/div898/handbook/mpc/section4/mpc452.htm.

Nonlinearities of gauges can be caused by the following facts:

- gauge is not properly calibrated at the lower and upper ends of the operating range,
- errors in the values at the maximum or minimum range,
- worn gauge,
- internal design problems (in, say the electronic units of the gauge).

5.3 Drift

Drift is defined as a slow change in the response of a gauge.

Short-term drift is frequently caused by heat buildup in the instrument during the time of measurement. Long-term drift is usually not a problem for measurements with short calibration cycles – see http://www.itl.nist.gov/div898/handbook/mpc/section4/mpc453.htm.

5.4 Hysteresis

Hysteresis is a retardation of the effect when the forces acting upon a body are changed (as in viscosity or internal friction); for example, a lagging in the values of resulting magnetization in a magnetic material (as iron) because of a changing magnetizing force. Hysteresis represents the history dependence of a physical system under real environmental conditions – see http://www.lassp.cornell.edu/sethna/hysteresis/WhatIsHysteresis.html.

Specific devices will posses their own set of additional error sources. A checklist needs to be developed and matured. The following is an example of such a list.

Hall Effect measurement error checklist – see http://www.eeel.nist.gov/812/errs.htm.

1. Are the probes or wires making good contact to the sample?
2. Are the contact I-V characteristics linear?
3. Is any contact much higher in the resistance than the others?
4. Do the voltages reach equilibrium quickly after current reversal?
5. Is there visible damage (cracks, especially around the contacts)?
6. Is the sample being used in the dark?
7. Is the sample temperature uniform?
8. Are dissimilar wiring materials used resulting in large temperature gradients across the wiring?

6 STANDARDS ON ERROR DESCRIPTION

Standards, when they are part of a single and coherent set of standards, promote market efficiency and expansion, foster international trade, encourage competition and lower barriers to market entry, diffuse new technologies, protect consumers against unsafe or substandard products, and provide trust and reliability – see http://www.iso.ch/iso/en/commcentre/events/2002/standardsforservices.html.

On the other hand, people talk about raising standards when they perceive slackness in the ropes of control, when they see a sloppiness infiltrating the verities of life, when they begin to be fearful about life-diminishing certainties. Talk of standards is to talk about conservation, about protecting the past in its imagined superiority and security, and defending the future through strong leadership – see http://epaa.asu.edu/epaa/v6n10/c6.htm.

Comprehensive and precise terminologies have an extraordinary importance to the industry. The following are examples:

ISO/TR 7178:1983
Liquid flow measurement in open channels – velocity-area methods – investigation of total error.
ISO 8655-6:2002
Piston-operated volumetric apparatus – Part 6: Gravimetric methods for the determination of measurement error.
ISO/IEC 10021-7:1997/Amd 1:1998
Security error diagnostic codes.
ISO/IEC 10166-2:1991/Amd 1:1995
Minor enhancement for additional error.
ISO 12142:2001
Electronic imaging – media error monitoring and reporting techniques for verification of stored data on optical digital data disks.
ISO 7509:2000
Plastic piping systems – glass-reinforced thermosetting plastic (GRP) pipes – determination of time for failure under sustained internal pressure.
ISO 10365:1992
Adhesives – designation of main failure pattern.
ISO 11782-1:1998
Corrosion of metals and alloys – corrosion fatigue testing – Part 1: Cycles to failure testing.
ISO 13953:2001
Polyethylene (PE) pipes and fittings – determination of the tensile strength and failure mode of test pieces from a butt-fused joint.

7 UNCERTAINTIES OF MEASUREMENTS

Uncertainty is a measure of the 'goodness' of a result. Without such a measure, it is impossible to judge the fitness of the value as a basis for making decisions relating to health, safety, commerce, or scientific excellence – see http://www.itl.nist.gov/div898/handbook/mpc/section5/mpc5.htm.

Uncertainty of measurement is a parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be expected – see http://physics.nist.gov/cuu/Uncertainty/glossary.html.

In this model, it is understood that the result of the measurement is the best estimate of the value of the measurand, and that all components of uncertainty, including those arising from systematic effects, contribute to the dispersion. Typical examples for systematic effects are uncertainties of

- systematic errors that generally can be corrected either numerically or technically,
- measurement standards that generally are negligibly small in comparison with the uncertainty of the measurement system in total.

Standard deviation is the generally used parameter for expressing the value of uncertainty. It is defined as the point of inflection in the Gaussian normal distribution – see Figure 4 – of randomly scattering values.
Evaluation of uncertainty is an ongoing process that can consume time and resources. It can also require the services of someone who is familiar with statistical data analysis techniques – see http://www.itl.nist.gov/div898/handbook/mpc/section5/mpc51.htm.
Measurement result is the best estimate of the value of the measurand.
Standard uncertainty in the measurement result is expressed with a standard deviation – see http://physics.nist.gov/cuu/Uncertainty/glossary.html.
Combined standard uncertainty in the measurement result has to be calculated by the error propagation law for statistical characteristics.
Type A uncertainty in the measurement result is expressed as a deviation evaluated by the method of statistical analysis from a series of observations.
Type B uncertainty in the measurement result is expressed as a deviation evaluated by methods other than the statistical analyses of series of observations.
Expanded uncertainty in the measurement result is expressed as the quantity of an interval that is large enough to include that fraction of the distribution function of the measured values that might be reasonably attributed to the measurand.

A special kind of expanded uncertainty is the confidence interval of a Gaussian normal distribution – see http://mathworld.wolfram.com/GaussianDistribution.html – where the factor $a > 1$.

Coverage factor is a numerical factor used as a multiplier or the combined standard uncertainty in order to obtain

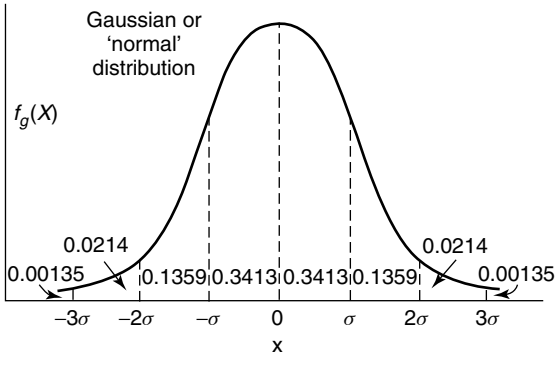

Figure 4. The Gaussian normal distribution (http://hyperphysics.phy-astr.gsu.edu/hbase/math/gaufcn.html).

Table 1. Selected glossary of terms on error and uncertainty (http://www.rit.edu/~vwlsps/uncertainties/uncertaintiespart2.html#glossary).

Term	Brief definition
Absolute error	An error in a quantity, having the same units as the quantity. For $c = (2.95 \pm 0.07)\,\mathrm{m\,s^{-1}}$, the absolute error is $0.07\,\mathrm{m\,s^{-1}}$.
Accuracy	How close a measurement is to being correct. $g = 9.7\,\mathrm{m\,s^{-2}}$ on earth is more accurate than $g = 9.532706\,\mathrm{m\,s^{-2}}$. See *precision*.
Average	When several measurements of a quantity are made, the sum of the measurements divided by the number of measurements.
Average deviation	The average of the absolute value of the differences between each measurement and the average. See *standard deviation*.
Confidence level	The fraction of measurements that can be expected to lie within a given range.
Deviation	A measure of range of measurements from the average. Also called *error or uncertainty*.
Error	A measure of range of measurements from the average. Also called *deviation* or *uncertainty*.
Estimated uncertainty	An uncertainty estimated by the observer based on his or her knowledge of the experiment and the equipment.
Gaussian distribution	The familiar bell-shaped distribution, assumed for random errors. Also called *normal distribution*.
Independent variables	Changing the value of one variable has no effect on other variables. *Error propagation* assumes this independence.
Instrument limit of Error (ILE)	Smallest reading that an observer can make from an instrument. This is generally smaller than the *least count*.
Least count	Size of the smallest division on a scale. Typically the *ILE* equals the least count or 1/2 or 1/5 of the least count.
Precision	The number of significant figures in a measurement. $g = 9.532706\,\mathrm{m\,s^{-2}}$ is more precise than $g = 9.7\,\mathrm{m\,s^{-2}}$.
Propagation of errors	Method of determining an uncertainty in a function of independent variables each with their own uncertainty.
Random error	Deviations from the 'true value' can be equally likely to be higher or lower than the true value. See *systematic error*.
Relative error	The ratio of absolute error to the average, Dx/x. Also called percentage error or fractional uncertainty. See *absolute error*.
Standard deviation	The statistical measure of uncertainty. See *average deviation*.
Systematic error	A situation where all measurements fall above or below the 'true value'. To realize and correct systematic errors is difficult.
Uncertainty	A measure of range of measurements from the average. Also called *deviation* or *error*.

an expanded uncertainty of combined measurements – see http://physics.nist.gov/cuu/Uncertainty/glossary.html.

Problems of uncertainties and error propagation and their solutions are collected in http://www.rit.edu/~vwlsps/uncertainties/Uncertaintiespart2.html#problems/.

The issue of error and uncertainty is covered in more depth in **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1** and other articles of the Subsection 'Errors and Uncertainty'.

8 GLOSSARY OF TERMS FOR ERRORS AND UNCERTAINTIES

A glossary of terms for errors and uncertainties is available that can be used as a checklist for error handling – see http://www.rit.edu/~vwlsps/uncertainties/Uncertainties part2.html#glossary.

Table 1 provides a selected glossary of terms on error and uncertainty from that source.

Terms used in the description of static system performance are also covered in **Article 57, Static Considerations of General Instrumentation, Volume 1** and **Article 58, Description of Accuracy, Linearity, and Drift, Volume 1**. Terms used to cover dynamic performance are dealt with in **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**.

REFERENCE

The Web sites cited above are possibly the best sources of information on the terms and concepts for errors and uncertainty. Generally, texts are not sufficiently standardized – often using terms that are now defunct – to act as definitive sources; their use is, as other expressions of what is not an easy topic to be made crisp and accurate.

1 DEFINITION OF A SYSTEMATIC ERROR

General definition states that error (of measurement) is a result of a measurement minus a true value of the measurand (see VIM, International Vocabulary of Basic and General Terms in Metrology, 3.10).

Since a true value cannot be determined, in practice a conventional true value is used. Measurement error consists of two parts, indicated as systematic and random error.

The same document defines systematic error as a mean that would result from an infinite number of measurements of the same measurand carried out under repeatability conditions minus a true value of the measurand (see VIM 3.14).

Such definition implies that systematic error is equal to overall error minus random error.

Following the definition, let us consider n measurements of the same measurand X, carried out under the same conditions that are designated $x_1, x_2, \ldots, x_n$. Arithmetic mean $\bar{x}$ is the most used estimation of the measurement result

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{1}$$

If x_{ctv} is the conventional true value of the measurand, absolute systematic error Δx is expressed as

$$\Delta x = \bar{x} - x_{\mathrm{ctv}} \tag{2}$$

Relative systematic error δ_x is calculated as

$$\delta_x = \frac{\Delta x}{x_{\mathrm{cvt}}} \tag{3}$$

Each particular measurement x_i from the series of n measurement is affected by the measurement error. Its systematic and random part is graphically represented in Figure 1.

General interest usually excludes systematic errors from the measurement results. In this situation, the VIM states the so-called uncorrected result of a measurement as being the measurement result before correction for systematic error (see VIM 3.3).

On the other hand, the corrected result of measurement is the result of a measurement after correction for systematic error (see VIM 3.4). Correction is then a negative value of the known part of the systematic error that must be added algebraically to the uncorrected result of measurement.

Like true value, systematic errors, and their causes cannot be completely known. Therefore, only an estimation of the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

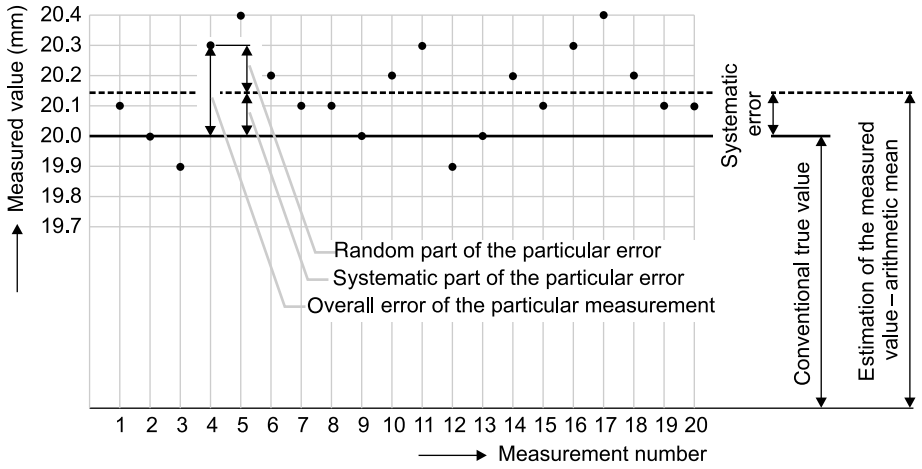

Figure 1. Graphical representation of the systematic error.

systematic error can be expressed. Such an estimation can be done by three ways:

1. analyzing the measurement process;
2. using available information on measuring instruments (they can be obtained from manufacturer's information, calibration certificates, etc.);
3. utilizing experiences from previous measurements.

Not all systematic errors can be estimated. Real systematic error can differ from that being estimated and subsequently being corrected. It appears in the measurement result in the form of the measurement uncertainty, usually being evaluated by the type B method (*see also* **Article 55, Uncertainty Determination, Volume 1**).

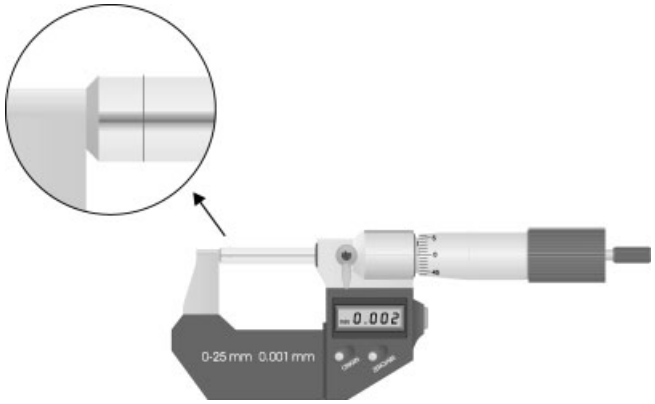

Figure 2. Micrometer with shifted zero position.

2 NATURE OF A SYSTEMATIC ERROR

Systematic error is caused by any factors that systematically affect measurement of the same measurand performed under the same conditions.

Unlike random error, systematic errors tend to be consistently either positive or negative. Because of this, systematic error is sometimes considered to be a bias in the measurement (*see also* **Article 50, Errors in Signal Systems, Volume 1**; and **Article 51, Errors in Digital Signal Systems, Volume 1**).

For instance, if the micrometer has a shifted zero position as shown in Figure 2, all measured dimensions are greater than the correct value. Subsequently, the mean of measured values exceeds the conventional true value, as shown in Figure 1.

As with all errors, systematic errors also arise from four main sources (*see also* **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; and **Article 51, Errors in Digital Signal Systems, Volume 1**):

1. *Measuring method*: improperly selected methods affect measurement the same way. For indirect measurements, rounded or uncorrected values of constants are often used, for example, $\pi = 3.141$ or improper gravity's acceleration rate g, and so on.
2. *Measuring instrument*: systematic error causes constant difference of the calibration curve from the characteristic curve.
3. *Measuring conditions*: measuring instruments being used in conditions differing from that specified by the manufacturer. A difference in temperature is the most common cause.
4. *Operator*: For example, wrong reading from the line scale. Use of digital indicators avoids this error.

Theoretical division of systematic errors states that two categories of errors exist – additive and multiplicative.

Additive errors are those values that do not change with the measured value, multiplicative errors change their value with change in measured value. The most common additive errors are offset errors and linearity errors; multiplicative error is presented as a gain error. Systematic error of the measuring instrument is manifested in most cases by a combination of those types of errors. Let us describe them in more detail:

1. *Offset error*: (see Figure 3a) the difference, under specified conditions of use, between the actual output value and the specified minimum value of the output range when the input is at the lower range value. Usually is expressed as a percentage of the specified span.
2. *Gain error*: (see Figure 3b) slope of the characteristic curve differs from that of the calibration curve. The absolute value of the gain error depends on the input value; the relative error remains the same.
3. *Linearity error*: (see Figure 3c) the absolute value of the maximum deviation between the calibration curve and the specified straight line. When expressed simply as the linearity error, it is assumed to be independent linearity error.

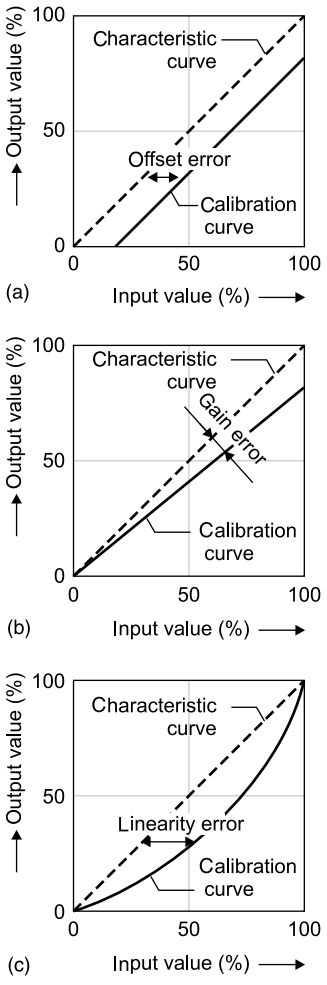

Figure 3. Systematic errors of the measuring instrument.

3 DEFINITION OF A RANDOM ERROR

The VIM defines random error as a result of a measurement minus the mean that would result from an infinite number of measurements of the same measurand carried out under repeatability conditions (see VIM 3.13). Again, such definition implies that random error is equal to the error minus systematic error as shown in Figure 1.

Only a finite number of measurements can be made in practice; therefore, it is possible to determine only an estimate of random error. A finite number of measurements can be plotted in the so-called histogram (see Figure 4), utilizing data as shown in Figure 1.

One should observe the whole range of obtained data and then divide the x-axis into suitable even-width bins. The number of measured values that fit within particular intervals is plotted on the y-axis. This procedure gives the so-called frequency distribution of the measured values.

Let us imagine that a large number of measurements with high accuracy will produce a particular histogram with a smoother shape. For an infinite number of measurements and infinitesimally small intervals (bins), this histogram transforms to a smooth curve that can be described by a theoretical equation and be replaced by a probability distribution function (see Figure 5).

Measurement theory most often assumes that a normal Gaussian distribution, also known as a *bell curve*, can describe the occurrence of any given error (see Figure 6). This assumption is based on the central limit theorem

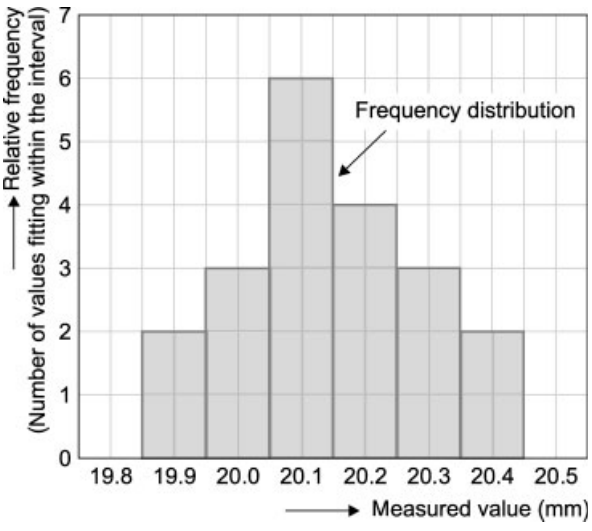

Figure 4. Histogram of the measured data.

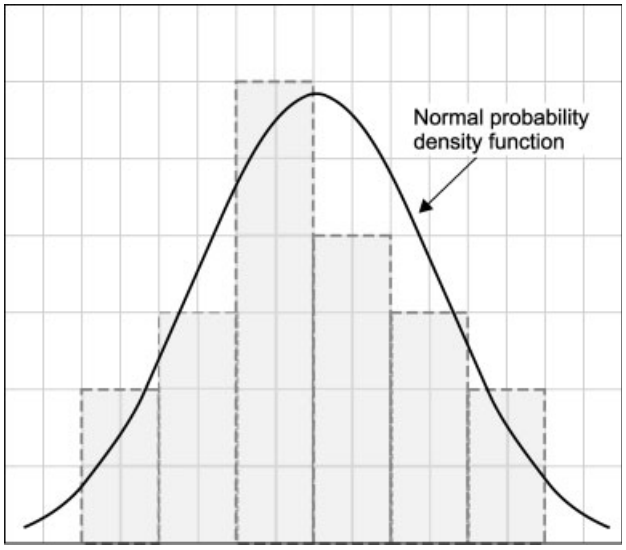

Figure 5. Replacing histogram by the probability distribution function.

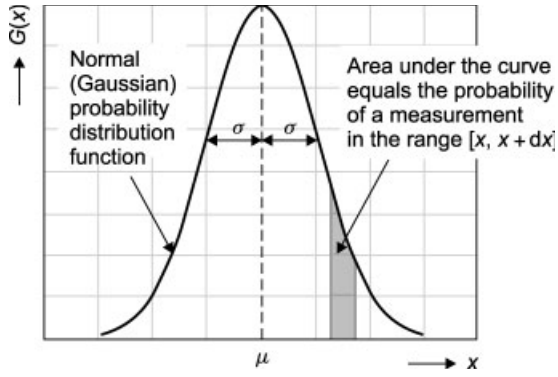

Figure 6. Gaussian distribution.

that does not necessarily always apply; its use must be confirmed by statistical tests.

The probability of finding a measurement in the range $[x,\ x + \mathrm{d}x]$ is equal to the area under the curve in that range. The curve is normalized to have a total area of 1, which is why its amplitude is not also a free parameter. The distribution is symmetric; an error is equally likely to occur in either direction. The equation describing this curve is

$$G(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[\frac{-(x-\mu)^2}{2\sigma^2}\right] \tag{4}$$

The Gaussian distribution has two independent parameters that completely determine the shape of the curve – the mean μ and the standard deviation σ. The standard deviation σ describes the width of the bell; the mean (x_{m}) lies on the axis of symmetry of the bell (see Figure 6). Both parameters are estimated by statistical methods – *see also* **Article 55, Uncertainty Determination, Volume 1**; **Article 52, Error Models, Error Budgets and their Calculation, Volume 1**; and **Article 53, Calculation and Treatment of Errors, Volume 1**.

4 NATURE OF A RANDOM ERROR

A random error is caused by any factor that randomly affects measurement of the measurand. The important thing about random error is that it does not have any consistent effect on the group of measured data. Instead, it pushes values obtained by measurement up or down randomly.

This means that if we could see all of the random errors in a distribution they would have to add up to 0 – there would be as many negative errors as positive ones. This introduces the important property of random error – it adds variability to the data but does not affect the average performance of the group – the mean (see Figure 9). Because of this, random error is sometimes considered as noise – *see also* **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; and **Article 51, Errors in Digital Signal Systems, Volume 1**.

The probability that a measured value appears in the intervals $\pm\sigma$, $\pm 2\sigma$, and $\pm 3\sigma$ is equal to the area bounded by the Gaussian curve within particular intervals – see Figure 7.

As stated before, the standard deviation σ describes the width of the bell, as shown in Figure 8. A higher standard

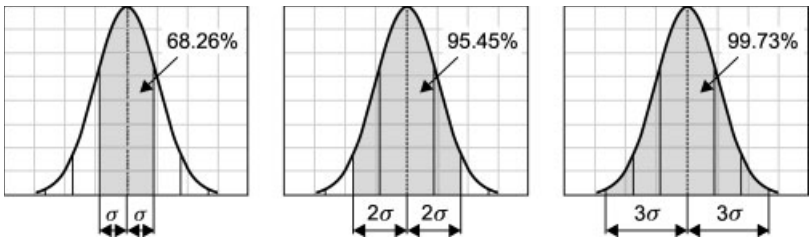

Figure 7. Probability of the presence of measured value within the range.

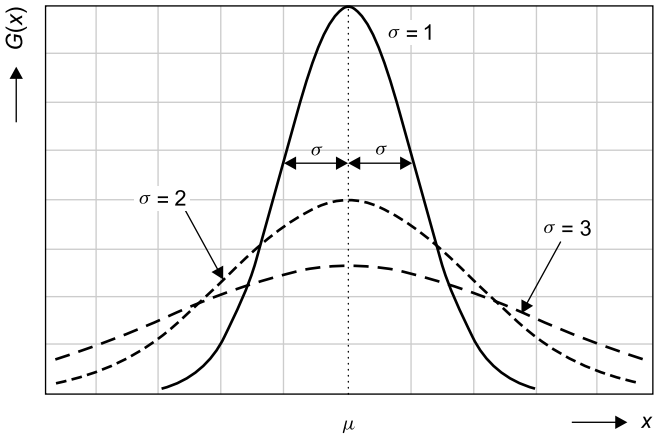

Figure 8. Influence of sigma on the bell curve.

deviation means large errors are more likely to exist. The mean μ (estimated usually as the arithmetic mean $\bar{x}$) lies on the axis of symmetry of the bell.

The mean (also called expectation, expected value) is defined as

$$\mu = \int_{-\infty}^{\infty} x f(x)\,\mathrm{d}x \tag{5}$$

An estimation of the mean μ for the set of measured values $x_1, x_2, \ldots, x_n$ used in practice is the arithmetic mean $\bar{x}$ is given by

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{6}$$

The variance of the random variable X (measured quantity) is defined as

$$\sigma^2 = \int_{-\infty}^{\infty} (x-\mu)^2 f(x)\,\mathrm{d}x \tag{7}$$

As can be seen from (7), the variance of the random variable is stated as the square of random variable units.

The empirical variance is the estimation of variance for the same set of measured values $x_1, x_2, \ldots, x_n$

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n} (x_i - \bar{x})^2 \tag{8}$$

The standard deviation, σ, obtained as a second root of the variance, is characteristic of measured data variability. Standard deviation σ is also designated as σ_X^2, $\sigma^2(X)$.

Estimation of the standard deviation for the set of measured data is the empirical standard deviation $x_1, x_2, \ldots, x_n$ defined as

$$s = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n} (x_i - \bar{x})^2} \tag{9}$$

Variability characteristics are used as a basis for determination of the measurement uncertainty. The Type A method for the uncertainty evaluation, utilizing statistical methods, states that

$$u_{\mathrm{A}} = \sqrt{\frac{s^2}{n}} \tag{10}$$

where u_{A} – standard uncertainty evaluated by the Type A method – (*see also* **Article 55, Uncertainty Determination, Volume 1**).

5 COMPARISON OF SYSTEMATIC AND RANDOM ERRORS

Systematic errors are caused by any factors that systematically affect measurement of the same measurand performed under the same conditions. They tend to be consistently either positive or negative; therefore, they are sometimes considered to be the bias in measurement. Their value remains, under identical conditions, the same, or its changes can be predicted and evaluated.

On the other hand, random errors are caused by any factors that randomly affect measurement. They do not have any consistent effect on the group of measured data. Random errors add variability (estimated by the standard deviation σ) to the data but do not affect the average performance of the group (estimated by the mean μ). Therefore, random error is sometimes considered to be noise.

These facts are documented in Figure 9. Three different situations can occur:

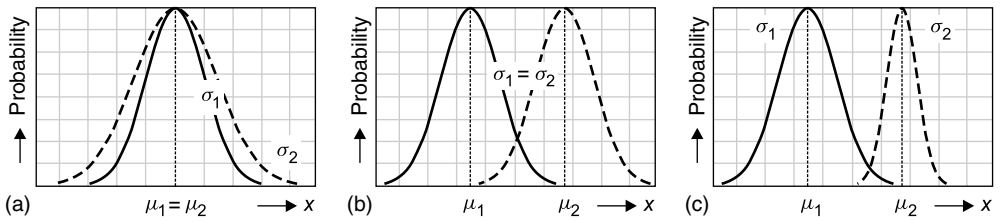

Figure 9. Influence of systematic and random errors.

1. Systematic errors affecting both measurements are the same; therefore, the mean of both data sets is the same. If their standard deviations differ, it points to a strong effect of random errors – see Figure 9(a).
2. Systematic errors differ; therefore, the mean of both data sets differs. Their standard deviations are the same so it points to a strong effect of systematic errors – see Figure 9(b).
3. Both systematic and random errors differ; therefore, the mean and standard deviations of both data sets differ. This is the most general case when both systematic and random errors affect measurements proportionally, as shown in Figure 9(c).

Determination of systematic errors is based on analysis of their sources – *see also* **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; and **Article 51, Errors in Digital Signal Systems, Volume 1**.

We tend to first determine systematic errors and subsequently either exclude them or correct them. Not excluded systematic errors have an unknown value so that they are estimated. Such estimation contains its own error sometimes called *nonexcluded systematic error*.

For a particular measurement, it has a random character with zero mean and certain variability. Determination and estimation of systematic errors can be a very complicated and difficult process. In practice, we often try to exclude only large systematic errors and keep the rest of them within certain limits.

Random errors are manifested in the case of repeated measurement and can be determined from measured data. They cannot be known so that they cannot be eliminated. We can, however, describe their stochastic behavior. The mean of random errors is zero; their variability is described by their standard deviation, which serves as a basis for evaluating their size.

6 EXAMPLE OF A SYSTEMATIC ERROR SITUATION

Systematic error is caused by any factors that systematically affect measurement under the same conditions. Their value (positive or negative) is either constant or can be calculated according to a known relationship.

As systematic errors can be estimated, their estimations can be subtracted from the measurement result so that the corrected measurement result can be obtained. While those errors are only estimated, and some of them we are not able to estimate, they occur in a measurement result in the form of measurement uncertainty.

All measurement is affected by some systematic errors. The tendency is to find their sources and evaluate their values before taking final measurements.

Systematic errors arise again from four main sources – *see also* **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; and **Article 51, Errors in Digital Signal Systems, Volume 1**:

1. *Measuring method*: sometimes uncorrected constants are used, for example, gravity's acceleration rate, air density, atmospheric pressure, and so on.
2. *Measuring instrument*: as described before, additive or multiplicative errors occur in measuring instruments. They usually result in (a) offset error, (b) gain error, or (c) linearity error. A combination of all these errors occurs very often.
3. *Measuring conditions*: they can differ from that specified by the manufacturer, standards, internal instruction, and so on. Temperature affects measurement in most cases; besides that, so does humidity, atmospheric pressure, and so on.
4. *Operator*: neglecting to set the measuring chain to zero before measurement, if required, introduces bias in all measurements.

Let us mention only a few examples of the sources of common systematic errors:

1. *Uncorrected constants*. Gravity's acceleration rate on 45° northern latitude, used as normal (standard) gravity's acceleration rate is $g = 9.806\,65\,\mathrm{m/s^2}$, 65° northern latitude is $g = 9.823\,03\,\mathrm{m/s^2}$.
   All measurement where g occurs can be affected if using an incorrect value. For example, measurement of the pressure using a U-tube filled with mercury, where the same difference in levels $h = 0.1\,\mathrm{m}$ is measured on both latitudes, differs by about 22.27 Pa (see Figure 10). This value represents an approximate relative error of 0.17% of the pressure measurement.
2. *Temperature effects*. Using the same example of a U-tube pressure measurement, let us measure the pressure at the same place, having the same difference between two mercury levels $h = 0.1\,\mathrm{m}$. The first measurement is performed at 0 °C, the second one at 20 °C. The difference between the two measured values at the two temperatures is approximately 48.52 Pa, resulting in relative error of 0.36%. Of interest is the fact that using water instead of mercury gives a relative error of 0.8% for the same measurement example.

The value of systematic error can be obtained by calibration – for example, the difference of the real weight mass

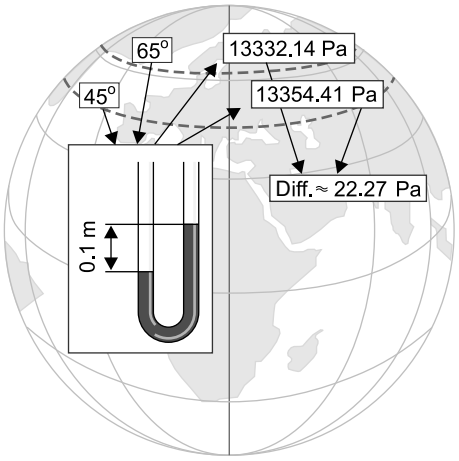

Figure 10. Example of the systematic error situation.

from the nominal value. Uncertainty of the systematic error estimation is also known.

7 EXAMPLE OF RANDOM ERROR SITUATION

The nature of random error implies that those errors are caused by any factors that randomly affect measurement – *see also* **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; and **Article 51, Errors in Digital Signal Systems, Volume 1**. A wide variety of such factors can occur in everyday life and, therefore, only a few examples of random error sources can be given here, those mainly experienced being as follows:

1. *Measuring method*: improperly selected method and measuring instrument for the intended measurement. For example, a level position of foamed liquid cannot be measured by the ultrasonic ranger; another type of measuring principle must be selected that avoids the effect of foam on measurement results.
2. *Measuring instrument*: wrong or defective parts of measuring chain. Simple examples are defective contact surfaces of micrometer, transient phenomena in electronic parts of the measurement chain, and so on.
3. *Measuring conditions*: the measuring instrument is used in conditions that vary among repeated measurements – temperature, humidity, atmospheric pressure, and so on. For example, the ultrasonic distance sensor is very sensitive to varying measurement conditions.
4. *Operator*: the classic and often seen source of random measurement errors. Usually a wrong reading out from the line scale occurs, followed by a different use of the measuring instrument in the repeated measurement (different positioning of the micrometer on the shaft, different depth of the thermometer in the liquid, etc.).

Figure 11 can be used as a slightly artificial example of the random errors sources when measuring product length with a simple caliper. The measuring method generates random errors by incorrect positioning of the measured object. Some kind of fixture should be used to assure the

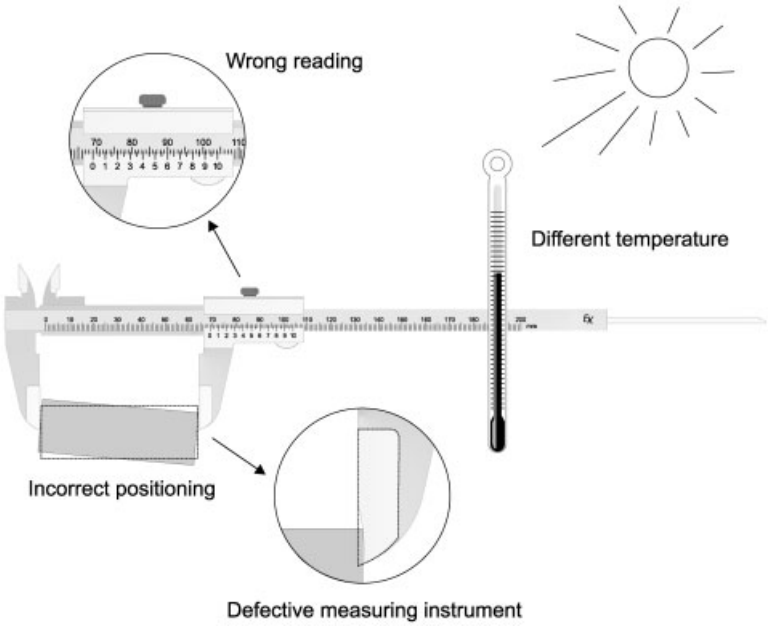

Figure 11. Example of the random error sources.

same position issued for each measured object. Wrong or defective jaws of the caliper contribute to random errors of the measuring instrument.

When positioning the measured object and caliper, different parts of the caliper jaws are in contact with the measured object.

Measuring conditions changing between the individual measurements can affect the measurement results significantly. Temperature changes have a strong influence in cases in which thermal expansion coefficients of the measured object and the measuring instrument differ significantly.

The operator usually contributes to random errors. Reading out the value of scale can depend strongly on the operator's skills and mood. This can be avoided by using a digital display readout device; however, the digital measuring device might introduce random errors caused by resolution of the displaying device.

When measurement is performed once, or only a few times, random error is estimated by a different way – not by the type A method. For example, in the case of single measurement, all errors and their uncertainties are estimated by the type B method. Therefore, uncertainties of the random errors must also be evaluated by the type B method.

8 ERRORS AND MEASUREMENT RESULT

Measurement result is given as a measured value (estimated) minus measurement error. If the errors could be known perfectly, a measurement result as defined above would be the final result. As the errors cannot be determined totally, but only their estimations are known, a measurement result must comprise also of the characteristics of the quality of such estimation. Error estimation is considered as a random quantity with an estimation of its quality expressed as standard deviation. Metrology uses the term measurement uncertainty (*see also* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**). Standard measurement uncertainty is equal to standard deviation.

Random errors are estimated as zero and standard deviation of the probability distribution of random errors is equal to standard measurement uncertainty caused by random error. Normal distribution of the random error is assumed in most cases.

Correctness of such an assumption can be verified by application of appropriate statistical tests. If repeated measurements under the same conditions are available, the measurement result will be given as the arithmetic mean of the measured value and the uncertainty will be given as an experimental standard deviation of the arithmetic mean.

If only one measurement is available, standard deviation is determined on the basis of other information on probability measurement of the random error (e.g. on the basis of previous measurements).

Estimations of systematic errors are based on analysis of the measuring process (measuring system, measurement conditions, measuring method, influence of operator, etc.). Uncertainties characterizing those estimations are determined on the basis of process analysis and different information obtained from the manufacturer of the measuring system, calibration certificates, literature, and so on.

The following sample situation occurs often in practice (*see also* **Article 55, Uncertainty Determination, Volume 1**):

1. Limits $\pm z_{\max}$ around the estimation of the systematic error Δ can be determined. Values of the systematic errors fit within this interval. The standard uncertainty $u(\Delta)$ of the systematic error Δ is then calculated as

$$u(\Delta) = \frac{z_{\max}}{k} \tag{11}$$

   where k is the value corresponding to the selected approximation of the probability distribution (see Figure 12).
2. When using a digital measuring instrument, resolution of a displaying device represents one possible error source. Even if the values in the case of repeated measurements do not change, uncertainty is nonzero. Uncertainty estimation is based on assumed uniform distribution

$$u(z) = \frac{\delta(z)}{2\sqrt{3}} = 0.29\delta(z) \tag{12}$$

   where $\delta(z)$ – resolution of the measuring device.

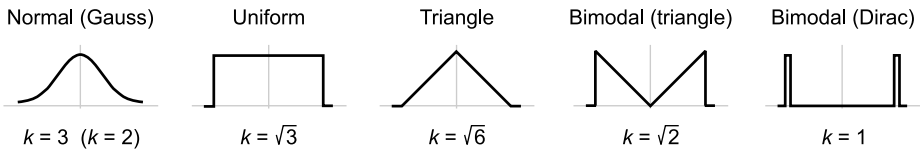

Figure 12. Probability distributions and corresponding k values.

3. When using an analog measuring instrument, the scale division δ_z is used instead of resolution of the displaying device. The uncertainty is calculated using (12).

Measurement result is then stated as

$$x = x^* \Delta \pm U \tag{13}$$

where U – expanded uncertainty is defined as

$$U = ku \tag{14}$$

where k – expansion coefficient – *see also* **Article 55, Uncertainty Determination, Volume 1**.

1 FIRST SECTION HEADING

As Figure 1 shows, the error ε is given by the difference between the output of the real system y_{real} and the ideal system without errors y_{id}

$$\varepsilon = y_{\text{id}} - y_{\text{real}} \tag{1a}$$

Equation (1a) may be interpreted either in the time or the frequency domain. In the time domain, it leads to a time error $\varepsilon(t)$. Of special interest is the mean-square value of this error

$$\overline{\varepsilon^2} = \lim_{t\to\infty} \frac{1}{2T} \int_{-\infty}^{+\infty} \varepsilon^2(t)\,\mathrm{d}t \tag{1b}$$

or in the frequency domain, leading to an amplitude error $|G_\varepsilon(\mathrm{j}\omega)|$

$$|G_\varepsilon(\mathrm{j}\omega)| = |G_{\text{id}}(\mathrm{j}\omega)| - |G_{\text{real}}(\mathrm{j}\omega)| \tag{1c}$$

with a phase error of

$$\varphi_\varepsilon(\mathrm{j}\omega) = \varphi_{\text{id}}(\mathrm{j}\omega) - \varphi_{\text{real}}(\mathrm{j}\omega) \tag{1d}$$

Because of the mean operation, the definition (1b) does not contain the whole information of (1c, d). It is, thus, possible to calculate the mean-square value $\overline{\varepsilon^2}(t)$ if the amplitude and phase errors are known, but the inverse operation is not possible.

As shown in **Article 30, Statistical Signal Representations, Volume 1**, noise signals z lead to statistical errors characterized by the spectral power density $S(\omega)$, or the mean-square value that is $\overline{z^2}$, related to the standard deviation σ by the relation

$$\overline{z^2} = \sigma^2 = \int_{-\infty}^{+\infty} S(\omega)\,\mathrm{d}\omega \tag{1e}$$

Noise is assumed to be generated at the input of the real system $S_\chi(\omega)$, as shown in Figure 1. The mean-square value of the noise at the output is then the statistical error (Woschni, 1988)

$$\overline{z}^2_{\text{output}} = \int_{-\infty}^{+\infty} S(\omega)|G_{\text{real}}(\mathrm{j}\omega)|^2\,\mathrm{d}\omega \tag{1f}$$

The total error $\overline{\varepsilon}^2_{\text{tot}}$ is the sum of both error components when there is no correlation between both error components. Otherwise, correlation has to be taken into consideration. This point is often overlooked.

$$\overline{\varepsilon}^2_{\text{tot}} = \overline{\varepsilon}^2(t) + \overline{z}^2_{\text{output}} \tag{1g}$$

Additionally, there may arise aliasing errors if the sampling theorem is violated. These are investigated in **Article 31, Discrete Signal Theory, Volume 1**.

2 ERRORS IN DYNAMIC MEASUREMENTS

For a description of the dynamic behavior of systems, it is usual and useful to introduce characteristic values that can be gained by means of approximations from the functions in the frequency and time domains (see Figure 2). The amplitude–frequency characteristic, Figure 2, yields the upper and lower critical frequencies $f_{c,u}$ and $f_{c,l}$ or $\omega_{c,u}$ and $\omega_{c,l}$, where $|G(j\omega)|$ decreases to $\sqrt{2} = 0.7 \triangleq 3\,\text{dB}$ of the reference value. From the transient response $h(t)$ (see Figure 4) the important transient time t_{tr}, dead time t_d, delay time t_l, compensation time t_c, and the maximum overshoot Δx_0 are obtained.

The transient time is given approximately as (*see* **Article 35, Systems in the Time Domain, Volume 1**)

$$t_{tr} = 3T_{max} \tag{2a}$$

From the sampling theorem, the transient time and the critical frequency are related by (Woschni, 2000)

$$f_{c,u} = \frac{1}{2} t_{tr} \tag{2b}$$

In measuring systems engineering, these approximate considerations are of importance as convenient ways to estimate performance, for example, as in the selection of suitable measuring instruments for a given task.

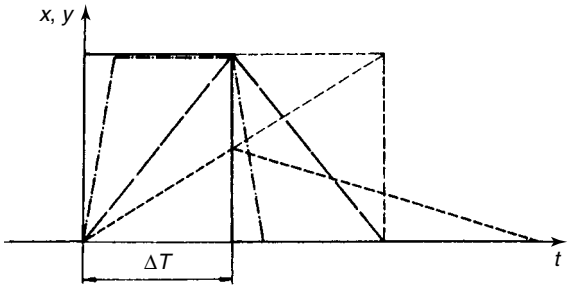

Figure 3. Approximation of the output for the case of a pulse-shaped input – pulse-shaped input $t_{tr} = \Delta T$ - - - -, transient time too long -----, $t_{tr} < \Delta T$ - - - - -.

Consider the following example. Figure 3 illustrates the problem of measuring a pulse-shaped input function (solid line), an approximation for numerous measuring tasks (Woschni, 1972). In this figure, three cases are presented. The long, dashed, triangular shaped response represents the example in which the transient time is equal to the pulse width, that is $t_{tr} = \Delta T$. The pulse height is still correctly indicated, whereas the pulse shape is strongly distorted. In contrast to this particular case, considerable error is introduced when measuring the pulse height if the transient time is too long (short dashes). To permit proper determination of the pulse shape, the transient rise time has to be substantially shorter than the pulse width (chain-dash curve).

The same considerations may also be useful for analyzing measuring errors. If one expects, for instance, a pulse-shaped behavior of the output and receives, as the response, an output variable with a heavily prolonged trailing edge, then an error will be present (short dashes in Figure 3).

It is noteworthy that minor and medium errors in amplitude measurement frequently produce more detrimental effects in practice than do large measuring errors. For errors of some 10%, the machine-made circuit element that has been sized according to this measurement will function for a certain time due to the safety margins, and will often withstand initial testing. After having been produced in series and operated for some time, however, all elements fail at the same point according to the fatigue curve for the number of stress reversals possible up to the failure of the element.

On the other hand, major measuring errors will mostly become evident during the testing period.

3 TYPICAL WAVE-SHAPE DISTORTIONS

Table 1 gives a survey of the more important measuring systems and their characteristic functions in both the time

and frequency domains (Woschni, 1988). The results in this table, in principle at least, may be used to find optimal parameters of a system. For example, the best damping of the spring–mass damping system, typical of a great number of measuring systems, can be seen to be approximately 1 (precise value 0.7). The transfer functions of typical systems, as illustrated in Table 1, allow the user to gain a survey of typical curve distortions and their causes using the methods for approximations given in Section 2 of this article. These considerations lead to the results summarized in Table 2. In these cases, the input function is assumed to be a pulse-shaped curve.

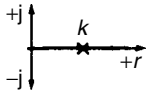
4 STATISTICAL ERRORS

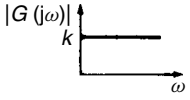
As treated in **Article 30, Statistical Signal Representations, Volume 1**, the sources of noise may be described by the Gaussian distribution density $w(x)$ (Jaffe, 2000) as shown in Figure 4.

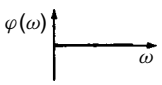
With the standard deviation $\sigma = \sqrt{x^2(t)}$ it yields

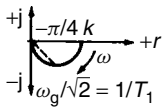
$$w(x) = \frac{1}{\sqrt{(2\pi)\sigma}} \exp\left(\frac{\exp\left(\frac{-x^2}{2\sigma^2}\right)}{2\sigma^2}\right) \tag{3a}$$

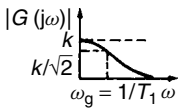
Table 1. Survey of typical systems and their characteristic functions.

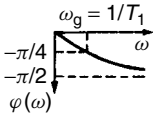


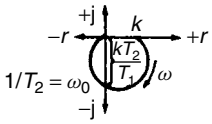


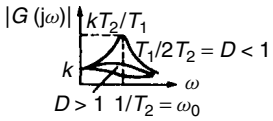


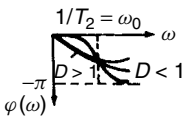


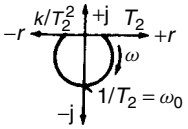


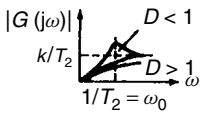


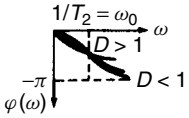


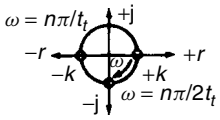


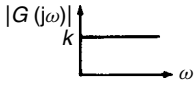


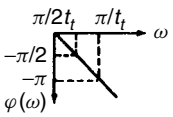


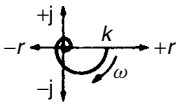


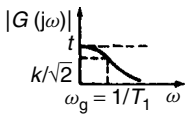


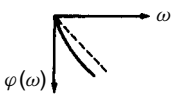


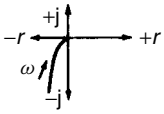


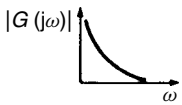


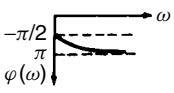


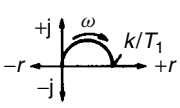


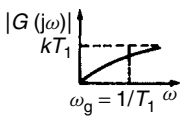


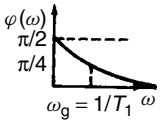


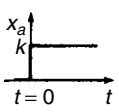


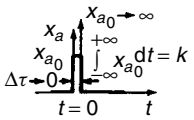


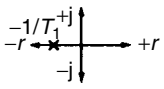


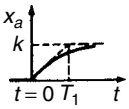


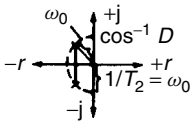


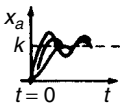


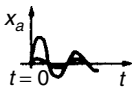


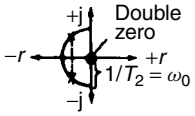


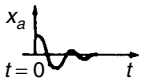


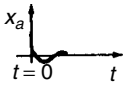


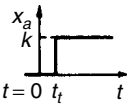


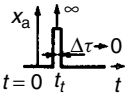


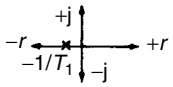


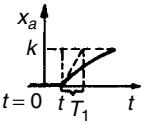


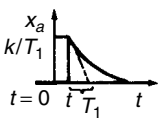


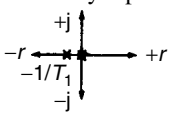


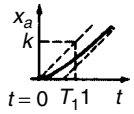


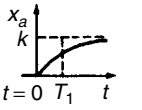


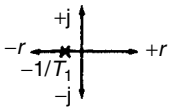


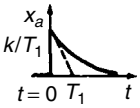


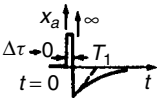












Mathematical formulation	Transfer locus	Amplitude phase curve	
k			
$\frac{k}{1+T_1p}$			
$\frac{k}{1+T_1p+T_2^2p^2}$			
$\frac{-kp^2}{1+T_1p+T_2^2p^2}$			
e^{-t_tp}			
$\frac{ke^{-t_tp}}{1+T_1p}$			
$\frac{k}{p}\frac{1}{1+T_1p}$			
$\frac{kp}{1+T_1p}$			

Table 1. (*continued*).

Poles (×) and zeros (0)	Function of time		Examples for systems with such behavior
	Transfer function $x_a/1 = h(t)$	Weighting function $a_a/1 = g(t)$	
None			Systems with proportional behavior (idealized)
			Temperature-measuring arrangements without protective tube; very heavily damped systems capable of vibrating with proportional behavior (idealized); system with delay of the first order and compensation
			Spring-mass damping system, $D \leq 1$, temperature-measuring arrangements with protective tube; $D < 1$, approximation behavior for vibration systems
			Spring-mass damping system without fixed point $D \leq 1$
Cannot be exactly represented.			System with pure dead time (idealization), caused, e.g., by pipeline, transport path, etc.
			Real systems with dead time, e.g., temperature-measuring arrangement with heat conductivity feed to transducer
Factor $e^{-t_t p}$ cannot be exactly represented.			
			Real integrator
			Real differentiator ($x_a \hat{\approx} \dot{x}_e$)

If this stochastic signal is passing through a linear system (Figure 5), the distribution is not changed. The frequency response of this system $G(\mathrm{j}\omega)$ influences the mean-square value of the noise at the output $P_y = \overline{y^2}(t)$ where $S_x(\omega)$ is the spectral power density of the input signal, as shown in **Article 27, Signals in the Frequency Domain, Volume 1** (Woschni, 1988; Jaffe, 2000)

$$P_y = \int_{-\infty}^{+\infty} S_x(\omega)|G(\mathrm{j}\omega)|^2 \,\mathrm{d}\omega \qquad (3b)$$

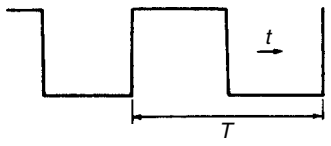
An important example is the calibration of a white noise source as shown in Figure 6. To find out the unknown value of S_0, a system of first order $G(\mathrm{j}\omega) = 1/(1 + \mathrm{j}\omega RC)$ is used – a so-called shaping filter – leading to the output power P_y

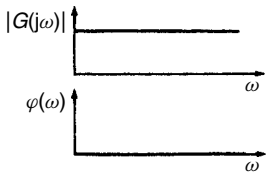
$$P_y = \int_{-\infty}^{+\infty} S_0 \frac{1}{1 + \omega^2 R^2 C^2} \,\mathrm{d}\omega = S_0\, \omega_0 \pi \qquad (3c)$$

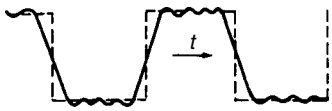
If the output power P_y is measured, the unknown spectral power density S_0 can be calculated

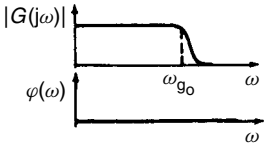
$$S_0 = \frac{P_y}{\omega_0 \pi} \qquad (3d)$$

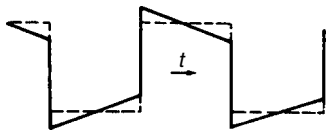
Table 2. Typical wave-shape distortions and their causes.

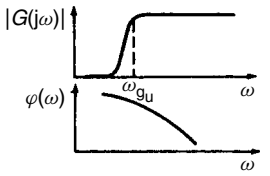


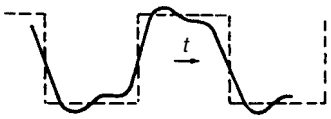


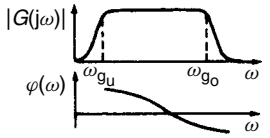


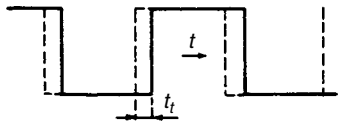


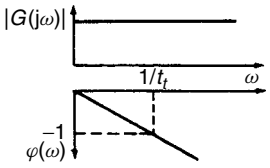


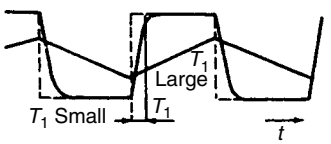


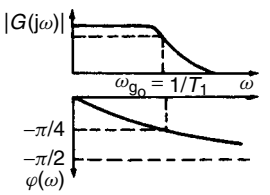


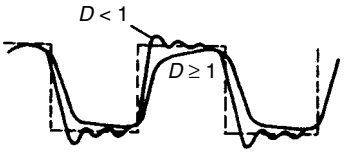


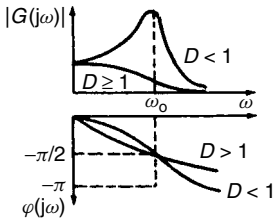


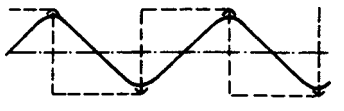


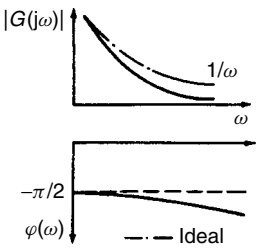


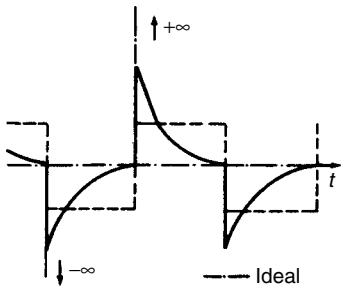


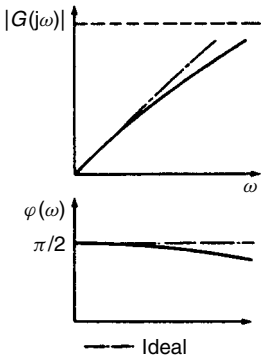


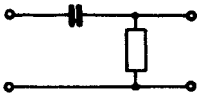












----- Output variable $x_a(t)$ —— Input variable $x_e(t)$ Curve shape	Typical features	Causes: amplitude curve, phase curve $\lvert G(j\omega)\rvert; \varphi(\omega)$	Typical features	Remarks
 1	Sharp corners ⌐ Steel edges ⌐ Straight top ¬		Ideal system, i.e. $f_{g_u} = 0$; $f_{g_o} = \infty$ ideal phase curve	Practically not fully satisfied; only approximately for slow process (T great)
 2	Blurred corners ⌐ Oblique edges ⌐ Straight top ⌒		Upper limiting frequency f_{g_o} too low; lower limiting frequency $f_{g_u} = 0$ ideal phase curve	Short peaks of the input function are not reproduced or are reproduced with wrong height; remedy: to increase upper limiting frequency, e.g. by reducing masses (idealized system)
 3	Sharp corners ⌐ Steep edges ⌐ Inclined top ¬		Lower limiting frequency f_{g_u} too high; upper limiting frequency $f_{g_o} = \infty$	Short peaks are correctly indicated; the error is increasing the faster the process runs; pure static calibration and measurement not possible (e.g. piezoelectric measuring device)
 4	Blurred corners ⌒ Oblique edges ∫ Inclined top ¬		Upper and lower limiting frequencies incorrect	Insufficiencies according to 2 and 3, i.e. short peaks wrongly reproduced; no transfer of static variables
 5	Curve shape correctly reproduced, only entire curve shifted by T_t		Ideal amplitude curve linear phase curve, i.e. pure dead time	With the exception of a time shift, no alteration of the output variable; time shift is often insignificant in measurement engineering; is often detrimental, however, in control engineering; idealized case: with $G(j\omega) =$ constant additional distortions as 2,3,4
 6	Curve consists of pure e-functions with time constant T_1 Oblique edges ∫ Straight top ⌒		Upper limiting frequency too low	Short peaks are not correctly reproduced; heavily damped systems with proportional behavior (idealized)

Table 2. (*continued*).

----- Output variable $x_a(t)$ —— Input variable $x_e(t)$ Curve shape	Typical features	Causes: amplitude curve, phase curve $\lvert G(j\omega)\rvert; \varphi(\omega)$	Typical features	Remarks
 7	For $D > 1$: blurred corners ⌜ Oblique edges ∫ For $D < 1$: oscillation		Upper limiting frequency too low; additionally for $D < 1$: resonance behavior	Short peaks are not correctly reproduced; $D \gtrless 1$: systems with spring–mass damping behavior, e.g. vibration meters $D > 1$: system for temperature measurements with protective tube
 8	Integral curve exhibits no corners at points where x_e jumps integrates correctly at low frequencies only		Integrator shows nonconstant phase rotation by $-\pi/2$; amplitude curve decreases more strongly than with $1/\omega$; has upper limiting frequency for integration	With nonelectric integrators, the influence of the masses is decisive for this effect; upper limiting frequency too low in electric techniques
 9	Differential curve rounded. Differentiates correctly at low frequencies only		Differentiator shows nonconstant phase rotation by $+\pi/2$; amplitude curve not ideal; has an upper limiting frequency f_{g_o} for differentiation	Unavoidable with simple CR component $T_1 = CR$ 

5 ERRORS IN OPTIMAL FILTERING

Gauss introduced the measure of the mean-square error $\overline{\varepsilon^2}$, because this definition leads to closed mathematic solutions as for instance with optimal filtering. As shown in Section 5 of **Article 38, Stability Issues, Volume 1**, the total mean-square error $\overline{\varepsilon^2}$ consists of two components.

As shown in Section 5 of **Article 38, Stability Issues, Volume 1**, a correction or compensation system is series connected with the real system; error can arise due to it having insufficient dynamic behavior $\overline{\rho^2}$ and to the error due to the disturbance P_z. If there is no correlation between signal source and disturbance source, as has been assumed here, the two error components must be added to arrive at the total error.

From 5 the total mean-square error is given by

$$\begin{aligned}\overline{\varepsilon^2} &= \int_0^\infty S_{xx}(\omega)|G_{\mathrm{id}}(\mathrm{j}\omega) - G_{\mathrm{real}}(\mathrm{j}\omega)G_{\mathrm{corr}}(\mathrm{j}\omega)|^2\,\mathrm{d}\omega \\ &\quad + \int_0^\infty S_{zz}(\omega)|G_{\mathrm{corr}}(\mathrm{j}\omega)|^2\,\mathrm{d}\omega \\ &= \overline{\rho^2} + P_z \end{aligned} \tag{4}$$

with the assumption having been made that the disturbances occur in the system prior to the correction computer.

When the error components and total error are plotted against the correction degree a, relationships will always result as presented in Figure 7. The dynamic error component $\overline{\rho^2}$ decreases as a increases and disappears for $a \to \infty$ (ideal correction), whereas the error component due to the disturbance increases with a. Figure 8 provides the

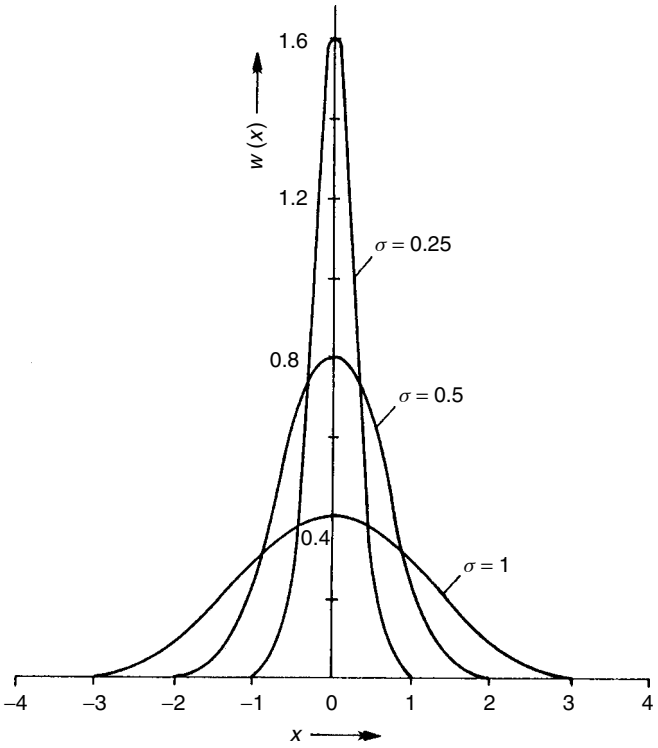


Figure 4. Gaussian distribution density.

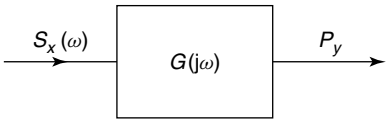

Figure 5. Calculating the noise at the output of a system.

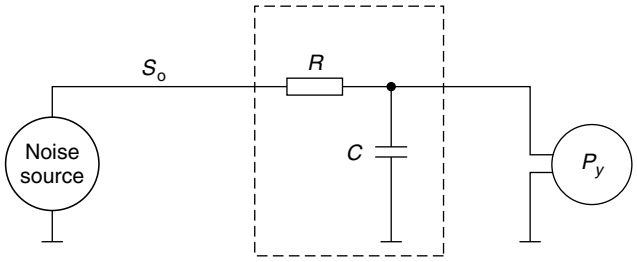

Figure 6. Calibration of a noise source.

physical demonstrative explanation for this. In this figure, the amplitude responses $|G_{\text{real}}(\text{j}\omega)|$ of the uncorrected system as well as of the correction system $|G_{\text{corr}}(\text{j}\omega)|$ are plotted.

To compensate for the decrease of the uncorrected system at frequencies above the limiting frequency $\omega_{\text{c,real}}$, the correction system must raise these frequencies correspondingly up to its limiting frequency $\omega_{\text{c,corr}}$. However, this inevitably causes the spectral frequencies of the disturbances that fall into this range to be raised so that the error component caused by the disturbance becomes the greater the higher the value selected for $\omega_{\text{c,corr}}$. Therefore, there will always be a minimum for the total error $\overline{\varepsilon^2} = \overline{\rho^2} + P_z$, this minimum being deeper and more pronounced the lower the inherent disturbances of the uncorrected system are, the better the dynamic behavior of this system will be. This minimum corresponds to the case of an optimum filter according to Schlitt (1960) and Levine (1996).

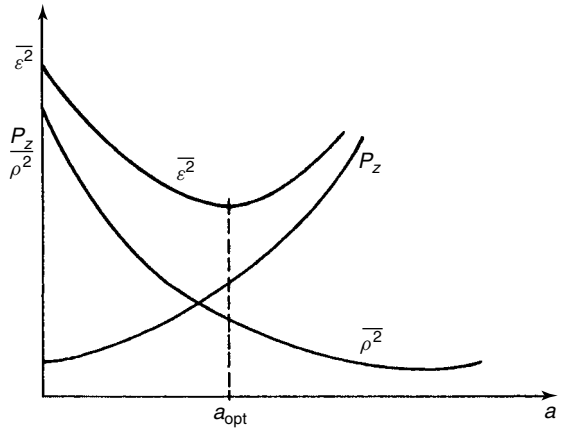

Figure 7. Behavior of the components of the error as a function of the degree of correction α.

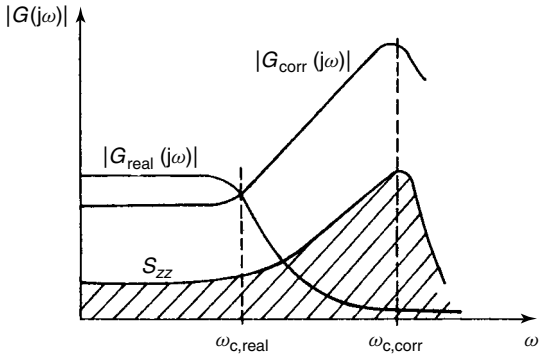

Figure 8. Physical explanation of the increase of the noise in case of correction.

6 AN EXAMPLE

An example considers the first-order system treated in **Article 35, Systems in the Time Domain, Volume 1** and **Article 37, Relationship Between Systems in the Time and Frequency Domain, Volume 1**. The frequency response there is

$$G(\text{j}\omega) = \frac{1}{1 + \text{j}\omega T} \tag{5a}$$

Let S_{x_0} be a white-structure signal applied to the input, let the band be limited to ω_x and let white noise S_{z_0} be the type of interference. Furthermore, no correlation is assumed between the signal and the interference.

The correction program of a series-connected system that can be realized, in this case reads

$$G_{\mathrm{k}}(\mathrm{j}\omega) = \frac{1 + \mathrm{j}\omega T}{1 + \mathrm{j}\omega T_{\mathrm{k}}} \tag{5b}$$

of which the factor

$$\frac{T}{T_{\mathrm{k}}} = \frac{\omega_{\mathrm{c,k}}}{\omega_{\mathrm{c}}} \tag{5c}$$

indicates the improvement of the bandwidth by use of the correction. If a microcomputer is used for the realization of (5b), the limit frequency of the digital conversion, with the sampling time t_{s}, is

$$\omega_{\mathrm{c,s}} = \pi / t_{\mathrm{s}} \tag{5d}$$

Thus, the mean-square error is

$$\overline{\varepsilon^2} = S_{x_0}\left(\int_0^{\omega_{\mathrm{c,s}}} \frac{\omega^2 T_{\mathrm{k}}^2}{1 + \omega^2 T_{\mathrm{k}}^2}\,\mathrm{d}\omega + \omega_x - \omega_{\mathrm{c,s}}\right) + S_{z_0}\int_0^{\omega_{\mathrm{c,s}}} \frac{1 + \omega^2 \mathrm{T}^2}{1 + \omega^2 T_{\mathrm{k}}^2}\mathrm{d}\omega \tag{5e}$$

In order to obtain values that can be compared with the original system and enable an estimate of the efficiency of the correction to be generated, we calculate the error of the system without any correction while assuming a bandwidth limited to $\omega_{\mathrm{c}} = 1/T$:

$$\overline{\varepsilon_0^2} = S_{x_0}\left(\int_0^{\omega_{\mathrm{c}}} \left|1 - \frac{1}{1 + \mathrm{j}\omega T}\right|^2 \mathrm{d}\omega + \int_{\omega_{\mathrm{c}}}^{\omega_x} \mathrm{d}\omega\right) + S_{z_0}\int_0^{\omega_{\mathrm{c}}} \mathrm{d}\omega = S_{x_0}\,\omega_{\mathrm{c}}\left(\frac{\omega_x}{\omega_{\mathrm{c}}} - \frac{\pi}{4} - \frac{S_{z_0}}{S_{x_0}}\right) \tag{5f}$$

To find a more favorable solution in each case, and thus obtain suggestions for synthesis, consider the following two cases: (i) the limiting frequency $\omega_{\mathrm{c,s}}$, that is, the sampling frequency, be adapted to the limiting frequency of the corrected system $\omega_{\mathrm{c,k}}$; and (ii) the limiting frequency $\omega_{\mathrm{c,s}}$ be adapted to the limiting frequency of the signal ω_x:

1. $\omega_{\mathrm{c,s}} = \omega_{\mathrm{c,k}}$. From (5e), for $\omega_{\mathrm{c,s}} = \omega_{\mathrm{c,k}} < \omega_x$, one obtains

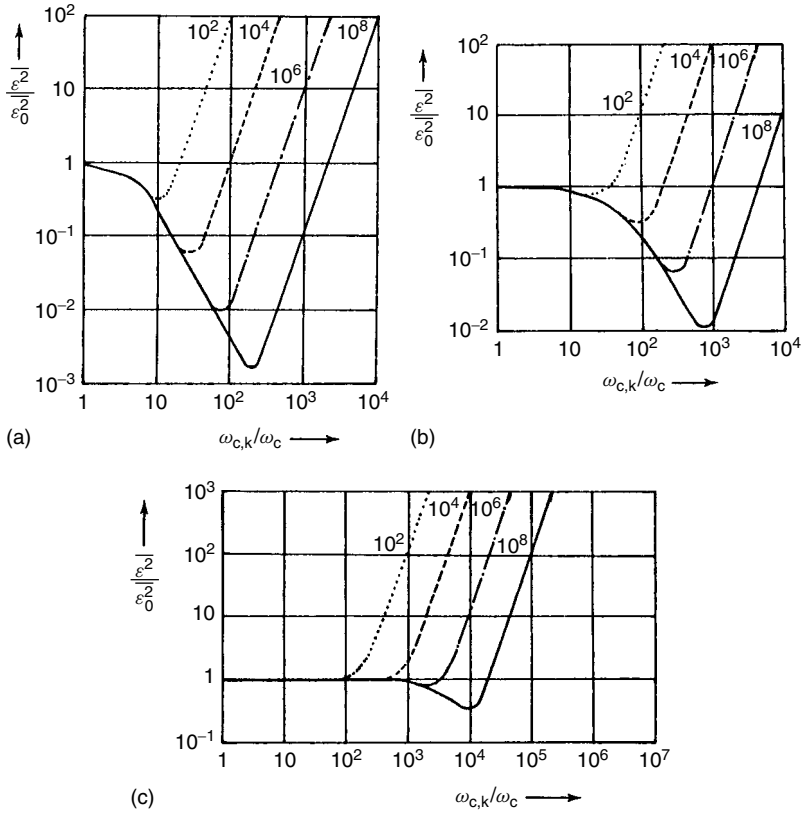

Figure 9. Dependence of relative mean-square error on the bandwidth improved by correction: $S_{x_0}/S_{z_0} = 10^2$; - - - - - $S_{x_0}/S_{z_0} = 10^4$; ·-·-·-·- $S_{x_0}/S_{z_0} = 10^6$; ——— $S_{x_0}/S_{z_0} = 10^8$; (a) $\omega_x/\omega_{\mathrm{c}} = 10$; (b) $\omega_x/\omega_{\mathrm{c}} = 10^2$; (c) $\omega_x/\omega_{\mathrm{c}} = 10^4$.

$$\overline{\varepsilon^2} = S_{x_0}\,\omega_{c,k}\left[\left(1+\frac{S_{z_0}}{S_{x_0}}\frac{\omega_{c,k}^2}{\omega_c^2}\right)\left(1-\frac{\pi}{4}\right) + \frac{\omega_x}{\omega_{c,k}} - 1 + \frac{S_{z_0}}{S_{x_0}}\frac{\pi}{4}\right] \tag{5g}$$

and for $\omega_{c,s} = \omega_{c,k} > \omega_x$, respectively,

$$\overline{\varepsilon^2} = S_{x_0}\,\omega_{c,k}\left[\frac{\omega_x}{\omega_{c,k}} - \arctan\left(\frac{\omega_x}{\omega_{c,k}}\right) + \frac{S_{z_0}}{S_{x_0}}\frac{\omega_{c,k}^2}{\omega_c^2} + \left(1-\frac{\pi}{4}\right) + \frac{S_{z_0}}{S_{x_0}}\frac{\pi}{4}\right] \tag{5h}$$

2.

$$\omega_{c,s} = \omega_x \tag{5i}$$

$$\overline{\varepsilon^2} = S_{x_0}\,\omega_{c,k}\left\{\left(1+\frac{S_{z_0}}{S_{x_0}}\frac{\omega_{c,k}^2}{\omega_c^2}\right) \times\left[\frac{\omega_x}{\omega_{c,k}} - \arctan\left(\frac{\omega_x}{\omega_{c,k}}\right)\right] + \frac{S_{z_0}}{S_{x_0}}\arctan\left(\frac{\omega_x}{\omega_{c,k}}\right)\right\} \tag{5j}$$

Any existing amplification or attenuation in the original system (static transmission factor) may be considered in the usual manner in the signal to noise ratio S_{x_0}/S_{z_0}.

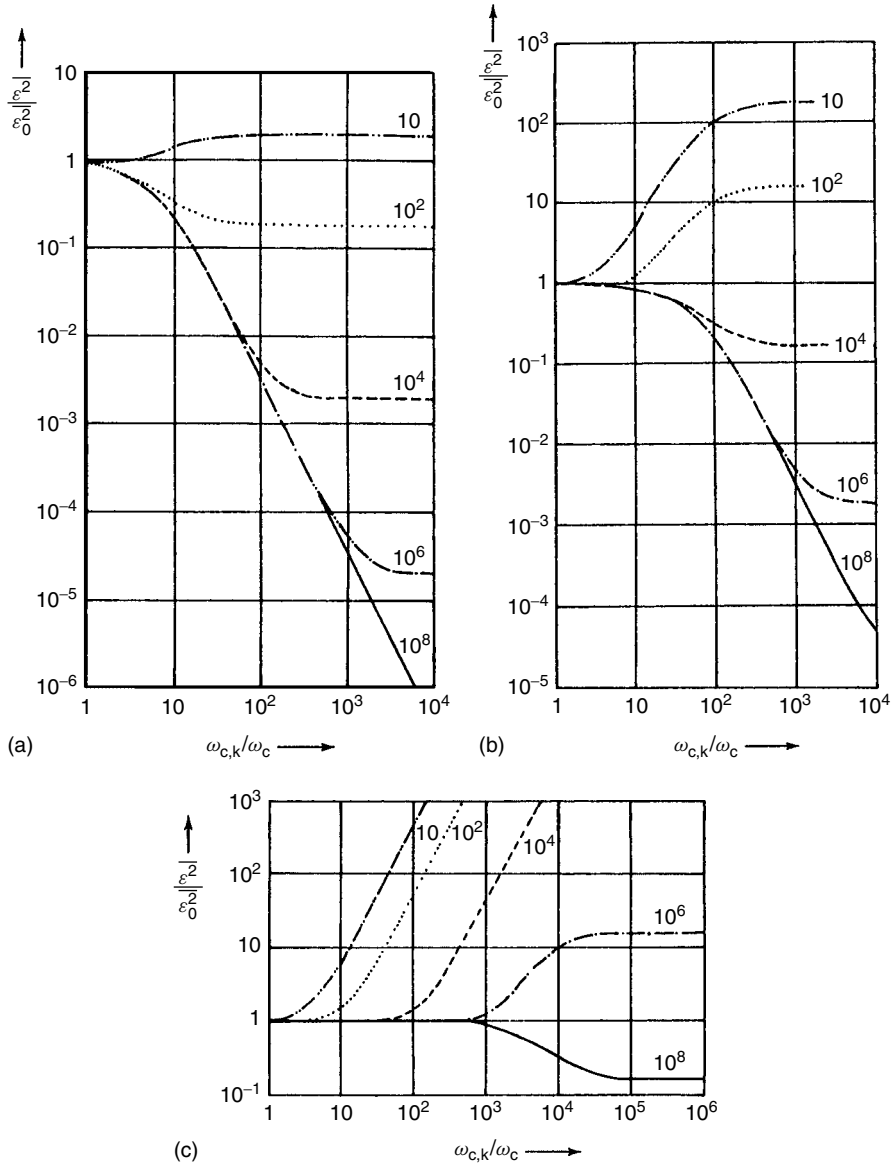

Figure 10. Continuation of Figure 9: ·····$S_{x_0}/S_{z_0} = 10$; · · · ·$S_{x_0}/S_{z_0} = 10^2$; - - - - -$S_{x_0}/S_{z_0} = 10^4$; -·-·-$S_{x_0}/S_{z_0} = 10^6$; ——$S_{x_0}/S_{z_0} = 10^8$; (a) $\omega_x/\omega_c = 10$; (b) $\omega_x/\omega_c = 10^2$; (c) $\omega_x/\omega_c = 10^4$.

In Figure 9(a, b, c), the results obtained from (5g, h) are shown for different values of the signal to noise ratio of 20, 40, 60, and 80 dB, that is for $S_{x_0}/S_{z_0} = 10^2, 10^4, 10^6$, and 10^8, in relation to the bandwidth increase by correction of $\omega_{c,k}/\omega_c$. The parameters of ω_x/ω_c were selected such that dynamically good systems (Figure 9a) as well as dynamically poor systems (Figure 9c) are involved. The values for the mean-square error ε^2 are related to the error of the uncorrected system $\overline{\varepsilon_0^2}$ according to (5f), so as to indicate directly the reduction of the error.

All the diagrams for the adaptation of the bandwidth $\omega_{c,k}$ to the bandwidth of the program for system correction $\omega_{c,s}$ (Figure 9a) reveals a minimum corresponding to the case of an optimum filter: while the dynamic portion of error (first term (5e)) decreases with the rising degree of correction, the interference-dependent portion increases with the rising degree of correction, this being due to the increase in the spectral portions $\omega > \omega_c$. The efficiency of the correction, therefore, will be higher, the dynamically better the system and the smaller the interferences. This substantiates the finding obtained by Woschni (1969) on the basis of physical considerations.

By adapting the bandwidth $\omega_{c,k}$ to that of the input signal (Figure 9b), the results shown in Figure 10(a, b, c) are obtained from (5j). The parameters were selected such that direct comparison with the results represented in Figure 9 is possible. In contrast to Figure 9(a), dependencies are obtained, which tend asymptotically to a limit value. This is because the interference-dependent portion does not rise any more because of band limitation. In dynamically very poor systems, that is, for the case of large values of ω_x/ω_c (Figure 10b, c), the error increases with correction. In these cases, the increase in the fraction of errors caused by interference predominates because of the increase in the high spectral frequencies.

Finally, it should be emphasized that, in practice, further limitations in efficiency occur due to the sensitivity of parameters, which in this investigation, have not been taken into consideration and may arise due to possibly existing nonlinearities (Woschni, 1967), (Bellmann, 1961) and (Levine, 1996).

1 UNCERTAINTY AND ERROR SOURCES IN DIGITAL SIGNALS

Digital systems are adopted today in a broad range of measurement applications. While supported by the current remarkable innovations in microelectronics and the related technologies, the reason for the widespread usage of digital systems in measurement is that they are inherently less prone to error in communication and manipulation.

Traditional measuring systems behave as transducers of measurands to quantities directly perceivable by human beings, such as angular deflections of needles on graduated scales. Their operation can be described in terms of physical transformations for which the interpretation of the physical states as information entities is left to the observer. In this case, any further data processing (leading to the so-called indirect, or derived, measurement) is accomplished by devices external to the measuring system, if not done manually by the observer.

On the other hand, characteristic of the concept of digital coding is the hypothesis that physical signals are simply carriers for univocally recognizable and mutually distinguishable symbols, so that physical transformations of signals are actually modeled and dealt with as formal data processing operations (i.e., mathematical functions) in the symbol domain.

Transition from hardware to software forms for the information medium is the paradigm of this transition. While the information content in analog systems resides entirely as features and states of their hardware, in the case of digital systems, a progressive virtualization of the content can be used that varies from hard-wired logic systems, to microprocessor-based programmable systems, to the so-called virtual instruments, whose operation could be even interpreted as if their characterizing software layer is executed in an ideal hardware subsystem (*see also* **Article 144, DSP Chip Sets, Volume 3**).

Corresponding to each of these levels of abstraction, arise different issues in the metrological characterization of the systems, and in particular in the identification of the typical sources of uncertainty/error, related to both the hardware and the (multiple) software layers.

The combined uncertainty u_Y summarizing the contributions of such multiple sources u_{X_i} depends additively on them, as formalized by the law of propagation of uncertainty, as recommended by the ISO *Guide to the expression of uncertainty in measurement* (GUM) (the simplified version of such a law is shown here, applicable in the case of statistically uncorrelated sources) (*see also* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**):

$$u_Y^2 = \sum_{i=1}^{N} \left(\frac{\partial f}{\partial X_i} \right)^2 u_{X_i}^2 \tag{1}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

where f is the function modeling the relationship that links the measurand to its influence quantities. Equation (1) is obtained as a first-order Taylor series approximation of the model function computed in a (N-dimensional) point assumed 'sufficiently closer' to the average values of the quantities X_i and under the hypothesis that f is 'sufficiently linear' in the neighborhood of such a point.

While usually reasonably correct in the case of instrumentation dealing with smoothly varying quantities, these assumptions could become quite critical for digital systems, for then nonlinearities that sometimes are very strong, such as those manifesting as the consequence of bugs in the software, are common.

Given the fundamental requirement to formalize any measurement result by expressing both a measurand value and an estimation of its uncertainty, the usage of digital signals and systems (particularly if under software control) usually implies to trade off flexibility for complexity.

2 LIST OF TYPICAL DIGITAL SIGNAL UNCERTAINTIES AND ERRORS

While in some specific cases digital systems integrally operate on digitally coded entities (e.g. in some cases of counting in which the measurand is inherently discrete), they are also widely used in the measurement of continuously varying quantities so that a preliminary stage of analog-to-digital conversion is implied.

Once such a transduction has been completed, the operations are performed on coded symbols, that is, on a purely algorithmic basis (*see also* **Article 33, Coding Theory and its Application to Measurement, Volume 1**). The results are then fed into a device that acts as an output transducer, which is sometimes required to convert the digital symbols back to analog signals.

As a consequence, a metrological characterization of digital systems involves the analysis of their behavior in reference to three general components, each of them being affected by specific causes of uncertainties/errors.

The input subsystem is set to acquire information on the measurand from the environment and, when needed, converting it into an equivalent digital form.

Its general structure includes a sensor, a signal conditioning component, and an analog-to-digital converter (ADC) that, in PC-based systems, is usually part of a data acquisition card – *see also* **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**; **Article 136, Quantizing Theory Relevant to DAS, Volume 3**.

Digital signals are obtained as the output of such a subsystem; hence, strictly speaking the input subsystem does not contribute to the budget of system uncertainties/errors related to digital signals. On the other hand, ADC characteristics and behavior significantly influence the quality of the generated digital signals (conceptually definable as the degree of correspondence with the originating analog signals and operatively affecting the possibility of reconstructing them from the converted digital signals) – *see also* **Article 138, Sampling Theory Relevant to DAS, Volume 3**

The data processing subsystem is aimed at dealing with digitally coded entities to transform them by means of suitably implemented algorithms and to transfer them to remote devices. Uncertainties/errors can appear in both hardware and software layers because of the presence of physical factors modifying the quantity on which the symbols are coded and the low quality of algorithms (or their implementations) adopted in the processing of such symbols. The latter issue grows in relevance as the software adopted for metrological purposes becomes more and more complex, as is the case with spreadsheets or virtual instruments.

Current developments in this area are particularly important, as witnessed by the emerging applications of pattern recognition, automatic control, and data fusion based on the so-called soft computing paradigm in which techniques such as neural networks and fuzzy logic inference are used to exploit uncertainty and partial information.

The output subsystem is finally aimed at making the processed data available to users and user devices (e.g., actuators of control systems) while possibly converting such data to a corresponding analog form. At this stage, raw data produced by the measuring system must be converted to information that is meaningful to the intended users and useful to them.

The sources of possible uncertainties/errors in the expression of measurement results from the digital signals representing the instrument readings are multiple, all basically related to the mathematical model of the measurement system – *see* **Article 104, Models of the Measurement Process, Volume 2**.

While having been traditionally assigned to a human user, the definition and the metrological qualification of this model is now the main task of the knowledge-based intelligent instruments – *see* **Article 128, Nature and Scope of AI Techniques, Volume 2**.

3 DIGITAL SIGNAL UNCERTAINTIES AND ERRORS IN DATA ACQUISITION

Digitalization of analog signals usually implies their time and amplitude discretization, the two basic parameters qualifying such operations being the sampling rate and the

amplitude resolution (also called *the bit depth*) of quantization, measured in samples per second and bits respectively – *see also* **Article 133, Amplifiers and Filters for DAS, Volume 3**.

Even in the case of an ideal ADC, limitations in the size of the data storage devices and bandwidth of the data transmission channels are sources of errors for the generated digital signals:

The sampling theorem shows that the information conveyed by an analog signal is integrally maintained whenever the signal is sampled at a rate greater than twice its bandwidth (for most applications the time interval between samples is kept constant). The usual technique of low-pass (sometimes band-pass) antialiasing filtering (*see also* **Article 125, Outline of Purpose of Analog Data Filters, Volume 2**) is in fact a trade-off between two systematic errors. Its application helps to avoid aliasing effects but removes any information contained in the cut-off portion of the signal spectrum.

The number of intervals (sometimes called *channels* or *cells*) in which the amplitude range is subdivided in quantization specifies the quantizer resolution, that is, the length of the binary word coding each sample. This establishes the amount of the error introduced by quantization.

In the simplest case of uniform quantization, when all intervals have the same half-width a, each sample of amplitude x is associated with a channel i whose midpoint (dealt with as the reference value to be coded) is c_i: the quantization error is then $x - c_i$ corresponding to a maximum quantization error of ± 0.5 least significant bits (LSBs) and a null average quantization error.

Here again a trade-off is implied: to reduce the quantization error, the bit depth of the code word must be increased. Thus, to enhance the accuracy of conversion by the ADC, its precision must also be increased.

To characterize the actual behavior of a physical ADC, some further parameters have to be taken into account, such as internal and external noise, settling time, short-term repeatability, and long-term stability, offset, linearity of gain, and, in the case in which two or more signals are acquired at the same time, cross talk.

It is usual that the specifications for such parameters are directly given by the ADC manufacturer as the interval $\pm a$ that certainly (i.e. with probability $= 1$) contains the corresponding values/errors.

This is the typical case in which the ISO GUM recommends type B uncertainty evaluations on the basis of uniform probability distributions (*see also* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**). The corresponding standard uncertainties are then computed as $a/\sqrt{3}$ and combined by means of (1).

4 DIGITAL SIGNAL UNCERTAINTIES AND ERRORS IN DATA PROCESSING

The simplest kind of data processing is the one performed by systems computing the identity function, that is, producing as their output the same symbols given at their input, as the ideal behavior of an ideal digital transmission channel.

In this case, the presence of errors (generally caused by noise sources external to the channel) is modeled in statistical terms by recognizing that for each input symbol x_i the channel does not deterministically produce an output symbol y_j but a conditional probability distribution $P(y_j|x_i)$ (for binary channels $x_i, y_j \in \{0, 1\}$, and $P(0|x_i) + P(1|x_i) = 1$).

The average value of $-\log_2(P(x_i|y_j))$, called *equivocation* and computed from $P(y_j|x_i)$ by means of the Bayes theorem, represents the average information lost in the transmission process because of errors.

From the channel equivocation $H(X|Y)$ and the source entropy $H(X)$, the channel capacity C is computed as

$$C = \max_X (H(X) - H(X|Y)) \tag{2}$$

a basic informational quantity, measured in bit per symbol (and more usually in bit per second by multiplying it by the rate of symbol transmission over the channel), whose physical grounds are clearly identified in the fundamental relation:

$$C = W \log_2 \left(1 + \frac{S}{N}\right) \tag{3}$$

where W and S/N are the channel bandwidth and signal-to-noise ratio respectively).

In the case in which the information flowing from the source has a rate lower than the capacity C of the channel, several techniques can be adopted to reduce the probability of error at the receiver. All are based on the introduction of redundancies and aimed at either error recognition or correction.

Typical applications of digital signal processing in measurement are digital filtering and DFT/FFT computation (*see also* **Article 143, DFT and FFTs, Volume 3**).

Higher-level operations are now common, for example, in computing statistical parameters as in the case of DC/RMS measurement.

The fundamental parameters qualifying the arithmetic of a processor are its overflow, underflow, and round-off error thresholds.

In the common case of the floating-point number representation (in which numbers are expressed as $(-1)^a \times b \times 10^c$ where $a \in \{0, 1\}$, the mantissa $b \in [1, 10)$ has a fixed

Table 1. Values of machine parameters in IEEE floating-point arithmetic.

Machine parameter	Single precision (32 bits)	Double precision (64 bits)
Machine precision	$2^{-24} \approx 5.96 \times 10^{-8}$	$2^{-53} \approx 1.11 \times 10^{-16}$
Underflow threshold	$2^{-126} \approx 1.18 \times 10^{-38}$	$2^{-1022} \approx 2.23 \times 10^{-308}$
Overflow threshold	$2^{128}(1-\varepsilon) \approx 3.40 \times 10^{38}$	$2^{1024}(1-\varepsilon) \approx 1.79 \times 10^{308}$

number of digits, and the exponent c is an integer spanning between two fixed values, the overflow and the underflow thresholds depend on the maximum positive and negative values of the exponent respectively.

On the other hand, round-off errors depend on the number of digits reserved for the mantissa; they are expressed in terms of the machine precision, a value generally related to the characteristics of not only the processor arithmetic-logic unit (ALU) but also the adopted software platform or compiler. This is an important source of complexity in the metrological qualification of data processing modules.

A commonly implemented reference for the values of these parameters is the IEEE Standard (see Table 1).

The data processing subsystem is usually so complex that, instead of identifying all the relevant sources of uncertainty that would be required to apply (1), a black box solution is sometimes adopted for its metrological qualification. A reference data set is chosen that contains a collection of sampled input data with the corresponding expected output; such input data are fed into the subsystem, and the results are compared with the references. From the analysis of the obtained error, an estimation of the uncertainty of the data processing results is then inferred.

The contribution of all possible hardware faults (and correspondingly the degree of fault tolerance of the system) should also be taken into account for a complete metrological qualification of the system.

1 DEFINITION OF AN ERROR MODEL

Uncertainty determination and presentation is covered in **Article 55, Uncertainty Determination, Volume 1**. This article introduces how errors and uncertainties of measurement are dealt with where many are present when determining a measured value.

The measurement error Δx is defined as a difference between the measured value x_m and true value x_S of the measurand X

$$\Delta x = x_m - x_S \tag{1}$$

If we want to introduce a factor of time, error is defined as

$$\Delta x(t) = x_m(t) - x_S(t) \tag{2}$$

The p domain for linear or quasi-linear measuring systems is

$$\Delta x(p) = x_m(p) - x_S(p) \tag{3}$$

where $x_m(p)$ – the measured value transformed by Laplace transform; $x_S(p)$ – transformed true value.

For simplicity, let us assume that x_S is the value at the input of the measuring system and x_m is the value at the output of the measuring system. Sometimes, value x_S, at the input of the measuring system, is not identical with the value of the measurand. Its inaccessibility and common impact on the measurand and measuring system may cause this. Similarly, the obtained value x_m may not need to be identical with the output value of the measuring system due to such things as signal processing taking place after the data leaves the measuring system.

Error is treated as a time function when quantity X is time dependent, or if the transient processes in the measuring system are still active, as shown in Figure 1.

Measurement error Δx consists of the static error Δx_{st} and the dynamic error Δx_{dy}.

Dynamic error arises when the measurand is time dependent and change occurs before the transient processes are completed or when the measurand is time steady but determination of the value in the time t^* arrives before the transient processes in the measuring system are over.

Measurement error (static and dynamic) consists of the systematic and stochastic part (*see also* **Article 49, General Characterization of Systematic and Stochastic Errors, Volume 1**).

If the transfer function of the measuring system is represented as

$$S(p) = \frac{x_m(p)}{x_S(p)} \tag{4}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

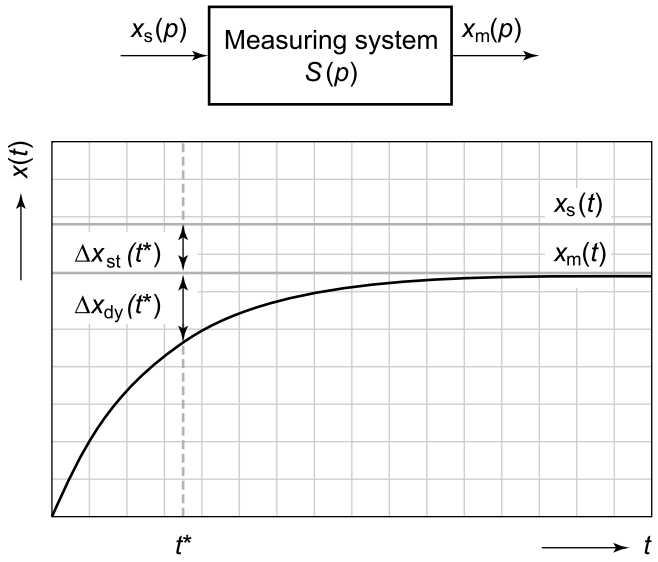

Figure 1. Relationship between the measured and true value of measurand. $x_s(t)$ – path of the input value; $x_m(t)$ – path of the output (measured) value; $\Delta x_{st}(t^*)$ – static measurement error in time t^*; $\Delta x_{dy}(t^*)$ – dynamic measurement error in time t^*.

the error is then

$$\Delta x(p) = \left(1 - \frac{1}{S(p)}\right) x_m(p) \tag{5}$$

The error value in the time domain is determined by the use of the reverse Laplace transformation.

Error Δx is also called an *absolute error*.

The ratio of the absolute error to the true value is called the *relative error*.

In the time domain

$$\Delta x_r(t) = \frac{x_m(t) - x_S(t)}{x_S(t)} = \frac{x_m(t)}{x_S(t)} - 1 \tag{6}$$

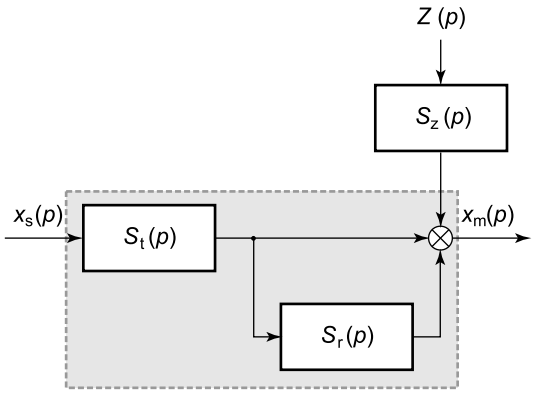

Figure 2. Scheme of the measuring system and the influence of errors. $S_t(p)$ – theoretical transfer function of the measuring system; $S_r(p)$ – transfer function of the inner error; $S_z(p)$ – transfer function of the injected error.

This transforms into the p domain as

$$\Delta x_r(p) = \frac{x_m(p) - x_S(p)}{x_S(p)} = S(p) - 1 = S_r(p) \tag{7}$$

The transfer function $S_r(p)$ characterizes the transfer of the error in the measuring system and does not depend on the value at the system input.

Figure 2 shows schemes of the measuring system with the influence of errors. This figure represents an example for realistic functioning of a measuring system.

2 ERROR BUDGET PRINCIPLES

Absolute measurement error at the output of the measuring system can consist of two parts:

1. Inner error of the measuring system is caused by difference between the theoretical $S_t(p)$ and real transfer function $S(p)$.
2. Error injected into the measuring system from the surrounding by disturbance value z.

Stated errors can comprise of systematic errors with transfer functions $S_S(p)$ and $S_{ZS}(p)$, and random errors with transfer functions $S_R(p)$ and $S_{ZR}(p)$. Figure 3 shows individual cases of the errors acting.

Error sources are associated with the

- measuring system,
- measuring method,
- environment,
- operator.

Details on individual error sources are stated in other articles – *see also* **Article 48, Common Sources of Errors**

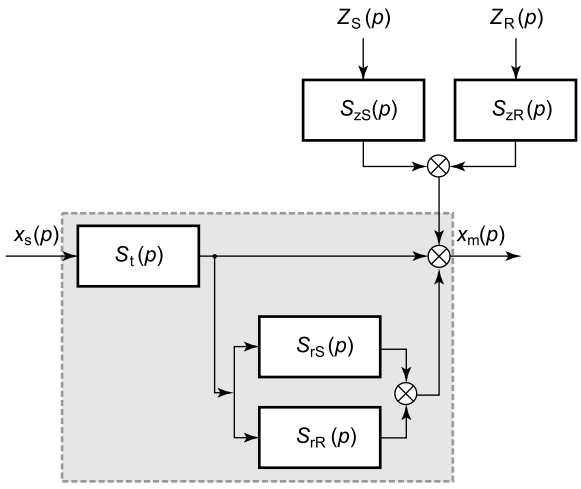

Figure 3. Influence of errors on the measuring system.

in Measurement Systems, Volume 1; **Article 51, Errors in Digital Signal Systems, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; and **Article 49, General Characterization of Systematic and Stochastic Errors, Volume 1**.

As stated before, during measurement of the quantity y, individual errors Δx_i arise and the overall error Δy must be determined. It is then necessary to determine for the quantity y, being a function of the quantities $x_1, x_2, \ldots, x_n$ (indirect measurement of the quantity y), that is,

$$y = f(x_1, x_2, \ldots, x_n) \tag{8}$$

Error is determined by the errors propagation law

$$\Delta y = \sum_{i=1}^{n} C_i \Delta x_i \tag{9}$$

where C_i – sensitivity coefficients being obtained as partial derivation of the f function by individual quantities x_i.

Equation (9) was obtained by expanding function (8) into the Taylor series, neglecting members of high order.

For determination of the uncertainty $u(\Delta y)$ of the error Δy (only if its estimation is known) using (9), the uncertainties propagation law is described by the expression (as the standard uncertainty is equal to the standard deviation):

$$u^2(\Delta y) = \sum_{i=1}^{n} C_i^2 u^2(\Delta x_i) + 2 \sum_{i=1}^{n-1} \sum_{j>i}^{n} C_i C_j u(\Delta x_i, \Delta x_j) \tag{10}$$

where $u(\Delta x_i)$ is the standard uncertainty of the error Δx_i; and $u(\Delta x_i, \Delta x_j)$ isthe covariance between errors Δx_i and Δx_j.

Uncertainties $u(\Delta x_i)$ and covariances $u(\Delta x_i, \Delta x_j)$ are determined by the type A and type B evaluation – *see also* **Article 53, Calculation and Treatment of Errors, Volume 1**; **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**; and **Article 55, Uncertainty Determination, Volume 1**.

If the individual errors Δx_i are not correlated, then

$$u^2(\Delta y) = \sum_{i=1}^{n} C_i^2 u^2(\Delta x_i) \tag{11}$$

The measurement result y obtained by the measurement of the Y quantity will be

$$y = y_{\mathrm{m}} - \Delta y \pm U(\Delta y) \tag{12}$$

where y_{m} is the value obtained from (8) for measured values $x_{\mathrm{m}i}$; and $U(\Delta y)$ is the expanded uncertainty of the error Δy.

Values $x_{\mathrm{m}i}$ can be obtained as

- results of individual measurements,
- arithmetic means or medians or other statistical characteristics of the set of repeated measurements,
- values of physical constants,
- values of different parameters,
- results of previous measurements, and so on,

for estimations of errors when their uncertainties and covariances are known.

3 SETTING UP AN ERROR BUDGET

Basic principles are available that show how individual errors combine and propagate (transfer and combination).

Tables 1, 2, and 3 introduce basic schemes for the transfer of the measurement errors in measuring systems, transfer functions of the measuring system seen from their errors point of view, relative, and absolute errors, and uncertainties of the measuring system.

Similar reasoning leads to the relationships given in Table 4, which shows typical cases for different functions occurring in indirect measurement.

4 CALCULATION OF AN ERROR BUDGET

For the measuring system shown in Figure 3, we can now determine the value of the measured quantity x_{m} in relation to the real quantity x_{s}, as absolute and relative measurement error.

For measured value x_{m}^*, we can determine an estimation Δx^* of the absolute errors Δx and estimation $(\Delta x/x)^*$ of the relative errors $\Delta x/x$, as well as for the uncertainty of estimation of such errors as $u(\Delta x^*)$, respectively $u(\Delta x/x^*)$.

The measurement result will then be an estimation x_{s}^* of the real value x_{s}, obtained as the measured value x_{m}^* corrected for systematic errors (their estimation) and the uncertainty of the estimations of those errors including the uncertainty of random errors.

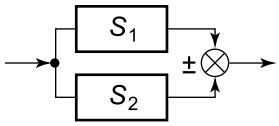
For a measuring system according to Figure 3, the measured value x_{m} in the p domain is given by:

$$x_{\mathrm{m}} = S_{\mathrm{t}}[1 + S_{\mathrm{S}} + S_{\mathrm{R}}]x_{\mathrm{S}} + S_{Z\mathrm{S}} Z_{\mathrm{S}} + S_{Z\mathrm{R}} Z_{\mathrm{R}} \tag{13}$$

The absolute error will be:

$$\Delta x = [S_{\mathrm{t}}(S_{\mathrm{S}} + S_{\mathrm{R}}) - 1]x_{\mathrm{S}} + S_{Z\mathrm{S}} Z_{\mathrm{S}} + S_{Z\mathrm{R}} Z_{\mathrm{R}} \tag{14}$$

Table 1. Transfer of errors and uncertainties through measuring system with serial sequencing of the measuring instruments.



Serial sequencing of the measuring instruments	
	
Transfer function	$S_1 S_2$
Relative error	$\frac{\Delta x_1}{x_1} + \frac{\Delta x_2}{x_2}$
Absolute error	$S_2 \Delta x_1 + S_1 \Delta x_2$
Relative uncertainty	$\sqrt{u^2\left(\frac{\Delta x_1}{x_1}\right) + u^2\left(\frac{\Delta x_2}{x_2}\right) + 2u\left(\frac{\Delta x_1}{x_1}, \frac{\Delta x_2}{x_2}\right)}$
Absolute uncertainty	$\sqrt{S_1^2 u^2(\Delta x_1) + S_2^2 u^2(\Delta x_2) \pm 2 S_1 S_2 u(\Delta x_1, \Delta x_2)}$
Used symbols:	
S_1, S_2	Transfer functions of the measuring instruments
$\Delta x_1, \Delta x_2$	Absolute errors of the measuring instruments
$\frac{\Delta x_1}{x_1}, \frac{\Delta x_2}{x_2}$	Relative errors of the measuring instruments
$u\left(\frac{\Delta x_1}{x_1}\right), u\left(\frac{\Delta x_2}{x_2}\right)$	Relative uncertainties of the measuring instruments (uncertainties of the relative errors of the measuring instruments)
$u(\Delta x_1), u(\Delta x_2)$	Absolute uncertainties of the measuring instruments (uncertainties of the absolute errors of the measuring instruments)
$u\left(\frac{\Delta x_1}{x_1}, \frac{\Delta x_2}{x_2}\right)$	Relative covariance among measuring instruments (covariance among relative errors of the measuring instruments)
$u(\Delta x_1, \Delta x_2)$	Absolute covariance among measuring instruments (covariance among absolute errors of the measuring instruments)

Table 2. Transfer of errors and uncertainties through measuring system with parallel sequencing of the measuring instruments.

Parallel sequencing of the measuring instruments	
Scheme of the measuring system	
Transfer function	$S_1 \pm S_2$
Relative error	$\frac{S_1}{S_1 \pm S_2}\frac{\Delta x_1}{x_1} + \frac{S_2}{S_1 \pm S_2}\frac{\Delta x_2}{x_2}$
Absolute error	$\Delta x_1 + \Delta x_2$
Relative uncertainty	$\sqrt{\frac{S_1^2}{(S_1 \pm S_2)^2}u^2\left(\frac{\Delta x_1}{x_1}\right) + \frac{S_2^2}{(S_1 \pm S_2)^2}u^2\left(\frac{\Delta x_2}{x_2}\right) \pm 2\frac{S_1 S_2}{(S_1 \pm S_2)^2}u\left(\frac{\Delta x_1}{x_1}, \frac{\Delta x_2}{x_2}\right)}$
Absolute uncertainty	$\sqrt{u^2(\Delta x_1) + u^2(\Delta x_2) \pm 2u(\Delta x_1, \Delta x_2)}$

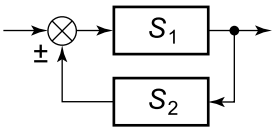
If absolute error is expressed as a function of x_m, then

$$\Delta x = \left[1 - \frac{1}{S_t(1 + S_S + S_R)}\right] x_m + \frac{1}{S_t(1 + S_S + S_R)}(S_{ZS} Z_S + S_{ZR} Z_R) \quad (15)$$

If we know the transfer functions S_S and S_R exactly, as well as the spurious influences and their transfer functions $S_{ZS}Z_S$ and $S_{ZR}Z_R$, we can determine the real value of the measured quantity x_S.

Where we do not know those values exactly, knowing only their estimations as well as the uncertainties of

Table 3. Transfer of errors and uncertainties through measuring system with feedback.



Sequencing of the measuring instruments with feedback	
Scheme of the measuring system	
Transfer function	$\frac{S_1}{1 \pm S_1 S_2}$
Relative error	$\frac{1}{1 \mp S_1 S_2}\frac{\Delta x_1}{x_1} \pm \frac{S_1 S_2}{1 \mp S_1 S_2}\frac{\Delta x_2}{x_2}$
Absolute error	$\frac{S_1}{(1 \mp S_1 S_2)^2}\Delta x_1 \pm \frac{S_1^2 S_2}{(1 \mp S_1 S_2)^2}\Delta x_2$
Relative uncertainty	$\sqrt{\frac{1}{(1 \mp S_1 S_2)^2}u^2\left(\frac{\Delta x_1}{x_1}\right) + \frac{S_1^2 S_2^2}{(1 \mp S_1 S_2)^2}u^2\left(\frac{\Delta x_2}{x_2}\right) \pm 2\frac{S_1 S_2}{(1 \pm S_1 S_2)^2}u\left(\frac{\Delta x_1}{x_1}, \frac{\Delta x_2}{x_2}\right)}$
Absolute uncertainty	$\sqrt{\frac{S_1^2}{(1 \mp S_1 S_2)^4}u^2(\Delta x_1) + \frac{S_1^4 S_2^2}{(1 \mp S_1 S_2)^4}u^2(\Delta x_2) \pm 2\frac{S_1^3 S_2}{(1 \pm S_1 S_2)^2}u(\Delta x_1, \Delta x_2)}$

Table 4. Determination of errors and uncertainties for indirect measurement.

Function	$y = \sum_{i=1}^{n} x_i$
Absolute error	$\Delta y = \sum_{i=1}^{n} \Delta x_i$
Relative error	$\frac{\Delta y}{y} = \sum_{i=1}^{n} \frac{x_i}{x_1 + x_2 + \cdots + x_n}\frac{\Delta x_i}{x_i}$
Absolute uncertainty	$u(\Delta y) = \sqrt{\sum_{i=1}^{n} u^2(\Delta x_i) + 2\sum_{i=1}^{n-1}\sum_{j>i}^{n} u(\Delta x_i, \Delta x_j)}$
Relative uncertainty	$\frac{u(\Delta y)}{y} = \sqrt{\sum_{i=1}^{n} \frac{x_i^2}{(x_1 + x_2 + \cdots + x_n)^2}\frac{u^2(\Delta x_i)}{x_i^2} + 2\sum_{i-1}^{n-1}\sum_{j>i}^{n} \frac{x_i x_j}{(x_1 + x_2 + \cdots + x_n)^2}\frac{u(\Delta x_i, x_j)}{x_i x_j}}$
Function	$y = x_1 - x_2$
Absolute error	$\Delta y = \Delta x_1 - \Delta x_2$
Relative error	$\frac{\Delta y}{y} = \frac{x_1}{x_1 - x_2}\frac{\Delta x_1}{x_1} - \frac{x_2}{x_1 - x_2}\frac{\Delta x_2}{x_2}$
Absolute uncertainty	$u(\Delta y) = \sqrt{u^2(\Delta x_1) + u^2(\Delta x_2) - 2u(\Delta x_1, \Delta x_2)}$
Relative uncertainty	$\frac{u(\Delta y)}{y} = \sqrt{\frac{x_1^2}{(x_1 - x_2)^2}\frac{u^2(\Delta x_1)}{x_1^2} + \frac{x_2^2}{(x_1 - x_2)^2}\frac{u^2(\Delta x_2)}{x_2^2} - 2\frac{x_1 x_2}{(x_1 - x_2)^2}\frac{u(\Delta x_1, \Delta x_2)}{x_1 x_2}}$
Function	$y = x_1 x_2 \cdots x_n$
Absolute error	$\Delta y = \sum_{i=1}^{n} \frac{x_1 x_2 \cdots x_n}{x_i}\Delta x_i$

Table 4. (*continued*).

Relative error	$\dfrac{\Delta y}{y} = \sum_{i=1}^{n} \dfrac{\Delta x_i}{x_i}$
Absolute uncertainty	$u(\Delta y) = \sqrt{\sum_{i=1}^{n} \dfrac{(x_1 x_2 \cdots x_n)^2}{x_i^2} u^2(\Delta x_i) + 2 \sum_{i=1}^{n-1} \sum_{j>i}^{n} \dfrac{(x_1 x_2 \cdots x_n)^2}{x_i x_j} u(\Delta x_i, \Delta x_j)}$
Relative uncertainty	$\dfrac{u(\Delta y)}{y} = \sqrt{\sum_{i=1}^{n} \dfrac{u^2(\Delta x_i)}{x_i^2} + 2 \sum_{i-1}^{n-1} \sum_{j>i}^{n} \dfrac{u(\Delta x_i, x_j)}{x_i x_j}}$
Function	$y = x_1^{l_1} x_2^{l_2} \cdots x_n^{l_n}$
Absolute error	$\Delta y = \sum_{i=1}^{n} \dfrac{l_i x_1^{l_1} x_2^{l_2} \cdots x_n^{l_n}}{x_i} \Delta x_i$
Relative error	$\dfrac{\Delta y}{y} = \sum_{i=1}^{n} l_i \dfrac{\Delta x_i}{x_i}$
Absolute uncertainty	$u(\Delta y) = \sqrt{\sum_{i=1}^{n} \dfrac{l_i^2 (x_1 x_2 \cdots x_n)^2}{x_i^2} u^2(\Delta x_i) + 2 \sum_{i=1}^{n-1} \sum_{j>i}^{n} \dfrac{l_i l_j (x_1 x_2 \cdots x_n)^2}{x_i x_j} u(\Delta x_i, \Delta x_j)}$
Relative uncertainty	$\dfrac{u(\Delta y)}{y} = \sqrt{\sum_{i=1}^{n} l_i^2 \dfrac{u^2(\Delta x_i)}{x_i^2} + 2 \sum_{i-1}^{n-1} \sum_{j>i}^{n} l_i l_j \dfrac{u(\Delta x_i, x_j)}{x_i x_j}}$
Function	$y = \dfrac{x_1 x_2 \cdots x_n}{z_1 z_2 \cdots z_m}$
Absolute error	$\Delta y = \sum_{i=1}^{n} \dfrac{x_1 x_2 \cdots x_n}{x_i z_1 z_2 \cdots z_m} \Delta x_i - \sum_{j=1}^{m} \dfrac{x_1 x_2 \cdots x_n}{z_j z_1 z_2 \cdots z_m} \Delta z_j$
Relative error	$\dfrac{\Delta y}{y} = \sum_{i=1}^{n} \dfrac{\Delta x_i}{x_i} - \sum_{j=1}^{m} \dfrac{\Delta z_j}{z_j}$
Absolute uncertainty	$u(\Delta y) = \sqrt{\sum_{i=1}^{n} \dfrac{(x_1 x_2 \cdots x_n)^2}{x_i^2 (z_1 z_2 \cdots z_m)^2} u^2(\Delta x_i) + \sum_{j=1}^{m} \dfrac{(x_1 x_2 \cdots x_n)^2}{z_i^2 (z_1 z_2 \cdots z_m)^2} u^2(\Delta z_j) + 2 \sum_{i=1}^{n-1} \sum_{j>i}^{n} \dfrac{(x_1 x_2 \cdots x_n)^2}{x_i x_j (z_1 z_2 \cdots z_m)^2} u(\Delta x_i, \Delta x_j) + 2 \sum_{i=1}^{m-1} \sum_{j>i}^{m} \dfrac{(x_1 x_2 \cdots x_n)^2}{z_i z_j (z_1 z_2 \cdots z_m)^2} u(\Delta z_i, \Delta z_j) - \sum_{i=1}^{n} \sum_{j=1}^{m} \dfrac{(x_1 x_2 \cdots x_n)^2}{x_i z_j (z_1 z_2 \cdots z_m)^2} u(\Delta x_i, \Delta z_j)}$
Relative uncertainty	$\dfrac{u(\Delta y)}{y} = \sqrt{\sum_{i=1}^{n} \dfrac{u^2(\Delta x_i)}{x_i^2} + \sum_{j=1}^{m} \dfrac{u^2(\Delta z_j)}{x_j^2} + 2 \sum_{i-1}^{n-1} \sum_{j>i}^{n} \dfrac{u(\Delta x_i, \Delta x_j)}{x_i x_j} + 2 \sum_{i-1}^{m-1} \sum_{j>i}^{m} \dfrac{u(\Delta z_i, \Delta z_j)}{z_i z_j} - \sum_{i-1}^{n} \sum_{j=1}^{m} \dfrac{u(\Delta x_i, \Delta z_j)}{x_i z_j}}$

those estimations, only an estimation of the real measured quantity x_S^* can be determined.

Transfer functions of random errors are estimated as zero, that is, $S_R^* = 0$, $S_{ZR}^* = 0$ and we presume that the uncertainties of those estimations can be determined from measured data; or that we know them.

For measured value x_m^* being valid (assuming $S_R^* = 0$, $S_{ZR}^* = 0$) then:

$$\Delta x^* = \left[1 - \frac{1}{S_t^*(1+S_S^*)}\right] x_m + \frac{S_{ZS}^* Z_S^*}{S_t^*(1+S_S^*)} \tag{16}$$

and the uncertainty of the absolute error is:

$$u^2(\Delta x^*) = \frac{(x_m^* - S_{ZS}^* Z_S^*)^2}{S_t^2(1+S_S^*)^4}[u^2(S_S^*) + u^2(S_R^*)] + \frac{1}{S_t^2(1+S_S^*)^2}[u^2(S_{ZS}^* Z_S^*) + u^2(S_{ZR}^* Z_R^*)] \tag{17}$$

for we do not assume dependence among individual errors.

For error and its uncertainty determined by this procedure in the p domain, we can then extract the error value and its uncertainty using the reverse Laplace transformation.

This is based on the assumption that x_s is the value at the input to the measuring system and value x_m is at the output from the measuring system.

5 EVALUATION OF THE FINAL ERROR FIGURES

If we proceed to use a time domain, the measurement result will be expressed as

$$x = x_m^* - \Delta x^* \pm U(\Delta x^*) \tag{18}$$

where $U(\Delta x^*)$ – expanded uncertainty of the measurement – is determined from the equation

$$U(\Delta x^*) = k u(\Delta x^*) \tag{19}$$

where k – expansion coefficient depending on the probability distribution of the error Δx (value $k = 2$ is often selected in practice).

Example: indirect measurement of the current by measurement of the voltage drop We wish to measure the electric current flowing through a circuit. We will measure the voltage drop on the resistor with a nominal value 1 Ω resistor using a digital voltmeter, as shown in Figure 4.

The surrounding temperature is within $(22 \pm 2)\,^\circ$C. The flowing electric current is expected to be around 50 mA. The calibration certificate of the measuring resistor states that its value for the temperature 22 °C and the current 50 mA is (1–0.0002) Ω and the corresponding expanded uncertainty for the expansion coefficient $k = 2$ is 0.0002 Ω.

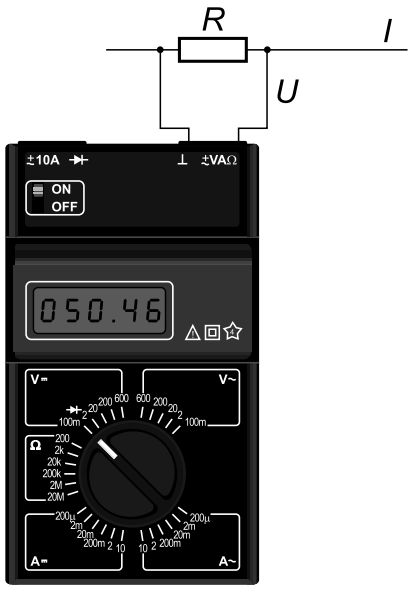


Figure 4. Indirect measurement of electric current I, via use of resistor R to generate voltage U from that current.

The manufacturer states that the digital voltmeter has the maximum permissible error 0.01% of the measured value plus 0.005% of the measuring range for the measuring range 100 mV with the surrounding temperature within 15 to 35 °C.

For the current determination, we use the Ohm's law relationship:

$$I = \frac{U}{R}$$

where I – measured electric current (mA); U – directly measured voltage drop (mV); R – resistance of the measuring resistor (Ω).

We have obtained 10 values by measurement, as listed in Table 5. Measurements were performed under the same conditions.

Following are the estimation results from the measured values:

$$\overline{U} = \frac{1}{10}\sum_{i=1}^{10} U_i = 50.44\,\text{mV}$$

Estimation of the electric current being measured is:

$$\bar{I} = \frac{\overline{U}}{R} = \frac{50.44}{1} = 50.44\,\text{mA}$$

Let us consider only the systematic error of the measuring resistor. This is

$$\Delta I = -\frac{\overline{U}}{R^2}\Delta R = \frac{50.44}{1}0.0002 = -0.01\,\text{mA}$$

Table 5. Values obtained by measurement.

No.	1	2	3	4	5	6	7	8	9	10
U_i (mV)	50.46	50.44	50.45	50.48	50.41	50.49	50.40	50.40	50.45	50.42

Table 6. Balance of errors and uncertainties.

Error ΔX_i	Estimation Δx_i	Standard uncertainty $u(x_i)$	Sensitivity coefficient C_i	Contribution to the standard uncertainty $u_i(y)$
Random	0.00 mV	1.011×10^{-2} mV	1 mA/mV	1.011×10^{-2} mA
Voltmeter ΔU	0.00 mV	0.58×10^{-2} mV	1 mA/mV	0.58×10^{-2} mA
Measuring resistor ΔR	$-0.0002\,\Omega$	$0.0001\,\Omega$	50.46 mA/Ω	0.55×10^{-2} mA
ΔI	−0.01 mA			1.27×10^{-2} mA

Components of the standard uncertainty are as follows:

1. Standard uncertainty of the voltage drop determined by the type A method:

$$u_{\mathrm{A}}(U) = s(\overline{U}) = \sqrt{\frac{1}{10(10-1)}\sum_{i=1}^{10}(U_i - \overline{U})^2}$$
$$= 1.011 \times 10^{-2}\,\mathrm{mV}$$

2. Standard uncertainty of the voltage drop determined by the type B method:

For the voltmeter used and considering the measured value 50.45 mV, the maximum permissible error of the measuring instrument 0.01% of 50.45 mV plus 0.005% of 100 mV, that is, approximately 0.01 mV. Considering the uniform distribution, standard uncertainty is $u_{\mathrm{B}}(U) = 0.01/\sqrt{(3)} = 0.0058$ mV. Current flowing through the voltmeter is neglected. The influence of the temperature that fits within the range $22\,^{\circ}\mathrm{C} \pm 2$ is covered in the basic permissible error of the voltmeter.

3. Standard uncertainty of the measuring resistor:

The expanded uncertainty of the measuring resistor for $k = 2$ is equal to $0.0002\,\Omega$ that matches the standard uncertainty $u(R) = 0.0002/2 = 0.0001\,\Omega$. The influence of the temperature within the range $(22 \pm 2)\ ^{\circ}\mathrm{C}$ on the electrical resistance can be neglected compared to other considered sources.

4. Standard uncertainty of the electric current measurement:

We do not consider any covariances in this case as we measure directly only the quantity of voltage drop. Estimations of the permissible error of the voltmeter and the measuring resistor are considered not to be correlated. Then:

$$u_{\mathrm{I}} = \sqrt{C_U^2 u_{\mathrm{A}}^2(U) + C_U^2 u_{\mathrm{B}}^2(U) + C_{\mathrm{R}}^2 u^2(R)} = 1.27^{-2}\,\mathrm{mA}$$

A summary of the procedure for the uncertainty determination gives the table of the uncertainties balance, see Table 6 and *see also* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**; and **Article 55, Uncertainty Determination, Volume 1**.

The final measurement result is

$$I = (50.440 + 0.010 \pm 0.026)\,\mathrm{mA} = (50.450 \pm 0.026)\,\mathrm{mA}$$

6 METHODS FOR EVALUATION OF UNCERTAINTIES

Uncertainties of individual errors are determined either by type A evaluation or by type B evaluation (*see also* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**; **Article 55, Uncertainty Determination, Volume 1**; **Article 53, Calculation and Treatment of Errors, Volume 1**).

Type A evaluation is based on statistical analysis of measured data.

Type B evaluation is every evaluation that is not of type A.

For example, in the case of a single measurement, all errors and their uncertainties are estimated by the type B method.

Therefore, uncertainties of the random errors must also be evaluated by the type B method (e.g. utilizing experiences, from data of the manufacturer etc.).

As random errors are generated by different influences acting on the measuring process, it is more accurate to perform repeated measurement for their evaluation.

For n repeated measurements under the same conditions, when a set of values $x^*_{\mathrm{m}1}, x^*_{\mathrm{m}2}, \ldots, x^*_{\mathrm{m}n}$ is available, the measurement result will be given as the arithmetic mean of the measured values $\bar{x}^*_{\mathrm{m}}$ reduced on systematic error.

Overall uncertainty of the random error is evaluated by the type A method according to equation

$$u = \frac{s_x}{\sqrt{n}} = \sqrt{\frac{1}{n(n-1)} \sum_{i=1}^{n} (x^*_{mi} - \bar{x}^*_m)^2} \qquad (20)$$

6.1 Covariances

Covariances among the estimations of individual errors determine how much those estimations are influenced by common sources.

Commonly bounded errors contribute to the overall uncertainty more or less than only merging their uncertainties.

Covariances can increase or decrease the resulting overall uncertainty. It depends on their character (whether increasing one error increases another error) and also on the shape of the function that binds them to the output quantity.

Type A evaluation of covariances between estimations of two errors Δx_i and Δx_j is used when n measured values of both quantities $x_{i1}, x_{i2}, \ldots, x_{in}$ and $x_{j1}, x_{j2}, \ldots, x_{jn}$ is available. Then

$$u(\Delta x_i, \Delta x_j) = \frac{1}{n(n-1)} \sum_{k=1}^{n} (x_{ik} - \bar{x}_i)(x_{jk} - \bar{x}_j) \qquad (21)$$

Covariances between two estimations evaluated by the type B method can be determined by studying certificates of the measuring instruments, from literature and so on, or from calculation using the following procedure:

1. For each pair of estimators, one estimates (on the basis of experiences) the correlation coefficient $r(\Delta x_i, \Delta x_j)$ expressing the degree of dependence between estimators.

   Covariance is then obtained from the expression

$$u(\Delta x_i, \Delta x_j) = r(\Delta x_i, \Delta x_j)\, u(\Delta x_i)\, u(\Delta x_j) \qquad (22)$$

2. If two quantities y_1 and y_2 act in indirect measurement and they are defined by the following functions

$$y_1 = f_1(x_1, x_2, \ldots, x_n) \qquad (23)$$

$$y_2 = f_2(x_1, x_2, \ldots, x_n) \qquad (24)$$

the covariance between the quantities y_1 and y_2 is calculated as

$$u(y_1, y_2) = \sum_{i=1}^{n} C_{1i} C_{2i} u^2(x_i) + \sum_{i=1}^{n} \sum_{j \neq i}^{n} C_{1i} C_{2j} u(x_i, x_j) \qquad (25)$$

and for $x_1, x_2, \ldots, x_n$ being commonly independent it is then

$$u(y_1, y_2) = \sum_{i=1}^{n} C_{1i} C_{2i} u^2(x_i) \qquad (26)$$

where C_{1i} respectively C_{1i} – sensitivity coefficients of the function f_1 or f_2 respectively.

Such an approach is used for excluding correlation when a proper measurement model is designed that comprises only independent quantities.

3. If the correlation coefficient cannot be determined and a proper model (excluding correlation) cannot be designed, the maximum influence of correlation to the resulting uncertainty should be determined.

   If $y = f(x_1, x_2)$ then:

$$u^2(y) \leq (|C_1 u(x_1)| + |C_2 u(x_2)|)^2 = C_1^2 u^2(x_1) + C_2^2 u^2(x_2) + 2|C_1 C_2|\, u(x_1)\, u(x_2) \qquad (27)$$

If we do not then have enough information for accurate evaluation of the covariances, and consequently also the resulting uncertainty, the upper limit of the uncertainty can be stated.

1 ERRORS IN MEASUREMENT

All measurements contain some variability, which obscures the true value of the measurand determination (Galyer and Shotbolt, 1990; Doebelin, 2003; Gregory, 1973; Helfrick and Cooper, 1990; Hofmann, 1982; Rangan, Sarma and Mani, 1983; Taylor, 1982).

The variability in a measurement is called the *error of measurement*, which is defined as follows: The error of a measurement is the discrepancy or difference between the result of a measurement and the absolute true value of the quantity measured.

An error of measurement is of little practical use when considered in isolation. A number of measurements of the same true value, each of which has an associated error of measurement, can be used to provide valuable information regarding the accuracy and repeatability of measurements taken.

Thus, measurement is more than just reading the display on the instrument and recording the data. It involves the process of treating and manipulating measurement data to gain maximum benefit from them by extracting as much information as possible from the data.

Although this process of data reduction causes a loss of information about each specific measurement, an overall benefit is achieved by the result of summarizing the typical characteristics of large amounts of data (Weinberg, 1975). McGhee *et al*. (1996) describes the process of treating measurement data as consisting of the following:

- Assessing the consistency of the data.
- Estimating the uncertainties in the result.
- Predicting the result from theory.
- Comparing the data with physical theories and previous, related experimental work.

It is very well known that no measurement is exact. However, it should be made to an acceptable degree of accuracy (Morris, 1997). It is, therefore, important to specify the uncertainty of the measurement along with the result of the measurement. Representing uncertainty numerically and graphically, as given by McGhee *et al*. (1996), is also described in **Article 55, Uncertainty Determination, Volume 1**. There are a number of different sources for measurement error, such as the measurement method, the measuring instrumentation, or the measurement environment. Therefore, it is important to identify the most significant source of errors so that less significant ones may be neglected if sufficiently small.

There are also a large number of terms used to describe different types of errors, such as systematic errors, random errors, parasitic error, method error, observer error, parallax error, interpolation error, error of indication, repeatability error, rounding error, discrimination error, hysteresis error, response error, datum error, zero error, influence error, temperature error, supplementary error, total error, and so on. The first step to be taken in the reduction of errors is understanding them. Some of these errors are covered here.

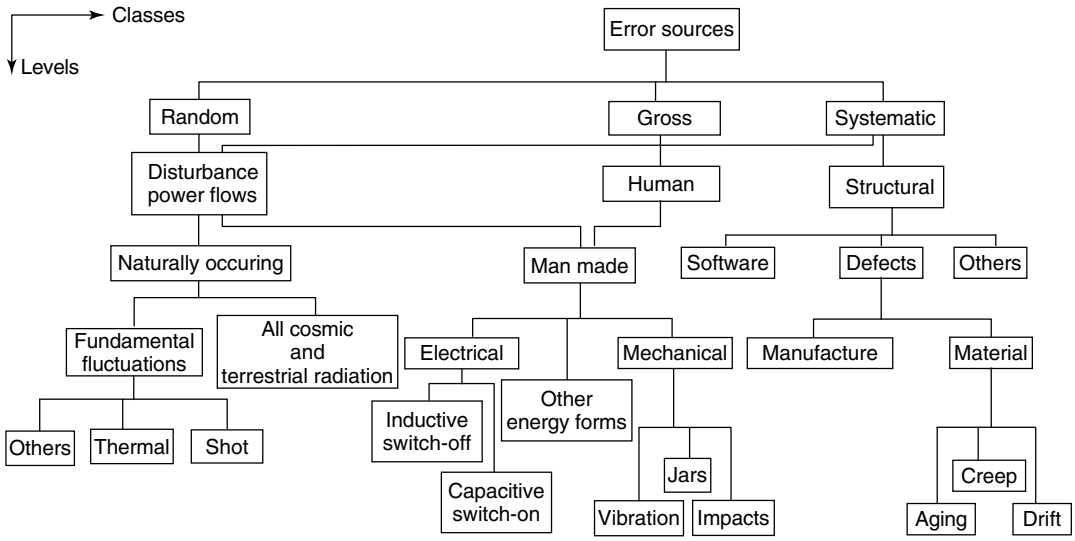

Figure 1. Classification of measurement errors.

2 CLASSIFICATION OF ERRORS

Errors can be classified according to their characteristics. Thus, Figure 1, which shows a summary of the three main groups of error classes, distinguishes between gross errors, systematic errors, and random errors (McGhee *et al*., 1996).

2.1 Gross errors

These are largely human errors. They may be caused by man-made power disturbance flows in any of the COMETMAN energy forms described in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. They also include misreading of instruments leading to incorrect recording of measurement results, which may compound any error due to miscalculation. Other possibilities are incorrect adjustment of an instrument or improper use of an instrument and any computational mistakes. Although gross errors may be difficult to eliminate entirely, they should be anticipated and corrected. Some gross errors can be easily detected but others are difficult to detect.

Gross errors cannot be treated mathematically. They can be avoided only by taking care in the approach and by using error detection routines. For example, errors can be minimized by taking more than one set of readings under the same conditions, or by taking more than one set of readings using different instruments or operators.

In high-precision applications, some measurements need to be taken for the same quantity under the same conditions, by using different operators. In some conditions, the error associated with an operator is included in the estimation of the measurement error.

2.2 Systematic errors

These errors are due to systematic disturbance power flows, caused by human activities, or by structural imperfections or defects in software, inadequacies in manufacturing methods, inadequacies in materials of instrument construction, or some other unidentifiable or unspecified causes.

When a measurand is repeatedly measured under the same conditions, systematic errors always have the same value. In other words although they are constant under constant conditions, they are caused by intrinsic errors arising from long-term variations.

Systematic errors have the property that the next individual measurement error value can be predicted once the error law has been determined.

Systematic errors are divided into instrumental and environmental errors according to their sources. They can also be classified according to their behavior into dynamic and static errors.

- Instrumental errors are defined as imperfections of the measuring instrument. They are inherent in measuring instruments because of their structure. There are many types of instrumental errors, which depend upon the instrument. Instrumental error can be avoided by selecting a suitable instrument for the particular measurement application, calibrating the instrument against a standard, adjusting the instrument before using it, and by applying the estimated factors of correction. Instrumental errors in a measuring instrument can be accounted for, approximately, by replacing it with an instrument of higher accuracy. In this case, the systematic error in

the instrument under test is the difference between the two results.

- Environmental errors are caused by conditions external to the measuring instrument. These conditions include changes in temperature, pressure, humidity, interference, magnetic field, electrostatic field, and many more. If it is possible to control the measuring environment by providing air-conditioning, then calibration accuracy may be improved. Also, if certain components can be hermetically sealed, then errors due to adverse environmental effects may be reduced. When measurements are conducted using appropriate shielding techniques, then errors due to electromagnetic interference can be totally removed.
- Static errors are caused by the limitation of the measuring instrument or the physical law governing its behavior.
- Dynamic errors are caused by the inability of the instrument to respond fast enough to follow the changes in the measurand. However, although systematic errors always exist in any measurement, they can be minimized to a degree suitable to the aimed uncertainty of measurement.
- The terminology for static systems is covered in **Article 58, Description of Accuracy, Linearity, and Drift, Volume 1** and **Article 57, Static Considerations of General Instrumentation, Volume 1**; dynamic description is covered in **Article 61, First-order System Dynamics, Volume 1**; **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**; **Article 62, Second-order System Dynamics, Volume 1**; and **Article 60, Zero-order System Dynamics, Volume 1**.

2.3 Random errors

Even when all systematic errors have been accounted for, a residual error will invariably occur. This residual error, due to unspecified or unknown causes, is normally assumed to have a random nature. Random errors are unpredictable in that the next occurring single data value cannot be predicted with certainty, whereas the behavior of the group can arise through irregular chances of random causes normally due to fundamental fluctuations or extraterrestrial generation.

McGhee, Henderson and Sankowski (1986) provide a comprehensive but incomplete list of starting point references. The random sources cause changes in the reading for each repeated measurement under the same conditions. In well-designed experiments, few random errors usually occur, but they become important in high precision measurements.

The only way to compensate for random errors is by taking a large number of readings and by using statistical methods to obtain the best approximation of the true value of the measurand.

In many cases, it is difficult to distinguish between systematic errors and random errors. This can be seen in the summary of the random and systematic errors in measurement and their sources, which is given in Figure 1.

1 MEASUREMENT RESULTS AND THEIR QUALITY

Measurement is a peculiar means of acquiring and formally expressing information about empirical systems. It is aimed, therefore, at setting up a bridge between the empirical world and the linguistic/symbolic world, the domains of the systems under measurement, and measurement results respectively.

A fundamental evidence is that these two realms exhibit extremely different characteristics. Empirical systems are embedded in the space–time universe, and this generates their space and time dependency: any system is only partially isolated from its environment and its dynamic forces distinguishing between the system itself and its temporal versions, that is, the system states. On the other hand, symbolic entities such as numbers are coextensive with their definitions (in a sense: they *are* their definitions) so that they are always identical to themselves. Paradigmatically, noise exists in the empirical realm, not in the symbolic one; real numbers exist in the symbolic realm, not in the empirical one.

Whenever the two realms interact with each other, as measurement does by means of the mediation of quantities, these diversities (a) require the introduction of a concept of quality of the symbols (in our case, measurement results) chosen as representatives for empirical states and (b) are the cause of several issues affecting such a quality.

The typical operative context of measurement that is presented in Figure 1 shows that the required empirical results ('the output') can be in principle obtained as the transformation of the same empirical states ('the input') by a direct manipulation (an 'empirical procedure') or a transduction to information entities, to be processed and finally transduced back to the empirical realm (an 'informational procedure') shown in Figure 2.

The benefits of informational procedures are commonly recognized (basically due to the fact that it is much easier to deal with symbols than with empirical things), but they depend on the faithfulness of measurement results as representative entities for the corresponding empirical states.

Such faithfulness, and therefore the quality of measurement results, is limited as a consequence of causes related to the following:

- *Model of the system under measurement*: incompleteness, if not faults, in the definition of the measured quantity (the measurand), as in the case of an ill-characterized system dynamics or only a partial identification of the quantities influencing the measurand.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

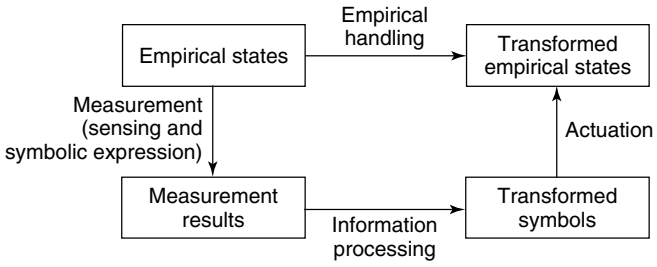

Figure 1. The role of measurement in the relations between empirical and symbolic realms.

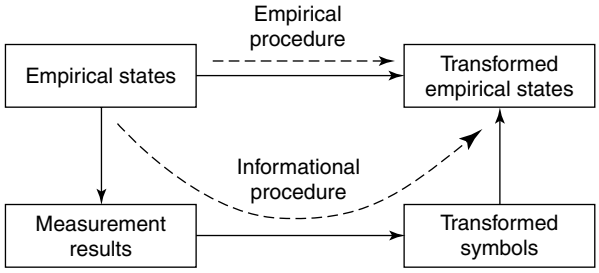

Figure 2. The (possible) equivalence of empirical and informational procedures.

- *Operative accomplishment of the measurement procedure*: poor repeatability, or stability, or selectivity of the adopted measuring system (*see also* **Article 104, Models of the Measurement Process, Volume 2**), if not faults in its usage.

The unavoidable presence of such flaws is the reason requiring us *to state any measurement result by expressing in symbols a measurand value together with an estimation of its deemed quality*.

2 THE CONCEPT OF ERROR

It is a well-known fact that the repeatability of measurements can be increased by

- improving the measuring system in its empirical characteristics,
- reporting the results with a reduced number of significant figures,

that is, by adjusting the sensing device or modifying the symbolic expression respectively (see Figure 3).

The repeatability of a measurement, and in more general terms its quality, is therefore a relative characteristic to be evaluated in reference to the goals for which the operation is performed and the available resources (in epistemological terms, this can be thought of as a confirmation that a concept of absolute, or complete, precision is simply meaningless).

It is amazing in this perspective to note that the indication of the estimated quality of the results became customary in physical measurement only in the late nineteenth century, and, however, several decades after the Theory of Error provided by Gauss at the beginning of that century. A plausible reason for this can be recognized in the commonly (in the past) assumed hypothesis that measurable quantities are characterized by a perfectly precise 'true value'. The choice of adopting the concept of error to model and formalize a less-than-ideal quality of measurements originates from this hypothesis: any discrepancy between the measuring system outputs and the measurand 'true value' should be taken into account as an error, and correspondingly dealt with (*see also* **Article 49, General Characterization of Systematic and Stochastic Errors, Volume 1**).

However,

- an error can be recognized as such only if a corresponding 'right entity' exists;
- errors can be corrected only if their corresponding 'right entities' are known;
- 'true values', that play the role of such 'right entities' in the case of measurement, are in principle unknown (otherwise measurement itself would be useless. . .) and cannot be operatively determined.

These assertions imply that the Theory of Error is grounded on metaphysical, empirically inapplicable bases. Consider the following two statements:

- 'at the instant of the measurement, the system is in a definite state';
- 'at the instant of the measurement the measurand has a definite value'.

Traditionally they would be considered as synonymous, whereas their conceptual distinction is a fundamental fact of metrology: the former represents a basic assumption for measurement (we are not considering here measurement in quantum mechanics), while the latter is epistemically unsustainable and, however, operationally irrelevant. Measurement results are symbolic, and not empirical, entities:

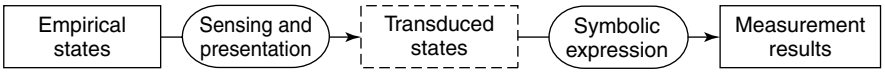

Figure 3. Abstract schematization of a measurement.

what in the measurement is *determined*, and therefore considered preexisting, is the system state, not the measurand value that is instead *assigned* on the basis of the instrument reading and the calibration information.

3 THE CONCEPT OF UNCERTAINTY

The search for a more adequate framework reached a crucial point about 30 years ago, when it was understood that a common approach for modeling and formally expressing a standard parameter describing the quality of measurement results was a condition for establishing strict cooperation among the national calibration laboratories. To build up and maintain mutual confidence between accreditation bodies and to build up and maintain compatibility for their calibration certificates required having the quality of their measurement results evaluated and expressed according to some harmonized protocol. To this goal, the *International Committee for Weights and Measures* (CIPM), started a project together with several international organizations involved in standardization (International Organization for Standardization (ISO), International Engineering Consortium (IEC), International Organization of Legal Metrology (OIML), ...): its final result is the *Guide to the Expression of Uncertainty in Measurement* (GUM), first published in 1993 and later introduced as a Standard by each of such organizations. While originally intended for calibration laboratories, the GUM is presently to be considered as the basis for expressing the results of any measurement performed in accordance with an international standard.

According to the GUM, the uncertainty of a measurement result is 'a parameter, associated with the result of a measurement, that characterizes the dispersion of the values that could reasonably be attributed to the measurand'. Apart from this rather classical definition, the most important innovation of the GUM stands in its recognition that the uncertainty of measurement results can be evaluated according to two distinct and complementary methods:

- some uncertainties, designated as 'of type A', are computed as suitable statistics of experimental data, usually obtained as repeated instrument readings;
- some other uncertainties, designated as 'of type B', are instead estimated on the basis of the observer's personal experience and the available a priori information, and therefore express a degree of belief on the possible measurand values.

The recognition that even measurement, an operation traditionally deemed as the paradigm of objective information acquisition, requires the introduction of some subjective evaluation is of capital importance. Therefore, the shift from 'error' to 'uncertainty' is far more than a terminological issue, and witnesses a conceptual transition from an ontological position to an epistemic one: according to the GUM standpoint, to establish the quality of measurement results is an issue related to the *state of knowledge* of the measurer, and therefore 'absolute quality' cannot be reached simply because some *intrinsic uncertainty* is always part of the measurement system.

The possible sources of uncertainty that the GUM itself lists are exemplar in this regard: together with the 'variations in repeated observations of the measurand under apparently identical conditions', the reason usually recognized for random variability, and some causes related to instrumental issues such as 'approximations incorporated in the measurement procedure' and 'instrument resolution or discrimination threshold', the GUM identifies several epistemic sources, among them the incomplete definition of the measurand and the imperfect realization of its definition (*see also* **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**).

4 CHARACTERIZING A MEASUREMENT WITH ITS UNCERTAINTY

To accomplish a measurement process, three distinct activities must be sequentially performed:

- *Acquisition*: by means of a sensing device, the measurand is transduced to a quantity suitable for direct access by the measurer (e.g. the angular position of a needle with respect to a reference scale), possibly through the mediation of an 'intermediate' quantity (a typical role for electrical quantities) to drive processing and presentation devices (see Figure 4).
- *Evaluation*: the access to the transduced quantity (i.e., the instrument reading) concludes the empirical part of the operation; by gathering and processing the available information (the transduced quantity itself, together with everything that is known on the measurement system: the measurand definition and realization, the instrument calibration diagram, the values of relevant influence quantities, etc.), the measurer evaluates the

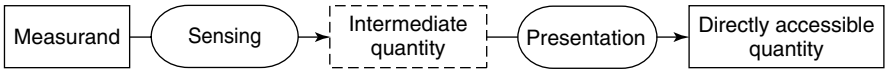

Figure 4. Abstract schematization of the empirical component of a measurement.

measurand value and its uncertainty; this inferential process is based on both objective and subjective information.
- *Expression*: the obtained information is expressed in symbolic form according to an agreed formalization.

It should be noted that the same information could be in principle expressed in different forms for different needs, by adopting, typically, a statistical or a set-theoretical formalization (or some generalization of the latter, as in the case of representations based on fuzzy sets: we will not deal with such generalizations here). Consider the traditional indication, $x \pm y$, that admits two distinct interpretations:

- the measurand value is expressed as the scalar x, with y as its estimated uncertainty;
- as the measurand value, the whole interval $(x - y, x + y)$ is taken, whose half-width, y, expresses the quality (sometimes called *precision*) of such a measurement result.

Neither of them is the 'right one': they should be selected according to the specific application requirements.

The GUM adopts this approach, and while basing its procedure on the first interpretation, recognizes that 'in some commercial, industrial, and regulatory applications, and when health and safety are concerned', it is often necessary to express the measurement results by means of intervals of values.

Measurement results must be therefore assigned according to the goals for which the measurement is performed; they are adequate (and not 'true') if they meet such goals. By suitably formalizing them, the measurer is able to express the available information of both the measurand value and its estimated quality. Quoting the GUM again, no method for evaluating the measurement uncertainty can be a 'substitute for critical thinking, intellectual honesty, and professional skill': indeed 'the quality and utility of the uncertainty quoted for the result of a measurement ultimately depends on the understanding, critical analysis, and integrity of those who contribute to the assignment of its value'.

5 THE EXPRESSION OF MEASUREMENT RESULTS AND THEIR UNCERTAINTY

For both type A and type B evaluation methods, the GUM assumes that measurands (but the same holds for all the quantities involved in the measurement system: influence quantities, correction factors, properties of reference materials, manufacturer or reference data, etc.) can be formalized as random variables, and as such characterized by statistical parameters:

- The measurand value is estimated as the mean value of the random variable; in the case of type A evaluations, for which an experimental population X of n repeated reading data x_i is available, it is computed as

$$m(X) = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{1}$$

- The uncertainty of the measurand value is estimated as the standard deviation of the measurand value, being itself a random variable; this parameter is termed as the GUM *standard uncertainty* and denoted $u(m(X))$; in the case of type A evaluations it is computed as

$$u(m(X)) = \sqrt{\frac{1}{n}\frac{1}{n-1}\sum_{i=1}^{n}(x_i - m(X))^2} \tag{2}$$

Measurement results can then be reported, for example, as $m_S = 100{,}021\ 47(35)\,\mathrm{g}$, meaning that the evaluated mass m of the system S (whose specification should include the indication of the operative condition in which the measurement has been performed) is 100,021 g with a standard uncertainty of 0,35 mg.

The same couple of values (measurand value, standard uncertainty) is adopted to express measurement results as intervals. To this goal, a *coverage factor* k (typically in the range 2 to 3) is introduced, such that $U(X) = ku(m(X))$, termed *expanded uncertainty*, is adopted as the half-width of the interval representing the measurement result: $[m(X) - U(X), m(X) + U(X)]$, commonly written as $m(X) \pm U(X)$ (if the probability distribution of the random variable is known, this interval can be thought of as a *confidence interval* whose confidence level depends on k).

In the case of *derived measurement*, that is, when the measurand Y is a quantity depending on N input quantities $X_i, i = 1, \ldots, N$:

$$Y = f(X_1, \ldots, X_N) \tag{3}$$

and for each quantity X_i, the estimated value $m(X_i)$ and uncertainty $u(m(X_i))$ are given, the issue arises of how to obtain the corresponding values $m(Y)$ and $u(m(Y))$ for Y.

The measurand value $m(Y)$ is simply obtained by introducing the estimates $m(X_i)$ in the model function f:

$$m(Y) = f(m(X_1), \ldots, m(X_N)) \tag{4}$$

The uncertainty $u(m(Y))$ is instead evaluated by means of the so-called *law of propagation of uncertainty*, that for

statistically noncorrelated quantities is

$$u^2(m(Y)) = \sum_{i=1}^{N} c_i^2 u^2(m(X_i)) \tag{5}$$

where the 'sensitivity coefficients' c_i that define the extent to which Y is influenced by variations of the input quantities X_i are computed as

$$c_i = \frac{\partial f}{\partial X_i} \text{ evaluated at } X_i = m(X_i) \tag{6}$$

In the general case of correlated input quantities (i.e. their covariance $u(m(X_i), m(X_j)) \neq 0$), (5) becomes

$$u^2(m(Y)) = \sum_{i=1}^{N} c_i^2 u^2(m(X_i)) + 2\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} c_i c_j u(m(X_i), m(X_j)) \tag{7}$$

in which the combined standard uncertainty of the measurement result $m(Y)$ is computed on the basis of a first-order Taylor series approximation of (3) (*see also* **Article 55, Uncertainty Determination, Volume 1**; **Article 52, Error Models, Error Budgets and their Calculation, Volume 1**).

6 THE PROCEDURE FOR ASSIGNING THE MEASUREMENT UNCERTAINTY: AN EXAMPLE

Measurement uncertainty is a *pragmatic* parameter: its value is not intrinsic to the measurand but is to be established in reference to the specific goals according to which the measurement is performed. No 'true uncertainty' exists, and the preliminary step of a procedure aimed at assigning a value to the uncertainty of a measurand value is therefore to decide a *target uncertainty*, the maximum value of uncertainty compatible with the given goals. In any step of the procedure, if the estimated value is reliably considered less than such a target uncertainty, then the procedure should be stopped with a positive result: the measurand can be evaluated with a satisfying uncertainty, and no further resources are required to refine the procedure. On the other hand, whenever the estimated uncertainty becomes greater than the target uncertainty, the procedure must be definitely stopped with a negative outcome, conveying the information that better measurements are required to meet the specified target uncertainty.

According to the GUM viewpoint, *any* measurand Y should be actually evaluated by derived measurement, that is, by firstly identifying its dependence on a set of 'input quantities' X_i, such as influence quantities, calibration parameters, correction factors, and so on. For each X_i, the values $m(X_i)$ should be obtained by statistical or other methods (e.g. as part of instrument specifications), and for each of such $m(X_i)$, the corresponding standard uncertainties $u(m(X_i))$ and covariances $u(m(X_i), m(X_j))$ should be evaluated, again by either type A or type B procedures.

In the case in which the functional relation f is known in its analytical form, the sensitivity coefficients c_i can then be computed; if, on the other hand, the complexity of the measurement system prevents the explicit formalization of (3), each coefficient c_j can be experimentally estimated by a suitable setup of the system in which Y is repeatedly measured while all the quantities X_i but X_j are kept constant.

When at least some $u(m(X_i))$, $u(m(X_i), m(X_j))$, and c_i are available, (6) can be computed to obtain an estimation of the measurand uncertainty $u(m(Y))$, to be compared to the specified target uncertainty.

1 GENERAL COMMENT ON UNCERTAINTY

Numerical information, like most other kinds of information, can always be presented in ordinary prose or text. However, unless the amount of numerical information is small, this method of presentation is clumsy. Consequently, other methods of presenting technical information are often used.

In many cases, the corresponding values of two or more variables have to be presented. It is, therefore, often more appropriate to use tables, graphs, or equations to show the relationships between variables. Before these methods are discussed in detail, a few points regarding units, uncertainties, and rounding off need to be settled.

Whenever numerical information is presented, it must be made clear what unit is being used; this is obvious but occasionally forgotten. In most technical writing, the units employed belong to the SI system.

2 REPRESENTING NUMBERS AND UNCERTAINTIES

Before continuing it is necessary to introduce the manner in which a number is represented. Suppose the number five thousand three-hundred and forty-two point 00... is to be represented. Following the usual procedure using digits, the number is 5342.00... This is the correct representation. However, if the number is fifty thousand three-hundred and forty-two point 00..., then writing it as 50 342.00... is a contravention of the relevant international standard. The standard recommends that, for numbers equal to or greater than ten thousand, the thousands should be separated from the hundreds by a space and not by a comma. The correct representation is thus 50 342.00....

For numbers greater than this, the digits should be grouped in threes, corresponding to increases of 10^3.

If the long-hand version of 2.35×10^6 is required, then it should be written as 2 350 000. In a similar way, the fractional decimal part should be written by grouping the decimal digits in threes so that 2.354×10^{-1} should be written as 0.2354, while 2.3546×10^{-1} should be written in long-hand as 0.23546 (while the standard calls for these formats, common usage still will place a point or comma as the separator).

When numerical information is quoted, the intention is to achieve a higher degree of precision than would otherwise be possible. However, perfect precision cannot be achieved.

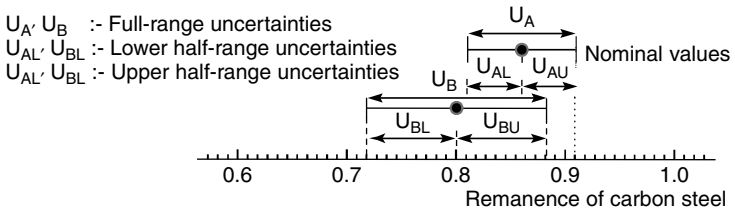

Figure 1. Graph comparing interval estimators and illustrating notation for uncertainties.

Precision is a statement about how exact a particular value is. Almost every quoted numerical value has some degree of uncertainty associated with it.

Quite often there is an interest in knowing just how large the uncertainty is. In particular, it is often impossible to make meaningful comparisons between numerical values unless their uncertainty is known. The combination of the numerical value and the uncertainty is called an *interval estimator*.

Interval estimators may be illustrated as shown in Figure 1. The full-range uncertainty defines the band within which the true value of the measurement is most likely to be located, while the half-range uncertainties, sometimes also called *tolerances*, define the upper bound and lower bound of this range.

Suppose, for example, that the measured remanence of carbon steel is reported as 0.86 ± 0.05 T. Here, 0.86 T is the measured value, and ± 0.05 T is the uncertainty in that value. This style of presentation indicates that the remanence is believed to lie close to 0.86 T and that any value between 0.81 and 0.91 T is also acceptable as being in agreement with the reported result.

If a second report specifies a measured value of $0.80\,\text{T} \pm 10\%$ for the same quantity, this means that values in the range 0.72 to 0.88 T are acceptable. Values in the range 0.81 to 0.88 T are acceptable to both writers. It can, therefore, be seen that the two measured values do not differ significantly. Although such a graphical representation is not of much value where only two values are being compared, it can be useful where three or more values are involved.

Obviously, any comparison of values depends on some knowledge of the uncertainty in both, or all, of the values being compared. In the above example, if only the two measured values of 0.86 and 0.80 T were reported, then it is not possible to judge whether the difference is significant or not. Specification of only these values is widely known as giving point estimators.

Where numerical information is presented in ordinary prose, in text, in a table, or by means of an equation, the statement of uncertainties is usually straightforward. In graphs, the method of representation shown in Figure 2 extended to two dimensions is used. For example, suppose that $X = 10 \pm 1$ and $Y = 3.0 \pm 0.5$. Bars are drawn

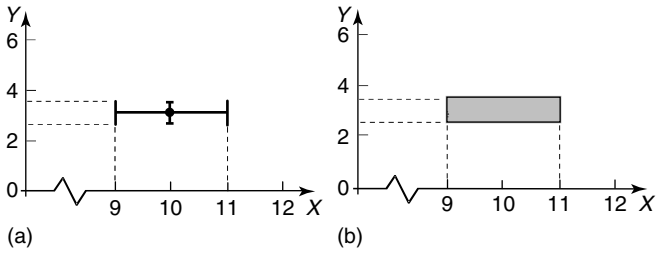

Figure 2. Interval estimators: (a) in the X and Y directions and (b) area of uncertainty of the estimators.

in the X direction from 9 to 11, and in the Y direction from 2.5 to 3.5. Hence, interval estimators are also known as uncertainty bars as the example in Figure 2(a) illustrates. This style of representation leads to drawing the point (10, 3) with the given uncertainty rectangle. However, it is acceptable to say that the 'correct' point is anywhere within the shaded rectangle shown in Figure 2(b).

To appreciate how the interpretation of a graph may be aided by the inclusion of interval estimators, consider firstly the points plotted in Figure 3(a).

Is there a 'kink' in the graph at about $X = 10$, or does the suggestion of a 'kink' result merely from random errors in the measured values?

On the information given in Figure 3(a), it is not possible to answer this question. Figure 3(b) and (c) shows the same plotted points as does Figure 3(a), but with interval estimators added. In Figure 3(b), the uncertainties are small, and the reader accepts that there is a kink in the graph occurring at about the value $X = 10$. This 'kink' probably corresponds to a real physical effect.

In Figure 3(c), where the uncertainties are much larger, it is clear that the information presented does not clearly establish whether any such 'kink' exists.

In practice, it is usually not necessary to show uncertainty bars on every point on a curve. To avoid unnecessary clutter, they can be shown on only two or three points, which are typically one near each end of the curve, with perhaps one about the center as well. If the uncertainties are small, they will be invisible on the graph. In such cases, their values should be stated elsewhere.

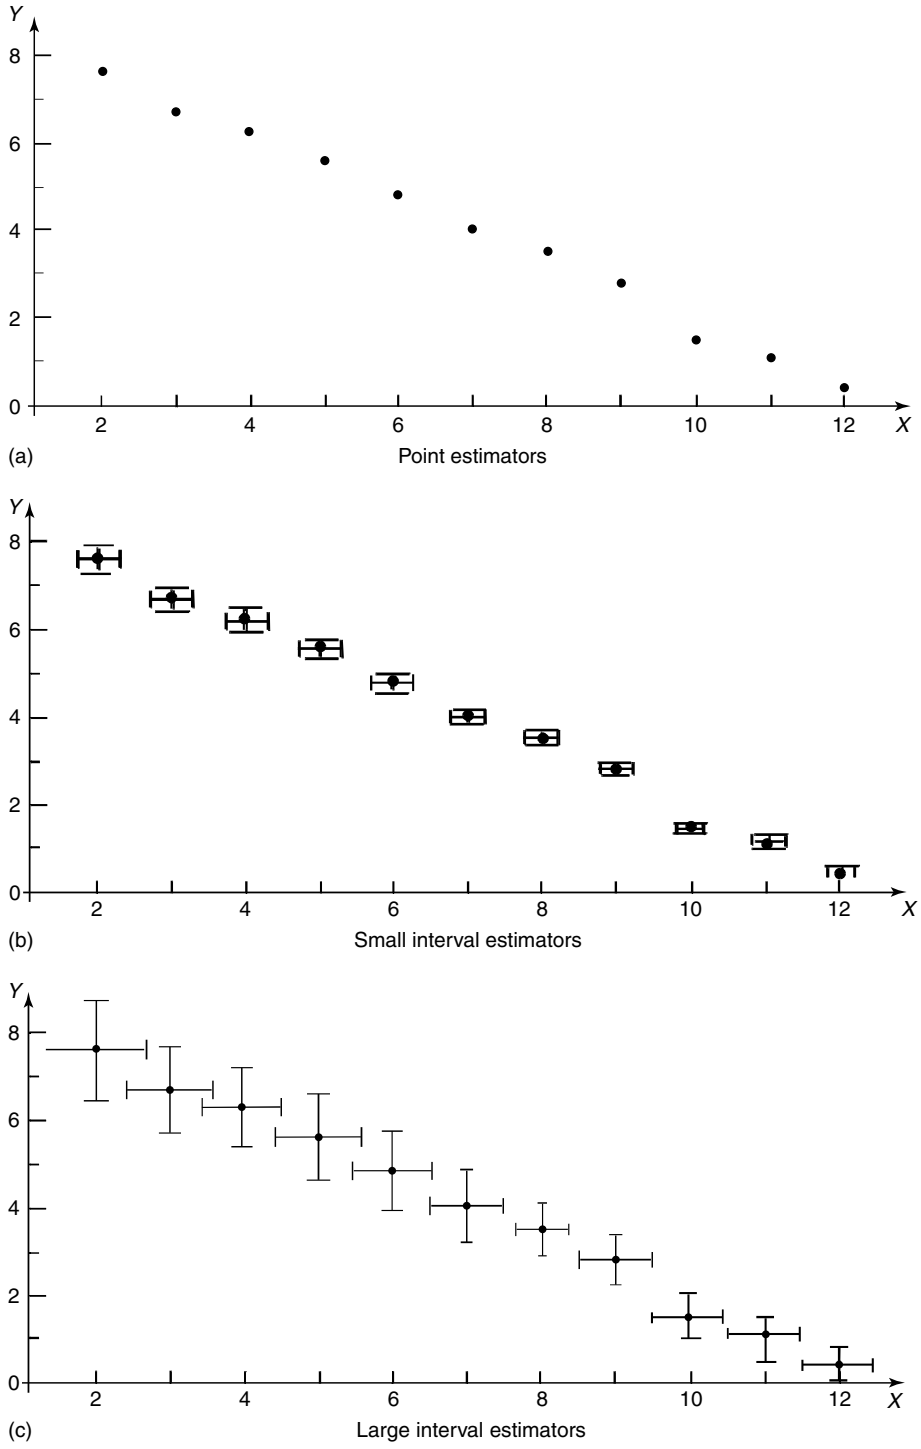

Figure 3. Graphical kink with different types of estimators: (a) point estimators, (b) small interval estimators, and (c) large interval estimators.

The above approach to the subject of uncertainties has been oversimplified. According to it, if a value is quoted as 3.5 ± 0.5, this means that a value of 4.01 will be interpreted as being in total disagreement with the result. This is clearly an unrealistic view.

To develop a more realistic approach to the subject of uncertainties, it is necessary to use statistical concepts.

The ability to estimate the uncertainty that exists in a measured value is an important part of the skill required

by experimenters. It often involves a blend of science and intuition.

The theory of probability and combinations provides the foundation upon which the calculation and treatment of errors is based.

3 EXAMPLE OF UNCERTAINTY IN DETERMINING TEMPERATURE

Four different experimenters measure the same temperature, and report their results as (i) $231.0 \pm 2.5\,^{\circ}\mathrm{C}$ (ii) $245\,^{\circ}\mathrm{C} \pm 5\%$ (iii) $227.2 \pm 5.2\,^{\circ}\mathrm{C}$ (iv) $225.0\,^{\circ}\mathrm{C} \pm 5\%$

Draw a diagram that will allow these results to be compared easily. Comment upon the results. Do they agree?

3.1 Solution

Before sketching the interval estimators it is necessary to convert the percentage tolerances to actual values of the measured temperature. Thus, for (ii), 5% of 245 equals 12.25 and 5% of 225 equals 11.25. The interval estimators may now be drawn as shown in Figure 4.

Examination of Figure 4 shows that the measurements agree due to the overlapping range of uncertainty indicated by the shading. This conclusion is justified for the following reasons.

Measurements (i) and (iii) have nominal values lying within the tolerance band for that of (iv). Hence, measurements (i), (ii), and (iv) exhibit good agreement. The nominal value of measurement (ii) lies outside the tolerance bands of (i), (iii), and (iv). However, as its lower half-range uncertainty totally includes the full-range uncertainty of measurement (i), then measurements (i) and (ii) may be taken to be in agreement. Because of this and in the interests of noncontradictory and consistent analysis, it must be concluded that all four measurements agree within the limits of the tolerances given.

Further justification of this opinion can be obtained by examining the relationship between the interval estimators for measurements (ii), (iii), and (iv). The nominal value and upper half-range uncertainty of measurement (iii) and part of the upper half-range uncertainty of measurement (iv) are also included in the lower half-range uncertainty of (ii).

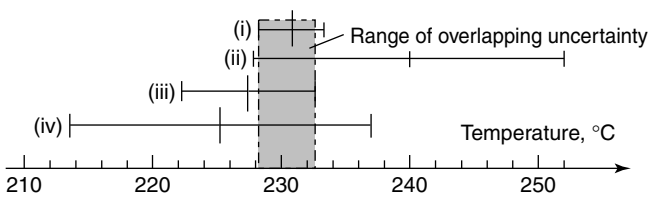

Figure 4. Interval estimators used to compare different measures of the same quantity.

The state of affairs illustrated by this example is far from satisfactory from the measurement point of view. Steps should be taken to see if paying closer attention to the measuring method could reduce the differences between the measured nominal values and the uncertainties, the instrumentation used, and the treatment of the measuring data from which the estimators are obtained.

4 ROUNDING OFF MEASUREMENT RESULTS

When a numerical value is quoted, a choice as to the number of digits to be used will need to be made, that is, it is necessary to decide whether to round-off the number by discarding some of the digits at its right-hand end. Where the first digit to be discarded is 5 or higher, the last digit retained is normally rounded up. Thus, 4.83500 rounded off to three significant figures becomes 4.84.

Suppose a numerical value is quoted as being 5.12. Usually, this does not mean 5.12 precisely; it means any number which, when rounded off to three significant digits, becomes 5.12. Thus, it means any number between 5.1150000... and 5.1249999..., that is, it practically implies 5.12 ± 0.005. Thus, rounding-off to the second figure after the decimal point has introduced an implied uncertainty of ± 5 in the digit immediately following the last digit quoted.

A number that is correctly rounded off fulfills two requirements. Firstly, the implied uncertainty is much smaller than the actual uncertainty, so that no meaningful information is lost in the process of rounding-off. Secondly, the implied uncertainty is not so small that the figures quoted suggest a higher degree of precision than is justified.

In cases in which the uncertainty is not calculated, a rough idea of how large the uncertainty might be is usually available. In rounding off, it is important to ensure that both these requirements are met. Where the uncertainty is calculated, it is possible to be more specific.

Suppose, for example, that it is required to quote the circumference of a circle, having measured its diameter as 20 mm with uncertainty of 1/30 mm in either direction. The circumference is then $\pi(20 \pm 1/30)$ mm and may be evaluated as $(62.831853 \pm 0.10471976)$ mm.

Looking at the uncertainty term, it can be seen that all digits before the decimal point are zero, while there is a 1 in the first place after the point. In the nominal value (62.83...), therefore, the first two digits are not directly subject to any uncertainty, while the third digit, which is the 8, in the first place after the decimal point, could reasonably

go either up or down by 1. With this uncertainty in the third digit, if we wish to ensure that the implied uncertainty is much smaller than the actual uncertainty, all digits beyond the fourth should certainly be discarded. On this basis, it is reasonable to round off the value of the circumference to (62.83 ± 0.10) mm.

This example suggests a useful working rule for rounding off, which can be adopted, as follows:

4.1 Rule

In rounding off, include one digit beyond the first uncertain digit, both in the nominal value and in the uncertainty.

The two exceptions to the rounding-off rule are as follows:

- Where a whole number ends in a zero. For example, 105 000 does not necessarily imply $105\,000 \pm 0.5$. To make the implied uncertainty clear, this number could be written as 105×10^3, $105.00 \times 10^3 \ldots$ as appropriate.
- Where the number quoted has no uncertainty such as in the statement that 1 inch = 2.54 cm, the number 2.54 is absolutely accurate by definition, or when the number quoted can take on only well-defined specific values, such as whole numbers. For example, the valency of oxygen is 2, or the number of cylinders in a certain car engine is 4.

5 EXAMPLE OF ROUNDING OFF OF LABORATORY MEASUREMENTS

A standards laboratory measured the nominal reference value, x_r, of a quantity as 19.5081 and the reference value uncertainty, u_r, as ± 0.8506. Round these values off and sketch the interval estimator representing it.

When the six laboratories, A, B, C, D, E, and F, use different measuring techniques to measure the same quantity, the nominal value and the uncertainty obtained by each method are as given in Table 1. Correct any mistakes in the rounding off, sketch the uncertainty intervals for each method and comment upon the result of each of the measuring methods relative to that of the standards laboratory.

Table 1. Reported measured nominal values and uncertainties of six laboratories.

	A	B	C	D	E	F
Nominal	18.503	20.5	19.0	21.0	19.5	20.0
Uncertainty	0.374	0.205	0.571	0.525	0.585	1.20

5.1 Solution

Applying the rounding-off rule to the reference measured value gives a rounded-up value of 19.51. In a similar way, the rounded-off uncertainty is 0.85. The corrected statement of the reference value is thus 19.51 ± 0.85, which is illustrated in Figure 5.

The correctly rounded-off values for the results quoted in Table 1 are given in Table 2.

The interval estimators may now be drawn as shown in Figure 6.

Although the measurements conducted by laboratories A, B, C, E, and F agree with the reference value, measure D

Table 2. Correctly rounded-off nominal values and uncertainties of six laboratories.

	A	B	C	D	E	F
Nominal	18.50	20.50	19.00	21.00	19.50	20.0
Uncertainty	0.37	0.21	0.57	0.53	0.59	1.2

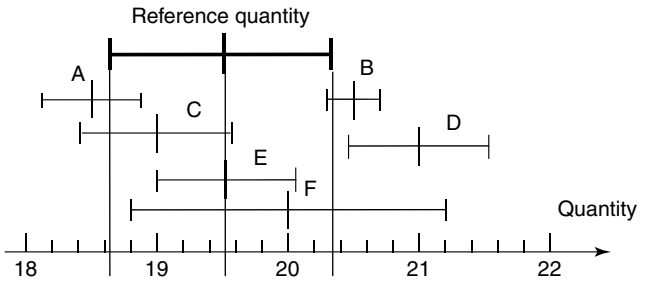

Figure 6. Interval estimators for the nominal values of A to F and their uncertainties.

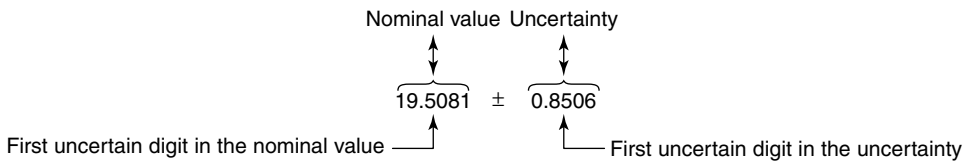

Figure 5. Illustration of rounding-off numerical values.

Table 3. Comments upon comparison of rounded-off values for the measurements of six laboratories.

	Values	Comment
Reference	19.50 ± 0.85	tolerance band is ±5% of nominal value
A	18.50 ± 0.37	nominal value outside tolerance band of reference; equipment requires recalibration
B	20.50 ± 0.21	nominal value outside tolerance band of reference; equipment requires recalibration; check measuring method
C	19.00 ± 0.57	nominal value inside tolerance band of reference; acceptable but check equipment and measuring method
D	21.00 ± 0.53	nominal value outside tolerance band of reference; equipment requires recalibration; check measuring method
E	19.50 ± 0.59	good consistency with the reference; measuring method is acceptable
F	20.0 ± 1.2	nominal value within tolerance band of the reference; check method to see if errors may be reduced

does not. The situation is not at all satisfactory. Table 3 contains appropriate comments.

6 PROSE METHODS OF RESULTS PRESENTATION

As has been mentioned above, the prose method of presentation is unattractive where a large amount of numerical information is involved. It can be useful for small amounts, as for example:

> The sample tested showed a resistivity of 12.42 Ωm ±2% when tested with an applied voltage of 100.0 V ±1% at a temperature of $(20 \pm 0.5)\,^{\circ}$C.

This example is not quite in accord with recommendations given above regarding uncertainties and rounding off. However, even partial adherence to these recommendations can make the writing seem rather pedantic. Consequently, there is a temptation to be less precise. Alternatively, a rearrangement of the information given in the above example is possible:

> The sample tested gave the following result:
> Applied voltage 100.0 V ±1%
> Temperature $(20 \pm 0.5)\,^{\circ}$C
> Measured resistivity 12.42 Ωm ±2%.

Obviously, this kind of list can be extended to include quite a large amount of numerical information without becoming as objectionable as a long prose statement containing a lot of numbers. Such a list in effect constitutes a one-dimensional table.

7 TABULAR METHODS OF RESULTS PRESENTATION

Tables can be useful where corresponding values of two or more variables are to be presented as in the example in Section 5.

A table is preferable to a graph where:

- the amount of information presented is small; there is little to be said for a graph that shows only two or three points;
- the information is to be presented with a higher degree of precision than can be achieved in reading values from a graph.

Compared with a graph, a table has the following disadvantages:

- the form of the relationship between the variables is not immediately apparent;
- interpolation between the values given is usually not easy.

8 GRAPHICAL METHODS OF RESULTS PRESENTATION

A brief examination of almost any manufacturer's data sheet or any scientific or technical specialist journal will show that graphs are more widely used than any other method for presenting a set of numerical information.

A graph allows a fairly quick and transparent impression of the kind of relationship that exists between two variables.

Two or more graphs, plotted on the same axes, allow rapid comparisons to be made. Interpolation between the plotted values is usually fairly easy. Unfortunately, it is usually not possible to read values from a graph with a high degree of precision. Appropriate choice of scale and section of range can make it more precise.

Where there are no limitations in the space allowed, the ideal arrangement is often to present the numerical information in both a table and a graph.

9 USE OF EQUATIONS TO DESCRIBE RESULTS OF MEASUREMENT

When numerical information is obtained as a result of a theoretical analysis, the information naturally makes its first appearance in the form of equations.

In the case of numerical information obtained by measurement, it is also sometimes appropriate to express the information by an equation. This can lead to a statement like the following:

> For the ten cores tested, the measured power loss P (watts) lay within $\pm 5\%$ of the value given by $P = 120B_m^{2.7}$ where B_m is the peak operating flux density in Teslas. This equation is valid over the range $0.1\,\mathrm{T} \leq B_m \leq 1.7\,\mathrm{T}$

This kind of statement can summarize a lot of information in a small space.

Two points in this example are worth emphasizing. Firstly, the statement indicates the range over which the equation is valid. Secondly, it indicates how closely the measured values lie to the values given by the equation. Without these two pieces of information, the communication of the ideas would not be so effective. It is also necessary to exercise care by also giving information on the uncertainties in the measured values of B_m and P.

There are at least three different situations that can give rise to a statement of the kind illustrated in the above example.

In some cases, the equation will have been derived from theoretical considerations. The statement will then constitute a comparison between theory and measurement.

In other cases, when theory may indicate the form of the equation, the parameters will have to be evaluated from the measured results.

In yet another case, the measured values will be used to indicate the form of the equation as well as the values of the parameters. In this last case, the equation is referred to as an *empirical equation* as it has no theoretical basis.

Graphical methods are useful if it is necessary to check or find the form of an equation that measured results fit, and in determining the parameters of the equation. A discussion of this process is called *curve fitting*. Where there are no limitations in the space allowed, the ideal arrangement is often to present the numerical information in both a table and a graph, as also stated above.

Table 4. A summary of methods for information presentation.

Method	Advantages	Disadvantages
Ordinary prose or text	1. Useful for small amounts of information	1. Unattractive where the amount of numerical information is large 2. Writing can seem rather pedantic 3. Temptation to be less precise
Tables	1. Can include a large amount of numerical information 2. Less objectionable than a long prose statement 3. Preferable to a graph if the amount of information is small 4. Higher degree of precision than in reading from a graph	1. Interpolation between given values is not so easy
Graphs	1. Easy interpolation between values 2. Kind of relationship usually transparent 3. Rapid comparisons of two or more graphs possible	1. Usually not possible to read values from a graph with a high degree of precision
Equations	1. Result of a theoretical analysis 2. Appropriate way to express the information 3. Information density is high 4. Possibility to compare theory and experiment	1. Must be supported by experimental measurement

10 COMPARISON OF METHODS FOR PRESENTING MEASUREMENT RESULTS

A summary of the advantages and disadvantages of the above methods of information presentation is given in Table 4.

1 REPRESENTING THE OVERALL RESPONSE OF A SYSTEM

To begin explanation of how to specify measuring systems, it is first necessary to understand the role of the various stages of an instrument system and how they change the energy variables from the input form into the required output. This article deals with the transfer characteristic. With that foundation in place, **Article 57, Static Considerations of General Instrumentation, Volume 1** and **Article 58, Description of Accuracy, Linearity, and Drift, Volume 1** describes the static regime with **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1** then introducing the more complex dynamic regime.

The stages used to form a measurement system can be represented as blocks of hardware that effectively transfer an input to its output either in the same energy form, such as the voltage ratio of an amplifier, or as a converted quantity, such as where a sensor converts relative humidity into a voltage and angular motion equivalents for a visual indicator.

The ratio of output to input quantities is termed the *transfer characteristic*. The magnitude of, and phase between, the two quantities are expressed as numerical quantities in terms of the units of the two variables involved. For example, the sensitivity of a humidity sensor might be designed to be 0.1 mV per 1% RH.

When the system is investigated further, it is seen that this transfer expression (the usual one quoted by manufacturers) is a great simplification of the existing full characteristic; it provides no information about the sensor's response to dynamic changes of relative humidity. What is missing is some form of statement as to how the system will respond to changing input signals. This can be done by adding a frequency-dependent component to the expression already given to represent the static behavior.

As simplification, to cover the static operational region of use only, suffices for many tasks, it is common practice to quote only the static transfer characteristic. The steady state equivalent is given in the case of a carrier system or a purposefully designed system made to operate at a given frequency. The steady state is also sometimes called the *quasi-static condition*.

In practice, the state-variable form of relationship between the input and the output for a stage often cannot be easily arranged in the form of independent input and output signals. For this and other reasons, it is common practice to convert that relationship into its Laplace transform equivalent, which can then be arranged to produce a transformed transfer characteristic called the *transfer function*.

As an example, the relationship between an input variable x and an output variable y existing through a measurement

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

instrument stage might be

$$\frac{d^2y}{dt^2} + \frac{3\,dy}{dt} + 2y = x + \frac{dx}{dt} \tag{1}$$

from which we require the ratio y/x to be formed to obtain the transfer characteristic. It will be noticed that measurement system behavior is generally described in terms of linear differential equations, this being in line with general physical systems description.

As the system is linear in the mathematical sense, the Laplace transform can be taken obtaining

$$s^2Y(s) + 3sY(s) + 2Y(s) = X(s) + sY(s) \tag{2}$$

This can be rearranged to give

$$\frac{Y(s)}{X(s)} = \frac{s+1}{s^2+3s+2} = G(s), \text{ the transfer function} \tag{3}$$

If the process involves a time delay, then terms of $e^{-s\tau}$ form will be included, for example,

$$\frac{Y(s)}{X(s)} = \frac{e^{-s\tau}}{s+1} \tag{4}$$

It is in the Laplace form that transfer characteristics are most usually expressed as they are immediately in a form that can be operated upon or studied directly.

It is generally permissible to use the operator D in place of s, and some authors use p instead of s. When the system is operating with sinusoidal signals (which can usually be the case because complex signals can be broken down into sinusoidal components), it is permissible to replace s by $j\omega$, enabling the response at any chosen angular frequency ω to be calculated.

2 TACHOMETER EXAMPLE OF SYSTEM DESCRIPTION

As an example, the tachogenerator, a device that generates output voltage proportional to angular shaft velocity and, therefore, maps shaft speed into an equivalent voltage representation, has the schematic electrical circuit shown in Figure 1.

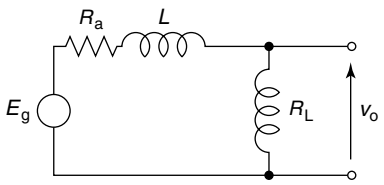

Figure 1. Electrical schematic circuit of tachogenerator.

Being a driven rather than driving mechanical device, its mechanical inertia and friction are not of importance in obtaining the transfer function between angular velocity input θ and the generator voltage output v_o. It is designed such that the voltage generated is proportional to the shaft speed according to $v_o = K_g\, d\theta/dt$; K_g being the generator or transducer constant.

The mechanical parts of the generator are forced (an assumption) to follow input demands and cannot cause lag or lead action because of the generator's compliance or angular mass. The electrical output circuit, however, contains energy storage in the form of inductance of the windings, and this can influence rapidly changing signals. Energy is dissipated via the two resistances, one of which is the load resistance of the next stage that it drives; let $R = R_L + R_a$.

The output voltage v_o, that generated across R_L, is, in Laplace form,

$$v_o = \frac{R_L K_g s\theta}{R + sL_a} \tag{5}$$

which can be rearranged to yield the transfer function:

$$\frac{v_o}{\theta} = \frac{R_L K_g}{L_a}\left(\frac{s}{s + R/L_a}\right) \tag{6}$$

Having developed the expression in this form, for this example, we can move on to explore the three regions of transfer characteristics that could be involved when describing the transfer characteristics of a stage in a measuring instrument or of the whole instrument system.

It can be seen, from the above example, that when s (that is, $j\omega$ for sinusoidal excitation) is zero, the system is operating with zero frequency, that is, at the DC point, in the electrical circuits. The generator is turning to produce an output related to the generator constant K_g, modified by the loading divider effect of R_a and R_L.

In this situation, all frequency-dependent components have no effect on the output. Transients that can arise in the electrical circuit when an input mechanical or an output load transient occur have, in fact, settled down: the generator is producing its steady state output. Thus, the generator constant K_g is, in fact, the response existing after internal transients have settled to be insignificant. It represents the steady state transfer characteristic, and this is generally the sensitivity figure quoted.

The generator will, however, not produce the simple steady state transfer relationship during dynamic changes to its state, that is, during transients. It may be necessary, in application, to make allowances for the transient characteristics, which are more complex. This certainly is the case if rapid-response, closed-loop operation with the

tachogenerator is sought. Phase-shift and gain changes during transients can cause instability.

If the component is to be used in applications where transient response is important, then it will sometimes be found that the manufacturer will quote the necessary additional component values (resistance and inductance in this case) so that the user can construct the full transfer function in order to obtain the transient behavior characteristics needed to condition a tight, stable system.

It is, however, often necessary for the user to conduct tests to obtain the additional values, the only parameter quoted being the steady state characteristic. For example, the data sheets for the previously mentioned humidity sensor contain no information about transient behavior, it being unnecessary for the market intended.

3 DC AND DYNAMIC CHARACTERISTICS COMPARED

There exists another description that can cause confusion for this too is often quoted as though the component only possesses a characteristic mode of behavior: this is the DC response. As the name suggests, this is the response characteristic of the stage when the input, measurement-bearing signal is at zero frequency – direct current or direct-coupled would appear to have formed the symbol DC. Not all systems possess a finite value for DC characteristics, nor is it always relevant.

As an example, consider the DC electronic amplifier. This has a certain gain value when operated at zero frequency. What is often not realized is that it has a transient response during which gain varies and it will exhibit differing gain with signal frequency. When used as an AC amplifier at a given frequency, it then has a certain steady state gain. Thus, use of the apparently simple amplifier block must make allowances for the various modes of transfer characteristic applications. Furthermore, the input signal level can often also alter the transfer characteristic.

It has been shown, by example, that stages used in a measurement system can possess three distinctly different transfer characteristic functions depending upon the time duration and form of the signal. Which are important must be decided for each application. The easiest to measure and quote are DC gain and/or the steady state value. The transient characteristic is much more complex to assess and express and it also varies with signal conditions. Any sensing system usually simply breaks down, by analysis, to yield its DC characteristics, but realization of complete dynamic transfer functions that would enable the transient response to be studied would require expenditure of considerably more effort. The development of transfer functions for very complex systems can often take many years of effort. Systems identification procedures attempt to obtain them from practical testing.

Further explanation about transfer functions, in general, is presented in the classic work of DiStefano, Stubberud and Williams (1976) and Doebelin (1975). Atkinson (1972) explains the difference between steady state and transient characteristics in terms of the solution of linear differential equations having constant coefficients.

Having shown how a stage can be modeled theoretically in terms of its transfer function, and therefore be uniquely described on paper or in a computer model, it is important next to realize that linear systems of interconnected transfer functions, no matter how complicated, can (in theory) be reduced to a single-stage transfer function. This means that a complex measurement instrument system, built from many stages as a serial path including feedback loops with other paths, can be reduced mathematically to just one transfer function that describes its complete overall static and dynamic behavior. This reduction allows the transient, steady state, and DC responses of any system to be calculated or simulated without need to assemble all stages.

There is no need here to elaborate on the techniques used in block-diagram algebra; they are well covered in DiStefano, Stubberud and Williams (1976). It basically stems from the prime fact that transfer functions are commutative, provided it can be assumed that they do not load each other when connected. Interaction of stages destroys the rule, making reduction more complicated. Interaction significantly changes the response, and so it may be necessary to build a slightly more complex system that incorporates buffering between blocks. This being done allows the system performance to be accurately modeled and thus optimized.

When compounding stages together to build up a measurement system, it is, therefore, necessary to consider if the stages interact to a significant degree. In electronic systems, this problem has generally been eliminated by designing integrated circuits to connect on the basis of low output impedance being connected to high input impedance in order to preserve voltage levels. In cases where power must be transferred efficiently, it is necessary to use stage impedances that are equal. For current transfer, another information transfer mode, the opposite to the first given voltage case, applies.

Electronic systems connections generally present few connection problems (provided well-established rules are adhered to), but the same is not true of mechanical, thermal, fluid, and optical stages, for in those disciplines, component design does not enable ideal matching arrangements to be performed so easily.

Transfer characteristics of a stage can be stated in terms of the response in either the time or the frequency domain. Conversion from one domain to the other is achieved via the Fourier transformation. When the signal is of a steady state, time-domain condition, because it is periodic, it can easily be transformed to yield the singular set of frequency components. Signals of transient nature present greater difficulties in transformation for the spectrum changes during the transient.

It is, therefore, quite reasonable for the response of a stage to be stated in terms of the frequency domain. The same information could be expressed in the time domain in terms of the stage's response to a suitable time variant input. In some applications, it is more convenient to obtain or describe a transient in time response form (such as to a step or impulse input) than it is in the frequency domain.

Zero-frequency response is, in the frequency domain, the value of amplitude, or phase, at zero frequency. As frequency response plots are generally expressed using logarithmic scales, zero frequency cannot actually be represented. Amplitudes are generally expressed in decibel form, but for some instrumentation, unconverted ratios may be preferable.

The above remarks apply to stages having at least one each of a clearly identifiable two-terminal input and output port, refer to **Article 108, Transducer Fundamentals, Volume 2**. In use, a two-terminal device, such as a capacitor or a spring, becomes a two-port device, either as a series (through-variable) or as a parallel (across-variable) arrangement, by suitable connection with common lines. The above remarks then apply, provided it is clearly stated what the connection arrangements and the terminating conditions existing are. Alternatively, the two-terminal device can be described in terms of its terminal impedance response, called the *driving-point impedance* (or *admittance*), which can also be fully expressed mathematically in Laplace form.

Simple common components, such as the electrical inductor or mechanical mass, are so well known that they usually do not need to be specified (for response reasons) in greater detail than the numerical constant of the parameter they provide, for example, inductance in henry units or mass in kilogram units. This information is sufficient for users to construct the response characteristics required. When the component is uncommon, a mathematical driving-point impedance expression is needed to provide adequate information about its static and dynamic behavior.

4 USE OF SIMPLIFICATIONS FOR SYSTEM PERFORMANCE DESCRIPTION

In many cases, it is not convenient to express the true response behavior of a terminal port, and approximations are used to map a many-variable parameter situation into a single one. A moving-coil loudspeaker (as an actuator or a sensor) mechanism is generally characterized by stating the impedance it presents at a given audio frequency, this being expressed as a pure resistance of $x\Omega$. In reality, the terminal impedance is a complex electrical quantity having both real and imaginary parts, and it varies greatly with frequency. This applies to the input and output impedances of many stage blocks used. This is, however, not always the case, a notable exception being the transmission line, which provides constant purely resistive impedance at any length, provided it works within certain assumptions of being lossless and properly terminated. Somewhat confusingly, the term impedance is often used synonymously with resistance: correctly, the former is the resistance to flow when both real and imaginary components exist as a complex variable.

5 PERFORMANCE VARIATION WITH SIGNAL PARAMETER VALUES

The tacit assumption often exists that components and subsystem blocks are what they are defined to be for all regions of operation. In practice, a component can behave quite differently for signal frequencies, levels, noise contents, and other parameters from those for which it was purposefully made to handle. For example, a capacitor becomes an inductor with rising frequency; a mechanical mass provides properties of spring compliance under certain conditions.

Ideally, all components and stages used in measurement systems should be defined to provide the user with information about their whole spectrum of response conditions, but this is not practicable. The instrument designer, in particular, must be aware that simplistic definitions, such as those giving no more than steady state or DC information, may not suffice. Lack of observance and understanding of this defect in subsystem description is a prime reason for failure of many designs when first assembled and for incorrect operation when fed with input and influence quantity signals that do not conform to those it is designed for.

It is, therefore in principle, possible to model any complete or part measuring system as a transfer function expression that enables its behavior to be understood without needing to resort to actual hardware. Whether this is worthwhile, however, depends upon the application and the extent of the system. A very practical point is that many of the constants required to provide a boundary to the mathematical model must come from measurement of existing phenomena.

Reduction, in this way, of an arrangement of many subsystems' mathematical models into one, retains all information about the overall behavior but does not allow interstage

signals to be studied. This realization is not to be confused with identification processes and simulations that can also provide overall input–output relationships that apply for some modes of operation and not others and that may be realized by quite different internal processes. If the internal subsystem transfer functions are adequate models of the stage that they represent, so also will be the overall reduction obtained by block-diagram algebra (provided conditions of connection and range of operation are met).

Transfer function representation is only as good as the assumptions on which it is developed. Many are, and need to be, simplifications of the real situation; often, they ignore the higher-frequency terms that can be considered to be of no practical consequence to response, thereby making them only applicable for a given range of frequencies.

6 TRANSFER FUNCTION EXAMPLE FOR PRINTED ARMATURE MOTOR

To illustrate the above ideas, consider the transfer function of a high-performance instrument printed-armature DC motor. This needs only to allow for response lag caused by the mechanical storage aspects of the armature disk, the electrical storage time constants of the armature circuit being much smaller than those of mechanical sources (50 μs compared with 30 ms). A conventional style, field-controlled, DC motor, however, requires a more complex transfer function, one having a second storage term to allow for the delay caused by significant storage effects in the electrical field-coil circuit. The two transfer functions are

Printed motor

$$G(s) = \frac{\omega_{\text{out}}}{\upsilon_{\text{in}}}(\text{s}) = C_1 \frac{1}{\tau_{\text{m}} s + 1} \tag{7}$$

Field controlled motor

$$G(s) = C_2 \frac{1}{(\tau_{\text{m}} s + 1)(\tau_{\text{f}} s + 1)}$$

where

ω_{out} = shaft velocity
υ_{in} = drive voltage
τ_{m} = mechanical time constant
τ_{f} = electrical time constant of field winding
C_1, C_2 = constants related to generator and torque constants and to mechanical friction and field-coil resistance.

1 DESCRIPTION OF THE STATIC OR STEADY STATE BEHAVIOR

As an example to illustrate the terms introduced in this article, consider the relative humidity sensor in which a humidity-sensitive membrane changes length with moisture take-up. The length change causes a metal spring strip to be strained. On the strip are strain gauges that transduce the strain into a voltage using a simple Wheatstone bridge. The voltage is amplified and adjusted to give a calibration and sensitivity facility. Static performance parameters are first considered to construct a block diagram showing the complete instrument broken down into serially connected paths formed as the stage described above. The spring also drives a mechanical pointer on a scale.

Two measuring paths can be identified from the sensing membrane through the instrument to the two outputs that produce an electrical and a mechanical output signal.

An overall transfer sensitivity (S_1 and S_2) can be developed through each path by multiplication of the static transfer characteristic for each of the stages connected to form a link. This yields

$$S_1 = \frac{V_{\text{out}}}{\%RH} = \left(a\frac{\Delta L}{\%RH}\right)\left(b\frac{\xi}{\Delta L}\right) \times \left(c\frac{\Delta R}{\xi}\right)\left(d\frac{\Delta V}{\Delta R}\right)\left(e\frac{V_{\text{out}}}{\Delta V}\right)$$
$$S_2 = \frac{\theta}{\%RH} = \left(a\frac{\Delta L}{\%RH}\right)\left(f\frac{\Delta L'}{\Delta L}\right)\left(g\frac{\theta}{\Delta L'}\right) \quad (1)$$

where $a, b, \ldots, g$ are the static, or quasi-static, transducer constants of the various stages that relate input to output variables when the stage is in a settled state of response.

Thus, the static sensitivity is found as the product of static transducer constants for all stages in a path. If a different gain is needed, it could be arranged anywhere in the path by altering any one of the constants by design alteration. This expression assumes that the instrument is not operating in a transient state as none of the stages have any frequency terms associated with their transfer characteristic.

2 RANGE FACTORS

Range, the factor that decides the extent of measurement ability from the smallest to the largest signal amplitude that can be accommodated without the system being overloaded or the signals becoming limited (saturated), is decided by the capability of all stages. If the signal level of any one stage moves into a region of improper operation, the whole system will fail to operate correctly.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

The effective measuring or working range is the 'range of values of the measured quantity for which any single measurement, obtained under specific conditions of use of a measuring instrument, should not be in error by more than a specified amount'.

The upper and lower range limits form the limiting boundaries inside which the instrument has been constructed, adjusted, or set to measure the specified quantity. The effective range may not necessarily be all of the instrument's interval between these two limits. Rangeability is the term sometimes used to relate, by some form of expression, the relationship between upper and lower limits of useful range.

In the humidity sensor example, the manufacturer states that the instrument has a range between 20 and 100% *RH*, but on the instrument itself is a warning that use outside of the interval 20 to 85% *RH* may lead to temporary loss of calibration. Furthermore, careful reading shows that the usability is only within given accuracy limits over 30 to 85% *RH*; thus, the range of reliable operation is within 20 to 85% *RH*, rangeability perhaps being given (there is no standard methodology for expressing this) as providing a ratio of maximum to minimum limits of 4.25:1. Rangeability is more useful with instruments having unbounded measurand possibilities, such as occurs in flowmetering where the two limits of practical flowmeters are often rather restricted compared with the interval that might be called for in practice.

A multirange instrument is one in which the range of operation can be selected by manual or automatic means, the latter being referred to as an *auto-ranging instrument*.

When describing the effect on a calibration of influence quantities, it is common practice to state the range over which such quantities can be tolerated. This is defined as the *reference range*. The humidity meter performance is stated for a reference range of 0 to 40 °C temperature variation.

As a guide, ambient environmental conditions may usually be taken as having a mean temperature and reference range of 25 ± 10 °C; relative humidity of 90% or less for general use (but 40–60% for storage of paper materials); and barometric pressure lying within 90 to 110 kPa (900–1100 mbar).

Many measurements can be performed more easily, or with improved accuracy, if the instrument is built to provide a limited effective range. This can be done by designing the lower range limit to be well above zero (the converse holds for measurands having values less than zero). Such systems are called *suppressed-zero systems*. A common example is the voltmeter used to indicate mains voltages in the range 200 to 250 V AC.

For such systems, sensing signal levels will not have a zero level coinciding with the output zero, that is, in the above example, a 200-V input may deliver 0 V to the indicator. Any other system of level shifting might be chosen. The degree of suppression is expressed as the ratio of scale interval omitted, above or below zero, to that presented. A similar and wider concept is when the range is expanded at any point. This is often termed *band* or *scale spreading*.

Range of operation for static and quasi-static use is often different to that in the instrument's dynamic transient mode. The term dynamic range is used to indicate which regime the quoted range relates to. It is generally stated in the same ratio form as is given above for rangeability and is presented in decibel form. At times, its common use would, however, appear to be really defining the static and quasi-static performance, not the time-dependent dynamic behavior.

Related to the range of an instrument is the scale factor that might need to be applied to the actual numerical value obtained in order to arrive at the correct magnitude. Scaling is often practiced to allow a normalized instrument to be applied to many ranges of tasks. Except where the instrument is multiranging, the system should be marked accordingly. Multiranging instruments usually indicate automatically the appropriate scale factor as the range changes.

3 ZERO VALUES OF OPERATION

Many instrument systems require an operation to set the position of the zero. For example, a gas analyzer and its sampling line may need to be purged with a suitable clearing gas before use. Electronic DC systems usually need periodic zero setting to compensate for the drift that has occurred.

4 DRIFT

Drift tends to be regarded as a DC property of a system, but this depends upon the time response needed. In many electronic systems, frequencies of operation less than 10 Hz are regarded as being at DC. In some disciplines, however, examples being earth tides or temperature variations in a cool room, responses may be concerned with frequencies of the order of cycles per year or per day respectively.

Drift, if studied closely enough, will be found to be a slowly moving dynamic phenomenon and may need description to allow for its actual behavior. The simplest form of expression is statement of the linear component in terms of drift occurring per variable of interest – such as time or supply level. In electronic amplifiers, drift with time is often quoted as though it were a linear-time function, but

in reality, it is often formulated on a square-root basis, for drift in this case does not accumulate linearly. Drift is a complex, often poorly understood, parameter that can defy generalization on a causal basis.

Related to the problem of drift specification is how to adequately describe aging effects. These also defy formal generalization. Aging is a factor, like drift, that brings about lack of reproducibility in an instrument because over time the values of components, and hence transducer constants, will change. Aging can also arise because of operational use of the components. There are no general rules to follow to reduce aging, but the problem usually is concerned with appropriate knowledge of material properties.

In the humidity sensor example, aging is to be expected in the membrane, the curved spring strip, in the strain gauges, and in the electronic components. Each of these changes will gradually give rise to a shift in calibration and in the position of the zero. Internal adjustments are provided so that these can be reset. Being an inexpensive design, intended for low-accuracy use, no figures of aging or drift are quoted. Higher-priced instruments usually quote such figures.

The task of deciding when an instrument should be recalibrated, to make up for errors of this kind, is very subjective. The history of an instrument's performance is an important factor in being able to predict when it will have drifted, or aged, out of the calibration tolerance band.

Drift is often allowed for in a measurement by returning to a known stable and fixed measurement point periodically through the test run. It is then possible to extract the drift and adjust the values.

5 HYSTERESIS AND DEAD-BAND

Measuring instruments do not respond in a completely continuous manner, nor do they always give the same value for both directions of closure to a point.

The term threshold is used to signify the smallest level of signal to which the system will respond. All measurements, no matter how well designed, will ultimately be limited by some form of discrete phenomenon. Another example is seen as the threshold of the zero-suppressed voltmeter mentioned above, which occurs at 200 V. Threshold is either caused by a feature of the physical principle involved (e.g. a turbine flowmeter will not respond correctly until there is sufficient fluid in the pipe) or it may be deliberately introduced (such as to suppress the zero). It provides a dead-band of operation.

Many instruments exhibit dead-band effects that are caused by backlash and play in the drives. These will provide different values for each direction of approach to the point of interest. Where it cannot be removed, it is common practice to approach the final value in the same direction each time. Dead-band can become particularly significant as a cause of instability in closed-loop systems; some, however, make use of it to allow the system to settle in the dead-band.

Dead-band produces a kind of hysteresis, but that latter term is more generally used to describe the magnitude of the hysteresis phenomenon arising internally in a material. Figure 1 shows a typical hysteresis loop with its measured quantities. Magnetic material, for instance, does not show the same magnetic field strength for rising and falling induction levels. The magnitude of the strain condition for a cyclically stressed mechanical member will vary depending on the direction of the stress. In each, hysteresis magnitude increases with increasing excursion. Hysteresis magnitude can be quoted as the ratio of maximum difference of the upscale and downscale variations to the full-scale excursion. Other expressions are used. In some applications, the total area is more important than this difference.

In the humidity sensor example, mechanical hysteresis arises in the strained member carrying the strain gauges

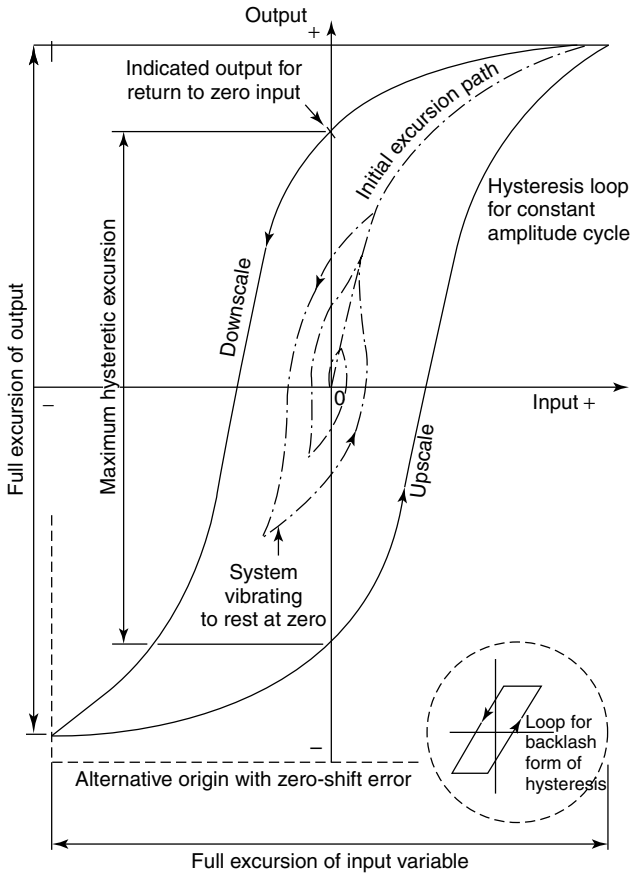

Figure 1. Schematic of a generalized hysteresis loop.

and certainly in the membrane. Backlash arises in the pin joints of the mechanical system (but is kept in control by a biasing tension), in the sector gear driving the pointer pinion, and because of slack in the bearing system. The art of good design is to ensure that these are not significant for the intended purpose and that they do not increase significantly as wear occurs overtime. A highly damped, resonant system and slowly moving signal systems will exhibit greater hysteretic effects than more rapidly moving arrangements.

Larger excursions also increase hysteresis error; systems that can resonate cyclically to rest will usually show less error from this source because the hysteresis loop traversed in each cycle will become progressively smaller, the system finally coming to rest in the center of the loop.

Electronic systems generally do not pose these problems, but some circuits purposefully introduce backlash. Storage effects in semiconductor elements can lead to backlash in fast-acting circuits.

Backlash, hysteresis, drift, creep, and aging are all subclasses of a general noise problem that instruments of measurement must cope with.

Noise is the general name given to unwanted sources of apparent signal that could lead to error in the measurement mapping process. Every energy regime has its own sources of noise. The user of an instrument will often need to know how tolerant an instrument is to common noise sources.

By suitable design, a stage can often be made such that noise quantities (of certain kinds) influence two features of the system in such a manner that their combined effect on the true signal is differenced, thus canceling. This is called *common-mode rejection*. Thus, deliberate introduction, through a second influence point, of correlated noise into the system can be used to dramatically reduce the original, impossible to eliminate, noise effect.

As no process is perfect, these common-mode rejection techniques need some means of stating their effectiveness. This is done through the use of the common-mode rejection ratio (CMRR), which is defined as the ratio of the common-mode noise signal amplitude to the common-mode error signal remaining after rejection. The term is used extensively in the description of electronic systems where it is usually quoted in decibels. It is, however, quite a general concept and can be applied to any common-mode signal-to-noise rejecting system.

As with many parameter statements, the need to keep the statement simple can lead to the assumption that CMRR is a simple fixed ratio. This is not always so; it will often be a function of many system variables. Average figures are frequently quoted. It can, at least in electronic systems, vary with temperature and usually decreases with decreasing frequency of the noise signal. Often, the CMRR quoted is for DC input signals.

6 SIGNAL-TO-NOISE RATIO ENTITIES

In some instances, the need is for definition of how well system signals exceed noise levels: this can be assessed from the signal-to-noise ratio (S/N or SNR). This is the ratio of the signal amplitude to the noise amplitude, again usually expressed in decibels. The amplitude used could be average, root mean square (rms), or peak-to-peak. Steady state AC signals are involved, and they may be of sinusoidal or complex waveform. Rarely are the waveshape or amplitude criteria quoted, leaving considerable room for imprecision, especially if the signal and the noise do not have the identical waveforms that a ratio properly demands.

The introduction of a stage into a measurement system usually degrades the SNR to some degree. The ratio, in decibels, of SNR at the output to SNR at the input is termed the *noise figure*.

Measuring instruments are designed to fulfill a certain task at a specified accuracy level. As increasing the accuracy of a measurement implies an increasingly costlier design, the general rule is to choose an instrument that just copes with the task needed.

It is quite pointless to specify an instrument that has accuracy exceeding the task; its capability will not be utilized and the maintenance costs will be greater than necessary.

To assist the specification and selection of instruments of appropriate accuracy, many disciplines issue standards documents that state accuracy classes. There is no general rule for the development of such classes, a dominant reason being that each kind of measurement presents different ranges of possibility and need.

For example, it is quite feasible to call up time measurements to errors of parts in 10^{12} but photometry can only be best achieved to parts in 10^4.

Where the need has arisen, agreed accuracy classes are defined, within which ‘the instrument will have certain declared metrological properties within specified limits of error’. A class is ‘usually identified by one of a set of symbols, adopted by convention, and usually referred to as the “class index”’. Definition of accuracy often ties in with that of linearity.

The term conformance is sometimes used to relate an instrument to a specified accuracy class. Interchangeability is the term used to describe how well an instrument can be exchanged with another having the same specifications; tolerances of manufacture and differences in the various manufacturers’ designs cause units to be slightly different to each other yet still be suitable for a given task.

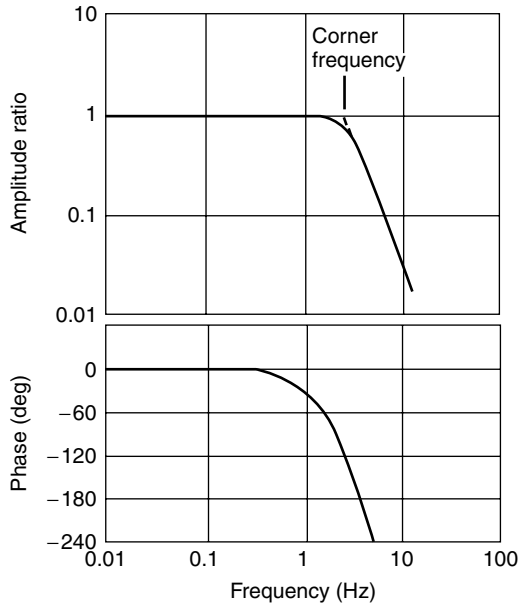

Figure 2. Amplitude and phase responses expressed in Bode diagram form.

7 FREQUENCY RESPONSE DESCRIPTION

Although the response of a stage is dependent upon its dynamic behavior, the frequency response of a stage is usually that of a steady state that is taken after the stage has settled to the final value after excitation has been applied at each frequency.

In the simplest form, the frequency response can be stated in a verbal manner describing it in such terms as 'flat to "*x*" Hz' (or 'between', or 'above'). In such cases, the extremes are denoted, by convention, to be where the response has fallen off (or risen) to the point where the ratio of input to output signal magnitudes has changed by 0.707. In some cases, the 3-dB points are used, both ratios being the half-power points. Some times, the response obtained is a function of signal amplitude. In such cases, it is necessary to state the amplitude of the test.

A more adequate, but harder to publish, description is to provide a magnitude and a phase plot as a Bode diagram. Examples are given in Figure 2. The true Bode diagram uses only straight-line segments to approximate the actual response, but this distinction is not always made. The upper curve is, by convention, the amplitude response.

Systems involving continuous cyclic signals require description of amplitude, phase angle, phase shift, power factor, and true and apparent power. Each of these terms is used in instrumentation in the same way as it is in electrical power systems. Probably, the greatest error that arises in their use in instrumentation is the lack of care in ascertaining that the system is operating with sinusoidal waveforms (which electrical power systems are generally assumed to be), for the parameters are often quoted in terms of sinusoidally based quantities such as r.m.s. and average amplitudes and power levels.

8 SYSTEM CONSTANTS

Constants quoted are often far from being so. Many are functions of several operational parameters. Noise figure for an electronic amplifier, for example, is a function of signal amplitude, frequency of operation, and the actual device used. Constants may vary with time.

There do exist, however, certain constants, called *physical constants*, that are believed to be unchanging. It is therefore often necessary to know more about the formulation of a given constant if more intelligent use is to be made of the number quoted.

The designer or user is usually left to explore such ramifications through reading the primary literature. In essence, consensus obtained from practice provides the published information generally required.

The difficulty is who shall decide what the general demand is, and how does the user know whether the factors given are entirely adequate for the task in hand. Overspecification can be useful but will increase the cost.

Terms used in the description of measuring systems are many. A useful service, but membership is needed, is that provided by the NCLS International http://www.ncsli.org//index.cfm. It is a searchable listing for a glossary of terms and for acronyms and abbreviations.

1 SIMPLIFICATION OF TERMS FOR ACCURACY

Having introduced the static regime in **Article 56, Transfer Characteristics of Instrument Stages, Volume 1** and **Article 57, Static Considerations of General Instrumentation, Volume 1**, this article concentrates on the description of a measuring system's accuracy, linearity, and drift.

For reasons of simplicity of specification and description, the system's performance features of accuracy and related linearity are often quoted in a simplistic manner by the use of a single numerical value. This practice might hide, from those persons who are not aware of the facts, that these are often gross simplifications of a much more complex reality. To illustrate this point, the following paragraph is taken from the terminology section of a Foxboro-Yoxall statement:

Accuracy includes the combined conformity, hysteresis, and repeatability errors. The units being used are to be stated explicitly. For example, expressed in output units, a typical expression might be $\pm 1\,^{\circ}\mathrm{C}$; expressed in percent of output span, the expression could be $\pm 0.5\%$ of output span; expressed in percent of the upper range value, it might read $\pm 0.5\%$ of upper range value. For indicators, it might read $\pm 0.5\%$ of scale length; or in some cases, it is expressed as a percent of actual output reading, such as $\pm 1.0\%$ of actual reading.

Confrontation with this variety of simplifications leads one to refer to approved standards documents, such as BS 5233 or AS 1514, to find that accuracy is defined only in a general sense and that no suggestion for a uniform methodology is provided. An ISA document, formulated by its SP37 subcommittee, on transducer specification, provided greater depth in the manner given above (issued as S37.1 or ANSI MC6.1:1975.)

In reality, the concept of accuracy is more properly discussed in terms of errors and the uncertainty of a measurement made with the measuring instrument. The term accuracy, one source suggests, should only be used as a general descriptor of system performance.

Implicit in any statement of uncertainty of an instrument is the apparent assumption that the instrument will provide the same absolute or proportionate performance at any part of its usable range. This is rarely a totally valid assumption. Uncertainty is covered in detail in **Article 52, Error Models, Error Budgets and their Calculation, Volume 1**.

2 LINEARITY DESCRIPTION

The manner in which error varies over the effective range of an instrument is expressed as the linearity of the instrument (but which correctly actually relates to the nonlinearity or lack of linearity between desired and actual performance).

A process is said to be linear when the relationship between two quantities is such that a change in one quantity is exactly proportional to the associated change in the other quantity.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Expression of the nonlinearity of an instrument is achieved in several different ways most of which, again, result in a simple statement that conveys information about how the signal deviates as it ranges over the available span.

Fundamentals of measurement indicate that a single numerical value can only characterize a single attribute of a situation. This is, therefore, the case in the statements of linearity: each method of description conveys different information about the linearity. Seldom is an actual curve presented, the exception being when a calibration chart is provided.

Linearity is expressed as deviation from a specified straight line. Four predominant reference lines might be used.

The first reference line uses a line placed so that it lies in the position satisfying the least squares criterion calculated for the data set available. It is often called the *best straight line* (BSL). It might also be referred to as a *least squares line*. Figure 1(a) is an example of this line.

In many instances, the system provides zero output for zero input, in which case a more appropriate line to use is a BSL that is computed so that it is constrained to make the line pass through the zero point. In suppressed or elevated-zero systems, the point of interest will be the pseudozero used. Figure 1(b) illustrates this line. This method describes the zero-based linearity of the system. One variation of this is to not use a zero-based line but some other suitable reference point. This is termed *BSL* with forced reference linearity.

In terminal-based linearity, a reference line is adopted that links the upper and lower limits of the span, a line drawn between its terminal points. It is also called *terminal linearity* or *end-point linearity*. The line so drawn is sometimes referred to as the *end-point line*. Figure 1(c) shows this line.

Added later in AS 1514 was another line that can be used (Figure 1d), being one that lies in the theoretical linear position of the principle invoked. This is called the *theoretical slope linearity*.

Having first decided which line is the most appropriate to use, the next step is to select a method of description that will express the magnitude of deviations from the line. In general, this will usually be the greatest departure from the line of the output variable. Linearity of instruments is generally determined as the result of a calibration test in which only a limited number of values would be determined. Some calibration processes provide a considerable number of values and if they are of random nature, the deviation might then be expressed in terms of the standard deviation or some other statistical descriptor.

A little thought reveals that the above methods of expressing linearity and accuracy of an instrument are

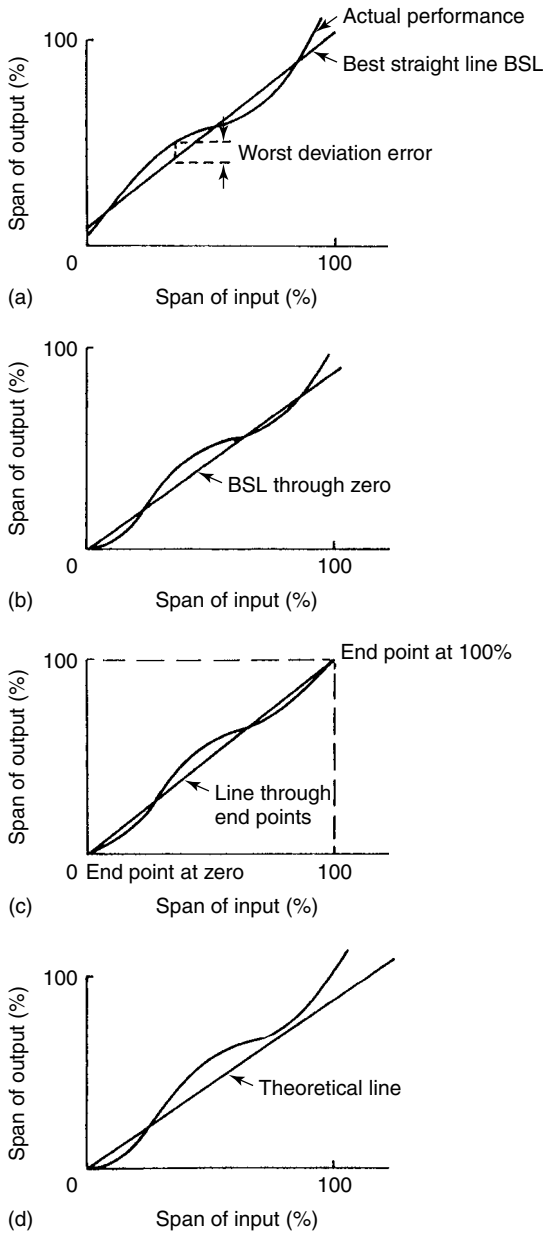

Figure 1. Four methods of specifying linearity of a response.

subject to many causes of error in their determination, expression, and subsequent interpretation. A process with significant hysteresis can exhibit quite different linearity with each direction of signal change and with signal amplitude. The magnitude of influence variables at the time of the determination also can alter the error magnitudes. The method of calculation of the best fit line and the number of data samples available will further influence the value that will be stated as the singular value of linearity of the instrument.

Expressions of the linearity of a system are invariably determined for a system in the steady or static

state. Rarely will the same relationship apply when the stage is in the dynamic state. Storage parameters will alter the instantaneous transfer characteristic according to the signal amplitude and history of previous signal excursions. This point is often overlooked when accuracy and linearity figures are taken from data sheets for application to sensors used for rapidly changing measurands. Pressure gauges, accelerometers, position sensors, thermometers, and the like will give very different instantaneous performance figures to those measured in the steady state and stated in their specification of calibration chart.

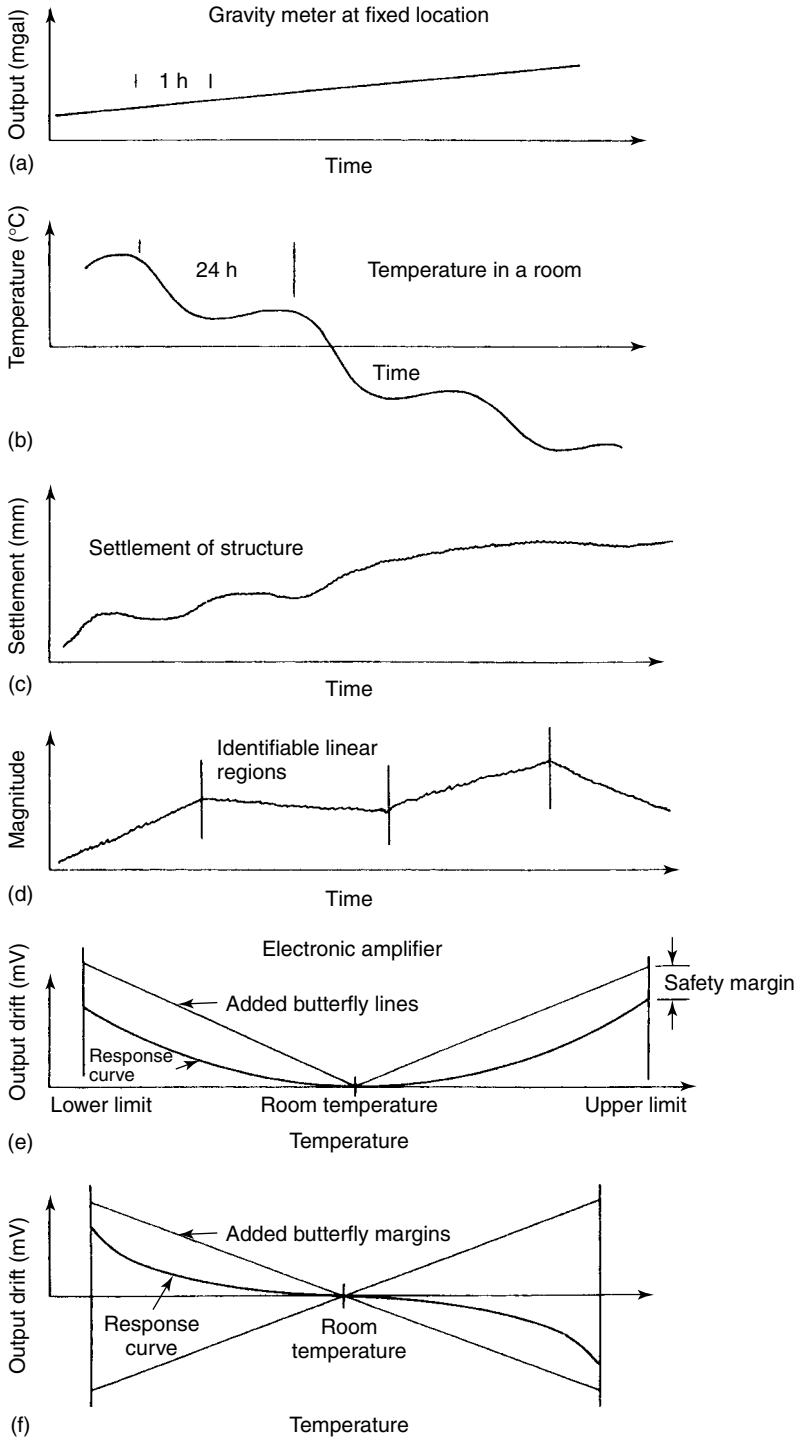

Figure 2. Typical drift curves, for example, instruments and measurands.

Another factor to be considered may be that the stage transfer characteristic may possess adequate linearity of response but that the BSL may slope at the wrong rate because of an inaccurate DC sensitivity coefficient for the stage.

Where possible, it may be preferable to provide a mathematical expression that describes a curve fitted to the data, an example being the relationship used for the output of a thermocouple.

It can be seen, therefore, that usually stated expressions of accuracy and linearity are invariably simplifications. Specifications of these parameters must be generated and interpreted with care and understanding if ambiguity is to be avoided.

Extending these ideas further, to cover other nonlinear responses, again introduces likely confusion as the direct result of seeking simplified statements of performance. Specification of drift is a related area where such problems arise.

3 DRIFT DESCRIPTION

Drift is the feature of a system that characterizes how a system variable, that is intended to be constant, changes with time. The drift of a gravity meter is one example. The term is also used to describe effects of influence quantities on the output, an example being the temperature drift of an electronic amplifier. It is also a term applied to explain how a measurand varies with time or other variables. An example of this use is to characterize settlement of a structure with time. It is sometimes used synonymously with the term stability. Some kind of qualifying statement is needed to uniquely define which context is being used.

Drift conveys very low frequency response information about the measuring instrument or of the measurand. It can, on occasion, be very difficult to separate the two.

Figure 2 shows several often-met drift curves. For each curve, the need is to formulate a simple expression that will convey information about the trend of the output away from a chosen reference value.

When the drift is linear, it is a simple matter to express the slope in terms of the two parameters involved. The gravity meter example of Figure 2(a) might be expressed as drifting at x milligals h^{-1}. Being entirely linear, it would not matter where the slope was determined along the curve.

The situation becomes a little more difficult when it is required to express the drift for the case shown on Figure 2(b). If the characteristic possesses a cyclic component of constant amplitude, then a mean line is easy to determine. If, however, the curve does not have obvious linear features, like that of Figure 2(c), then a best fit line must be fitted from which the drift can then be assessed as for the previous cases.

When the curve clearly possesses two or more linear regions (Figure 2d), each of a different slope, a more extensive statement will be required. No standards of practice appear to exist for such cases, so the description should carry a statement of the additional features rather than simply quote a fixed numerical drift coefficient.

If the drift curve returns to the original value (Figure 2e), quoting the mean drift that has occurred between the two end points would imply that the system is perfectly stable. Furthermore, nonlinear curves, such as that given in Figure 2f, would be grossly misrepresented. One approach, outlined in Stata (1969) for example, is to use a butterfly characteristic curve. Typical boundary curves have been superimposed onto the two amplifier drift curves. Drift is calculated as that occurring from the reference point (which is often room temperature at which the amplifiers were adjusted for the test) to the extremities of workable range, plus a margin of safety. This coefficient then provides a conservative figure within which drift can be expected to lie for a given temperature excursion. Such simplification, however, is at the expense of possible overdesign on the part of the user.

These examples clearly show that the specification of drift can be a complicated matter and that simplistic definition, as with those for nonlinearity, can be misleading.

Manufacturers have been known to use the shortcomings in the understanding of descriptions to their advantage when specifying equipment.

Further detail on accuracy and related concepts is to be found in CORD (1999) and Westgard (1997).

1 INTRODUCTION TO THE DYNAMIC REGIME OF MEASUREMENT SYSTEMS PERFORMANCE

The dynamic regime of an instrument stage is generally a more complex aspect to characterize and test than the stage's static performance. To fully understand the behavior during the dynamic state, it is necessary to allow additionally for the transient solution of the transfer characteristic when forced by an input function, a factor that is not important in understanding the steady state and static regime behaviors.

Dynamic behavior of systems has been well explained at the theoretical level if the performance remains linear during the dynamic state. It has been shown that the energy relationships of electrical, mechanical, thermal, and fluid regimes can each be characterized by the same mathematical description and that a system containing a cascaded chain of a mixture of these, as is typical of instrument systems, can be studied in a coherent manner by the use of such mathematical techniques. This body of knowledge and technique lies in the field of the dynamics of systems. (This is not to be confused with a subject area called *Systems Dynamics*, SD, that is somewhat different to that being described here.) It has progressively grown from isolated, unconnected explanations of the analogous situations existing mainly in electrical, mechanical, and acoustical areas, into one cohesive systematic approach to the study of the dynamics of linear physical systems.

The approach has been widened considerably (see Klirs, 1972), to take in philosophical concepts, such as are found in social systems, this broader assembly of knowledge usually being referred to as *general systems theory*. General systems theory certainly has application and potential in some instrument systems, but most designers and users of instruments will find that the more confined and mathematically rigorous assembly of technique and knowledge (systems dynamics) will be that found to be usefully applicable in practical realization and understanding of measuring systems. The use of the word systems is extremely common and carries numerous connotations ranging from a totally general concept to the quite specific use that is based in mathematical explanation.

As indicators of the part that is useful to measuring instrument dynamic studies the reader is referred to some classic texts that sorted out this field well. Karnopp and Rosenberg (1975), MacFarlane (1964), Paynter (1961), Shearer, Murphy and Richardson (1967), and Zahed and Desoer (1963) for general expositions, and to Coughanowr and Koppel (1965), Fitzgerald and Kingsley (1961), Koenig and Blackwell (1961), and Olson (1943) for more specific uses in areas of chemical plant, electrical machines, electromechanical devices, and the so-called analogies,

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

respectively. Other more recent works of the engineering systems kind are Franklin (1997), Hsu and Hse (1996), Nise (2000), Oppenheim *et al*. (1996).

Several authors have extracted, from the total systems knowledge contained in such works, the much smaller part that is needed by measuring systems interests, presenting this as chapters in their works. Such accounts are to be found in Beckwith and Buck (1969), Doebelin (2003), and Neubert (1976).

Notable foundation papers have also been published that further condense the information for measurement systems application (see Bosman, 1978; Finkelstein and Watts, 1978). Finally, many control-theory-based works are of relevance.

There exists, therefore, a considerable quantity of well-organized knowledge about the physical behavior that may be encountered in measurement systems studies. When response is linear it is possible to make use of mathematical models to obtain a very workable understanding of the dynamic behavior. If it is nonlinear, however, then the situation is not so well catered for because no such widespread and generally applicable mathematical foundation has been forthcoming in truly formal description terms. In practice, however, designers and users of instruments can find considerable value in assuming linearity, if only for a limited range of operation. For this reason, it is important to know how to recognize whether a system functions in a linear manner and which techniques apply in such cases. Further, it is often up to the designer to chose methods and, thus, it is recommended that consideration be given to the use of those modules that do respond in a linear manner for their operation can be modeled precisely using long hand math or modeling tools.

The purpose of this article is not to expound the mathematical modeling and design of transducers in a concise and rigorous manner, but to present the commonly seen characteristics of linear dynamic systems that will be encountered so that they can be recognized and operated upon by using a fundamental approach that is based on knowledge of their characteristics, *see* **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1**. It also provides the basic descriptive terminology needed in specification of response characteristics.

2 FORCING FUNCTIONS

To see how a stage performs to various kinds of changing input signals, it is forced into its transient state by one or more external inputs. These are termed *forcing input* or *excitation functions*. They may be applied to the intentional input of the stage or cause transient behavior by entering, as influence quantities, through numerous other unintentional ports. In reality the true two-port, four-terminal, instrument stage can rarely be realized for virtually all designs are influenced to some extent by unwanted noise perturbations entering through many mechanisms.

When considering the dynamic response that might arise for a stage it is, therefore, necessary to first decide the ports through which a forcing function signal might enter. This decided, the next step is to assess which kind of forcing function is relevant and apply this to the real physical device, or to its correct mathematical model expressed in the state-variable or transfer function form. Alternatively, it might be simulated in a digital computer. When the transfer function model is used, the product of the Laplace transform of the forcing function and the transfer function can be solved to provide the transient dynamic behavior in a reasonably simple manner, *see* **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1**. This method is dealt with in detail numerous electrical engineering and systems texts. Here are presented some typical forcing functions that might be used to test or study an instrument stage.

Certain types of forcing function lend themselves to analytical solution being easy to apply to the Laplace method of response evaluation. They are also simple to procure as practical test signals that, although not perfect, come close enough to the mathematical ideal. For these reasons, testing and evaluation of systems tends to attempt first to make use of one or more of several basic forcing functions.

These functions (see Figure 1) are the discontinuous unit step and the unit impulse, the ramp plus the continuous sine wave. They are described elsewhere and, therefore they do not need further theoretical expansion here.

These functions are easy to produce and apply in practice, but it must be recognized that they may not provide an adequate simulation of the real forcing signals existing. This point is not always made clear in the general treatment of the dynamics of common linear systems stages.

When such simplifications are not adequate, other more suitable ones must be applied. If they can be transformed with the Laplace transform expression, and if the product with the transfer function can be arranged so that a solution into time-variant terms is obtained, then a theoretical study can be made. In many cases, however, this is not possible within bounds of realistic adequacy, and alternative methods of study must be employed if no way can be seen to simplify satisfactorily the forcing transfer function. Simulation using a computer-based tool often provides the means to a solution.

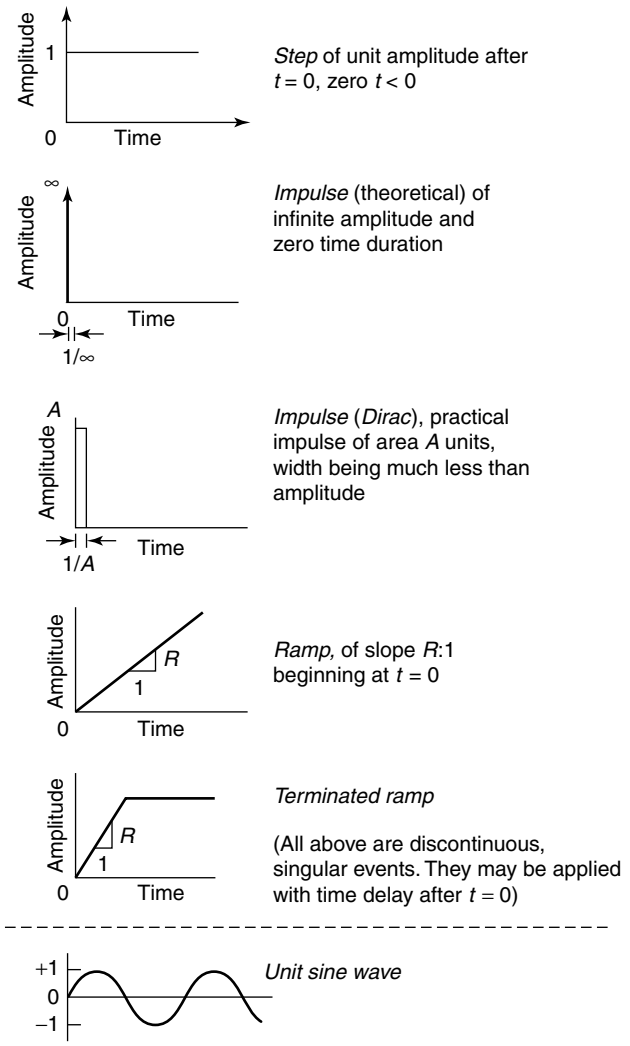

Figure 1. Typical forcing functions used in testing and study of the dynamic response of systems.

3 APPLICATION OF FORCING FUNCTIONS

A step or impulse will excite a system into its dynamic transient response as might a sudden change of demand in a control loop, or a sudden change in a measurand as exists when an indicating voltmeter is first connected to a live circuit. Many physical systems, however, cannot provide such rapidly changing signals. Mechanical and thermal systems often cannot supply a rate of rise that is great enough to be regarded as a step because of the presence of significant storage of energy within the components. For example, attempting to square-wave modulate the dimensions of a piezoelectric crystal at relatively high frequency will produce quasi-sinusoidal output response, not a square wave – the crystal acts as a filter. Similarly, it is not possible to provide a perfect step function to a pressure sensor to obtain its step response. Faster acting systems, such as found in the electronic and optical disciplines, can supply rapid changes.

When the response to a slow-to-rise input signal is needed, the use of the step or impulse function may provide misleading information. A ramp function is more applicable in such cases. Many of the published systematized transient behavior descriptions have not included this particular forcing function, the solutions usually presented being for impulse, step, and sine wave inputs. Sinusoidal excitation can, however, sometimes be used to approximate ramp responses.

The unit impulse function represents the input provided by a sudden shock in a mechanical system – it might be due to slackness in a drive link taking up. In electronic systems, it represents such events as a high-voltage pulse generated by lightning or the switching surges from a nonzero crossing controlled silicon controlled rectifier. In practice, a pseudoimpulsive function, called the *Dirac* or *delta function*, is used instead of the true impulse. As will be seen, the transient solutions of typical linear systems to impulse and step functions are somewhat similar in transient shape.

The third most commonly used input function is the sine wave (or cosine wave, which is the same function, phase-shifted in time). This acts to excite a system in a continuous cyclic manner forcing it to be excited in both the transient and steady state when the sine wave is initially applied, the former dying away to leave the latter as the solution most usually discussed.

In practice, systems are often likely to be disturbed by a continuous complex input waveform. As complex waveforms can be broken down, by Fourier techniques, into a set of sine waves of different frequencies, amplitudes, and phases, the use of sine waves of the correct amplitude and frequency enables the system to be studied one component at a time. Sine wave response is also called *frequency response*, *see* **Article 27, Signals in the Frequency Domain, Volume 1**; **Article 28, Signals in the Time Domain, Volume 1**; and **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**.

The concept that a complex continuous waveform can be so resolved into separate components rests on the assumption that the system is linear and that superposition applies. Nonlinear systems can behave quite differently to complex signals, creating, for instance, harmonics of lower frequency than those existing in the original signal.

It is often considerably easier, and more reliable to obtain the transient response of a system by practical testing than it would be to develop a mathematical model. This is one of the reasons why the data sheets of instrument products

often include graphical statements of transient response. Further, a detail about forcing functions can be found in chapters of classical control texts such as Atkinson (1972), Coughanowr and Koppel (1965), and Shearer, Murphy and Richardson (1967).

1 GENERAL REMARKS ON LINEAR SYSTEMS RESPONSES

The following discussion applies only if the dynamic behavior of the system of interest can be adequately characterized by a suitable linear ordinary differential equation, this often being found to be the case in instrumentation, but by no means always so. The theoretical foundation given in this article provides the basis for understanding the behavior of linear systems in general. The first-order system is covered in **Article 61, First-order System Dynamics, Volume 1** and the second-order system in **Article 62, Second-order System Dynamics, Volume 1**.

These equations will have the general form (called the *nonhomogeneous linear differential equation*) for input variable x and output variable y and unit amplitude input:

$$a_n \frac{\mathrm{d}^n y}{\mathrm{d}t^n} + a_{n-1} \frac{\mathrm{d}^{n-1} y}{\mathrm{d}t^{n-1}} + \cdots + a_0 y = x(t) \qquad (1)$$

The coefficients $a_n, \ldots, a_0$ are constants. They could be functions of t but not of y. Powers of derivatives do not occur in this class of differential equation. Not all orders of derivatives less than the highest are necessarily present.

The expression on the left-hand side is the characteristic equation of the differential equation. It contains the information that characterizes the physics of the system of interest and how it will provide output when it is excited. The expression on the right-hand side characterizes the forcing function, the input signal, applied to that system. Thus, both sides contain independent information about, on the one hand, the inherent transfer characteristic of the stage and, on the other hand, the forcing function applied to the stage. As both functions are linear expressions, by the above definition of requirement, they can both be transformed into transfer functions by Laplace methods.

System performance can thereby be obtained theoretically if the nonhomogeneous linear differential equation for the specific system can be solved to yield the output versus time relationship.

In providing the explanation of dynamic response, authors can make use of the differential equation format given here but often using other symbols: they may make use of the operator D to replace derivatives; the explanation might be presented directly in transfer function form; differential equations might be presented in complex number form, plus other variations. These tend to confuse the issue somewhat but each produces the same result.

2 SUMMARY OF SYSTEMS ORDERS IN TRANSFER FUNCTION FORM

The above given general differential equation can be written in the specific sense as an ascending order of equations

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

when additional derivative orders are progressively added. For unit amplitude input, these become

$$\begin{aligned}
&\text{zero order} && a_0 y = x(t)\\
&\text{first order} && a_1 \frac{\mathrm{d}y}{\mathrm{d}t} + a_0 y = x(t)\\
&\text{second order} && a_2 \frac{\mathrm{d}^2 y}{\mathrm{d}t} + a_1 \frac{\mathrm{d}y}{\mathrm{d}t} + a_0 y = x(t)\\
&n\text{th order} && a_n \frac{\mathrm{d}^n y}{\mathrm{d}t^n} + a_{n-1} \frac{\mathrm{d}^{n-1} y}{\mathrm{d}t^{n-1}} + \cdots + a_0 y = x(t)
\end{aligned} \tag{2}$$

Zero-, first-, and second-order systems are all that need usually be considered in this discussion of the transient response of instrument stages because higher-order differential equations can be reduced, if need be, to these, through suitable manipulation. Also, establishing analytical solutions, which requires the roots to be found to higher orders can be far more difficult, if at all possible, than for these three cases. This may seem rather short of real requirements but, in general, a very large part of instrument testing and characterization can be done with the understanding of these three types of system response.

Transformed into typical unitized transfer functions, the differential equations become

$$\begin{aligned}
&\text{zero order} && \frac{Y(s)}{X(s)} = 1\\
&\text{first order} && \frac{Y(s)}{X(s)} = \frac{1}{\tau s + 1}\\
&\text{second order} && \frac{Y(s)}{X(s)} = \frac{1}{(\tau_1 s + 1)(\tau_2 s + 1)}\\
&n\text{th order} && \frac{Y(s)}{X(s)} = \frac{1}{(\tau_1 s + 1)(\tau_2 s + 1)\cdots(\tau_n s + 1)}
\end{aligned} \tag{3}$$

where $\tau_1, \ldots, \tau_n$ are termed time constants and $Y(s)$ and $X(s)$ the output and inputs respectively. This groundwork laid now enables the three types of systems to be studied in order. This article covers the simplest, almost trivial one – the zero-order system. *See* **Article 61, First-order System Dynamics, Volume 1** for first order, **Article 62, Second-order System Dynamics, Volume 1** for second order.

3 DEFINITION OF THE ZERO-ORDER SYSTEM RESPONSE

The zero-order system is so trivial mathematically that it is rarely mentioned in texts on dynamic response. In practice, however, it is often (but not always) a most desirable response, one that the designer strives to achieve but rarely obtains in a perfect sense.

The differential equation form, given above, shows that there are no derivatives, meaning that the system does not alter the time features of a time-dependent function introduced to the system by the forcing function. Thus, the zero-order stage cannot introduce phase shifts between the input and output, alter frequencies, or provide changing amplitude with frequency. It can, however, provide constant attenuation or gain and it can transform energy variables. The numerical coefficient a_0 is the static sensitivity of the stage, the constant of transduction. In principle, the zero-order stage provides perfect dynamic response for situations where the input variable must not be processed with respect to its time features as it passes through the stage.

Considering the transfer function form, it can be seen (but this will become clearer when the higher-order systems are studied) that the stage contains no storage mechanism because there is no time constant associated with it.

In many design situations, a zero-order response is highly desirable. For example, consider a resistance strain gauge (Figure 1a) in which extension of the electrical resistance wire, attached to a sample, alters the resistance proportional to the strain so induced. In normal use, the gauge, being apparently purely resistive electrically, will respond completely in phase with strains of the sample. No matter how rapid the input signal is, within practicality, the output follows without delay, without signal amplitude change, and without frequency change (Figure 1b).

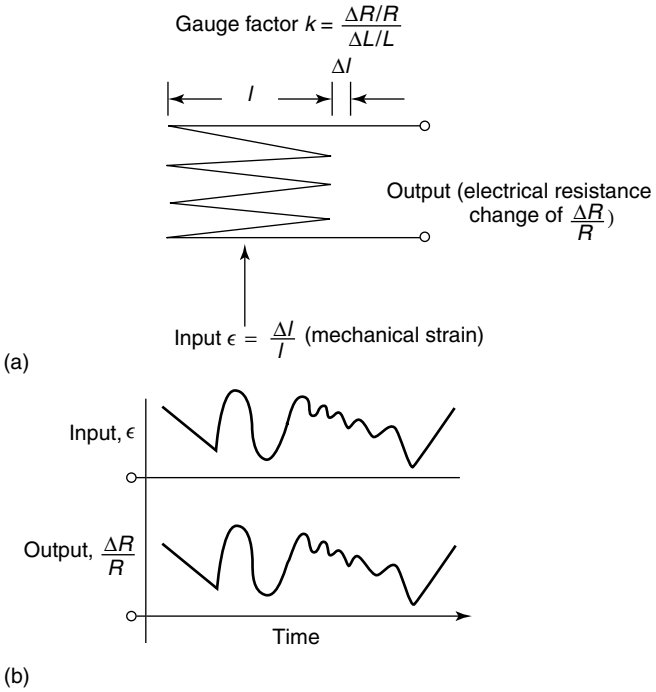

Figure 1. Example zero-order system – a resistive strain gauge: (a) gauge and its mathematical model; (b) responses.

As the gauge is presumably being used to monitor the strain behavior of the sample, zero-order response will yield the observer true information about what is actually happening to the sample with time and in amplitude. In control-loop design, zero-order sensing components often help the designer obtain a very tight, responsive system.

In practice, the designer or user must decide if zero-order characteristics are what are needed (see below). Assuming this to be so, it is then necessary to ascertain that the device does indeed produce them to the dynamic performance level desired, for, in reality, a perfect zero-order system is a mathematical abstraction. All systems include some measure of storage effects; it is these that will degrade the zero-order response into a higher-order system where they become significant.

In the strain gauge example, storage might arise through thermal capacity of the gauge and sample; through after-elastic mechanical effects in the gauge material; through parasitic electrical inductance and capacitance when the frequency of response or excitation increases sufficiently; through mechanical compliance (and its capacity to enable the mass of the gauge to move out of phase with the sample) in the bonding of the gauge to the sample via the thin layer of adhesive; plus other reasons. These, in practice, will each introduce time-dependent features situated over the frequency spectrum of response, from virtually DC to the radio frequencies.

4 DESIGN AIMS FOR MEASUREMENT SYSTEMS BEHAVIOR

The art of good instrument design and application is to select a stage that performs with the response that just suffices. In a relative humidity sensor, it can now be seen that the hygroscopic membrane, the strained metal beam, the strain gauges, and the electrical resistance Wheatstone bridge used can each be regarded as zero-order elements for the purpose of studying and designing the sensor for the application it was built to fulfill.

If a response less than several minutes is needed, then the various elements must be viewed as higher-order components, and a more complex model must be used to study and improve the overall dynamic behavior.

Design of instrument systems does not, however, always require zero-order performance. In many instances, there is need for storage in a system. Storage helps provide such often-desirable effects as integration and differentiation, which, in turn, enable frequency filtering to be devised. Applicability of the relative humidity sensor is enhanced in many applications by the long storage time of the membrane. This helps average (integrate) fluctuations that might occur in a room in which a fan circulates pockets of air differing in %RH that would otherwise cause a closed-loop controller to attempt to smooth out to the detriment of the real need.

5 EXAMPLES OF ZERO-ORDER MEASUREMENT SYSTEMS

Of the texts already referenced concerning dynamic response, only Doebelin (2003) makes specific mention of zero-order systems. His description includes another example – that of a resistance potentiometer used as a position-sensitive sensor.

It will probably now be clear that it is not possible to provide a list of zero-order instrument devices and stages for that attribute is decided by the use to which the stage is applied. As a guide, if the energy storage effects are minimal compared to existing energy levels and if only relatively low-frequency forcing functions are to be applied to the stage, then zero-order response probably occurs. The important factors are the relative values of these parameters and not their absolute magnitudes. A device operating at picowatt energy levels can provide delays of hours and conversely, a megawatt energy system might respond in milliseconds.

It can be very dangerous, in practice, to assume the response order for a given system. Simple testing will easily establish the order for the application in question. This is to be recommended where possible. Many of the problems that arise in measuring system design and application occur as a result of assuming that a sensor or stage provides zero-order response when, in the specific application, it actually operates with higher-order responses present. One example is the use of a classical flat bed plotting table that will filter signals that are too fast for it to respond to. It will still record them, but with diminishing amplitude as the frequency of the component rises. Phase shift will also occur between signals being recorded on multichannel recorders.

6 SPECIFYING ZERO-ORDER SYSTEMS

Each kind of response can be described in simple terms by stating certain simple descriptors. In the case of the zero-order system, these are as follows:

- Systems type is of zero order
- Amplification constant.

There is no need to describe any frequency features for it is known that zero-order systems do not exhibit any frequency varying behaviors. The other orders need additional descriptors.

1 DESCRIPTIVE EQUATIONS FOR FIRST-ORDER SYSTEM AND AN EXAMPLE

The dynamic regime of systems is introduced in **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**. For linear signal systems the various responses can be ordered. The zero-order system is covered in **Article 60, Zero-order System Dynamics, Volume 1**. This article deals with the dynamic behavior of first-order systems. Second-order responses are discussed in **Article 62, Second-order System Dynamics, Volume 1**.

The differential equation for a first-order system is, with a unit amplitude forcing function:

$$a_1 \frac{dy}{dt} = a_0 y = x(t) \tag{1}$$

Rearranging the coefficients to yield a unit coefficient for y gives

$$\frac{a_1}{a_0}\frac{dy}{dt} + y = \frac{1}{a_0}x(t) \tag{2}$$

Taking Laplace transforms produces

$$\frac{a_1}{a_0}sY(s) + Y(s) = \frac{1}{a_0}X(s) \tag{3}$$

Rearrangement again gives the transfer function as

$$G(s) = \frac{Y(s)}{X(s)} = \frac{1}{a_0}\frac{1}{(a_1/a_0)s + 1} \tag{4}$$

At zero frequency, and with sinusoidal excitation, the operator 's' validly becomes jω and is equal to zero. Thus:

$$G(s) = \frac{1}{a_0} \tag{5}$$

The coefficient $1/a_0$ represents the static regime transduction constant or amplification factor, often denoted as K. It may involve either attenuation (or gain) of a common input–output variable or relate one form of variable to another.

The ratio a_1/a_0 is termed the *time constant* for reasons that will become clear below. It has dimensions of time and it is generally denoted as τ. All first-order systems have the same characteristic kind of time response to any given forcing function and τ specifies the actual numerical magnitude of that response, this being regardless of the energy regime of the system.

The mercury-in-glass thermometer is what is chosen by many authors to illustrate a first-order system. In use, the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

thermometer is immersed in a fluid bath and is intended to transduce fluid temperature into an equivalent capillary-tube mercury movement without introducing delay or being affected in amplitude by the speed of the input temperature change. In practice, the thermometer can only be regarded as a zero-order system when very slow changes are to be monitored. For changes that take place in a few seconds, the thermal storage effect of the mercury and the heat flow restriction of the thermal film transfer effect that thermally couples the fluid to the mercury, provide first-order action.

Figure 1 is a schematic of the system including all variables that experience shows to be relevant in order that the system can be adequately treated by a first-order model.

The physical operation of the system must first be studied to discover assumptions that can be made in order to obtain an adequately descriptive model that is also reasonably workable, mathematically.

Assumptions in this example relate to such factors as the majority of resistance to heat transfer between the fluid and the mercury being provided by the heat transfer film, the glass being of insignificant thermal resistance. The mercury is presumed to have perfect heat conducting properties and to respond to heat changes producing instantaneous corresponding volume changes. Other factors assumed are that the glass envelope changes volume at the same rate as the mercury, an assumption that is not exactly true when high discrimination is needed since the glass takes considerable time to return to a smaller volume after being expanded. Other factors that must be presumed to hold are that heat transfer is achieved over a constant surface area and that it is not a function of the actual temperature. At least two more important requirements that do not strictly hold are that heat is only stored in the mercury, not in the glass, and that no heat is lost to the environment via the heat conduction path of the thermometer stem.

Despite the obvious presence of these many imperfections, the first-order model that can be developed for the thermometer does provide quite a reasonable estimate of the dynamic performance of the thermometer under changing bath temperature conditions.

Derivation of the differential equations, on the basis of energy balance and knowledge of the physical process by which heat changes cause a rise in the mercury meniscus, leads to the actual development of numerical quantities for the time constant and the transduction constant. This example is worked through in both Coughanowr and Koppel (1965) and Doebelin (2003) each providing a slightly different form of expression of the resulting numerical factors.

In terms of the parameters defined in Figure 1, it can be shown that

$$\left.\frac{\Delta y}{\Delta x}\right|_{\omega=0} = K = \frac{\Delta V \times V}{a} \tag{6}$$

and

$$\tau = \frac{\rho s V}{h A} = \frac{\text{heat stored}}{\text{resistance to heat flow}} \tag{7}$$

Note that the time constant parameter concerns one storage and one energy dissipative parameter.

It is, therefore, possible to determine theoretically not only the transduction constant as a numerical value (as also could a practical test) but it also provides knowledge of

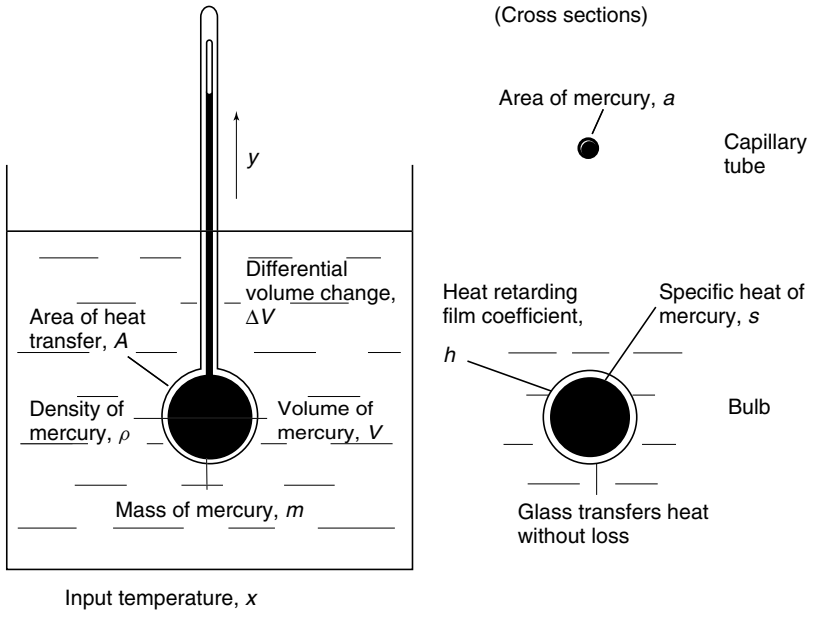

Figure 1. Basic physical system of a mercury-in-glass thermometer modeled at a first-order system level.

the factors of the system upon which it depends; similarly so for the time constant. Knowing these parameters enables the system to be tuned to provide whatever static and dynamic response is needed or to learn that existing materials and other practical constants might not allow a specified performance to be realized. They also enable the system to be easily specified in terms of three statements: the system order, K, and τ. The constants, however, vary greatly depending on the system conditions into which the thermometer is coupled. They cannot be quoted without reference to the model conditions that are applicable.

The importance of τ can now be considered in its capacity as a unique descriptor of the transient behavior of a first-order system when excited by certain given forcing functions.

Of the forcing functions introduced above, the step (the impulse, being similar, need not be covered in the same detail here), the ramp, and the sine wave are the most useful inputs to consider. Other input functions will require a special mathematical study of the transfer function along the lines now outlined.

2 RESPONSE OF FIRST-ORDER SYSTEM TO STEP FUNCTION INPUT

The Laplace expression for a step function of amplitude A is

$$X(s) = \frac{A}{s} \tag{8}$$

Response of a first-order system, which has $G(s) = K/(\tau s + 1)$ (where K is the transduction constant and τ the time constant) is given by

$$G(s)X(s) = \frac{K}{\tau s + 1}\frac{A}{s} \tag{9}$$

Expansion by partial fractions yields

$$Y(s) = \frac{AK}{s} - \frac{AK}{s + 1/r} \tag{10}$$

Using tables of Laplace transformations of common functions to invert this expression gives, for t from zero onward:

$$y(t) = AK(1 - \mathrm{e}^{t/\tau}) \tag{11}$$

This expression describes the dynamic behavior of the first-order system to which a step function of a given amplitude is applied at $t = 0$. For the above to hold when the step is applied, the system must already be in the steady state, meaning that the storage element is completely discharged through the dissipative path; the initial conditions are thus satisfied. If energy is already being discharged, that is, the system is still in the transient state of a previous forcing function application, then the response will be the result of two forcing functions and not the step applied here.

Being generally applicable, this time function can usefully be drawn as a graph in which the input is normalized to a unity maximum and the time scale is expressed in terms of a time-variable ratio. This is shown in Figure 2.

If the step is applied as a decrement, or fall, rather than the rise shown here, the curve is simply reversed, the shape is identical. It will then follow the form

$$y(t) = AK\mathrm{e}^{-t/\tau} \tag{12}$$

It can be seen that τ is an important descriptive constant of the system, deciding the curve's actual magnitude. It also directly describes the initial rate of rise; a tangent to the original line will intercept the final value level at the $1\,\tau$ point. This implies that if the system were to maintain (which it does not) the initial slope, the output would reach the final value in the time of $1\,\tau$. In general, this slope, for any order of system, is termed its *slewing rate*.

It can be seen from Figure 2 that the continued response reaches what might be considered to be close enough to the final value, at 86.5, 95.0, and 98.2%, levels for 2τ, 3τ, and 4τ, respectively. By 5τ, it is certainly close enough to a settled value for most applications. Although the time constant is the key parameter of definition, it must be realized that for final values to be reached, it takes a longer time than that given by the appropriate factors presented above. In 1τ, the response has only reached 63.2% of the final value. Furthermore, it rises to 63.2% of the remainder in the next 1τ period, and so forth.

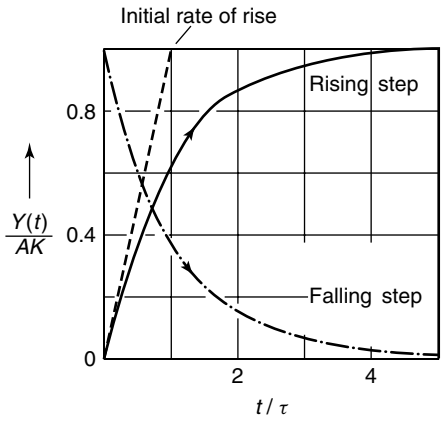

Figure 2. Normalized response of a first-order to a step input function.

Respective values for a falling unit step are that it falls to 36.8% in 1τ, to 13.5% in 2τ, to 5% in 3τ, and 1.8% by the time 4τ has passed.

In order to provide a general descriptive term that applies to any instrument response, linear or nonlinear, instrument users have adopted the term *settling time*. This is usually quoted as the time needed for the system to settle to within given percentage limits of the final value. These limits may be expressed as an error band. For example, it will take a first-order system, excited by a unit step function, a time of 3τ to come within $\pm 5\%$ limits. Note that a first-order system cannot overshoot the final value but approaches it from one side only.

Detailed analysis of impulse input function response is to be found in Coughanowr and Koppel (1965).

3 RESPONSE OF FIRST-ORDER SYSTEM TO RAMP FUNCTION INPUT

Step inputs may give an unrealistically severe rate of rise. Using a step or impulse in such cases will provide an output response that is much greater in transient deviation than what actually occurs. Slower rise rates, as represented by the ramp input function, are often more realistic forcing functions to use. As will be seen, the output response to a ramp follows the input more faithfully but quite an unexpected delay and possibly a progressively increasing deviation error results.

Using the same mathematical technique as was applied in the previous step response explanation, it is first necessary to obtain the Laplace transform for a ramp function of rate of rise, R. Forming the product of this with the transfer function for a first-order system having a transduction constant of K yields

$$Y(s) = G(s)X(s) = \frac{K}{\tau s + 1}\frac{R}{s^2} \tag{13}$$

Rewritten, this becomes

$$Y(s) = \frac{RK}{\tau}\frac{1}{s^2(s + 1/\tau)} = \frac{a}{s^2(s + b)} \tag{14}$$

where

$$a = \frac{RK}{\tau} \quad b = \frac{1}{\tau} \tag{15}$$

Expanding this into partial fractions gives

$$Y(s) = \frac{a/b}{s^2} - \frac{a/b^2}{s} + \frac{a/b^2}{s + b} \tag{16}$$

reverting a, b to physical constants

$$Y(s) = \frac{RK}{s^2} - \frac{RK\tau}{s} + \frac{RK\tau}{s + 1/\tau} \tag{17}$$

These are now in the form from which inverse Laplace transforms can be recognized from standard tables. Three time functions result to make up the whole response function:

$$Y(t) = RKt - RK\tau u(t) + RK\tau e^{-t/\tau} \tag{18}$$

that is, output = ramp + step + exponential transient.

This is interpreted to be a ramp function response of slope rate RK. It will have a different rate to the input when the stage has either attenuation or gain for the common input and output variables (that is, volts in, and volts out, as would occur in an RC stage) and the rate will differ when the rate is not linked to the input because the transduction constant is one of conversion (that is, temperature change yielding a length change output). If the transduction constant is unity, then input and output slopes will be identical.

The second term, a step of $RK\tau$ amplitude, and negative in sign, tells us that the output response begins to occur at $t = 0$ after a time lag. If the rates of the input and output are identical, there will exist a constant lag with time, but if they differ, the lag magnitude will be proportionately related to the time that has elapsed after initiation of the input signal. This lag effect has been interpreted by some authors as meaning that this combination of input to a first-order system will produce a system in which the output measured value at a given time is that of a fixed time before. This observation only holds true if the rates of the input and output ramps are identical. If not, the steady state error changes with time.

Finally, the third component of the total response is a transient signal of exponential form that occurs at the commencement of the ramping action to die away to virtual zero within a short time.

The total response is shown diagrammatically in Figure 3. The form of the transient part of the response, when isolated, follows that given as the falling curve in Figure 2.

Clearly, if the output is to be a faithful replica of the ramp input, then the time constant of the first-order stage must be sufficiently small in magnitude. Furthermore, the transduction constant K needs to be unity. When these conditions are met, a ramp will be followed with negligible droop, with minimum time delay, with minimal transient component, and with a small fixed, rather than changing, magnitude error. (Under such conditions it virtually becomes a zero-order system.)

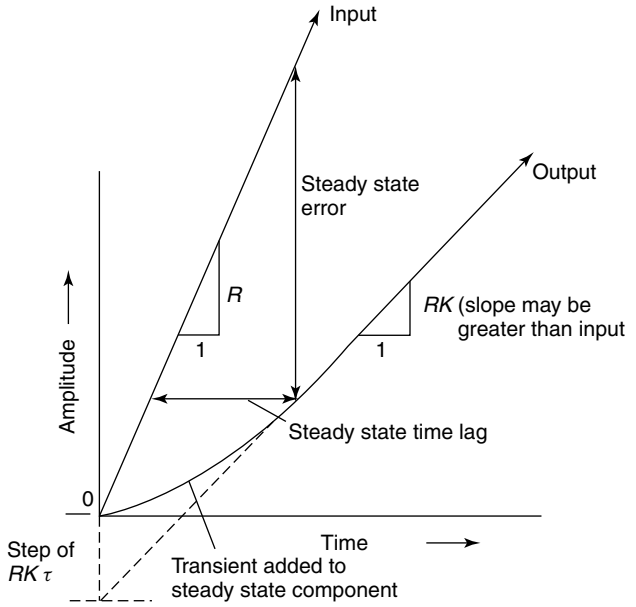

Figure 3. Response of a first-order system to a ramp input function.

4 RESPONSE OF FIRST-ORDER SYSTEM TO SINUSOIDAL FUNCTION INPUT (FREQUENCY RESPONSE)

The requirement for testing, or understanding, may relate to the behavior under conditions of continuous steady state excitation of the system stage. This is fundamentally approached using the sine wave signal train as the forcing function since all other continuous complex signals can be reduced to the sum of such responses. The forcing function in this case in the untransformed time domain is

$$X(t) = A \sin \omega t \tag{19}$$

In Laplace form

$$X(s) = \frac{A\omega}{s^2 + \omega^2} \tag{20}$$

Thus, the response of a first-order network to this will be

$$Y(s) = G(s)X(s) = \frac{K}{\tau s + 1}\frac{A\omega}{s^2 + \omega^2} = \frac{AK}{\tau}\frac{\omega}{(s^2 + \omega^2)(s + 1/\tau)} \tag{21}$$

This can be shown to be as in Coughanowr and Koppel (1965), after rearrangement, taking partial fractions and then inverse Laplace transformation:

$$Y(t) = \frac{AK\tau\omega e^{-t/\tau}}{\tau^2\omega^2 + 1} + \frac{AK}{\sqrt{(\tau^2\omega^2 + 1)}} \sin(\omega t + \phi) \tag{22}$$

where $\phi = \tan^{-1}(-\omega\tau)$; that is,

$$\text{output response} = \text{transient} + \text{steady state components} \tag{23}$$

The transient term is short lived, decaying to leave only the steady state component, that is, the contribution described as the frequency response of a system. The steady state term is a sine wave of the same frequency as the forcing function but it is phase shifted as a lag, by angle ϕ. It will have the so-called DC gain decided by the amplitude of sine wave at that frequency and the transduction constant. The gain factor, however, will progressively decrease (be attenuated) as frequency rises, the magnitude of this attenuation being dependent upon the time constant and the frequency.

It is clear, from the presence of the transient term, that a first-order system will not immediately respond in the steady state form but will undergo initial exponential behavior. Thus, the system will not ring (oscillate) but does need a certain amount of time to establish its intended frequency response action.

The steady state normalized frequency responses of a first-order system with transduction constant K, to input sine wave frequencies of amplitude A are plotted in Figure 4, being given with respect to the amplitude and phase of signals.

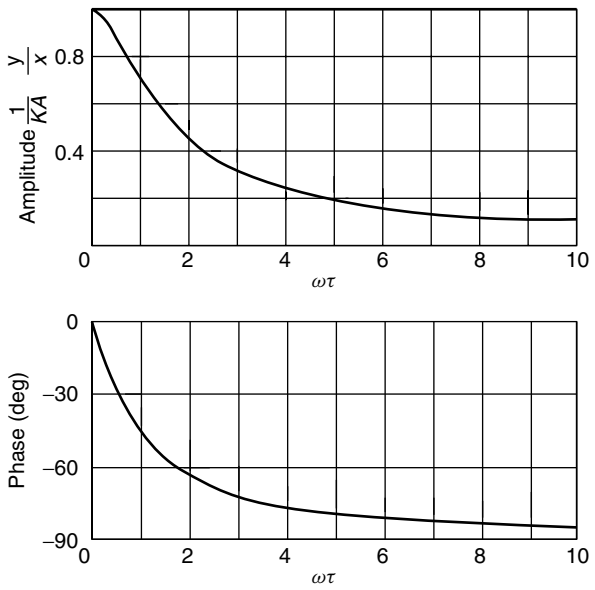

Figure 4. Normalized response of a first-order system to sinusoidal signals of varying frequency.

A first-order system will, therefore, not alter the applied frequency but may attenuate the amplitude and introduce phase shift rising, in a lagging sense, to a maximum of 90°, the degree of these effects depending upon the time constant of the system and the frequency of operation in question.

By way of an example that shows how these dynamic features can provide incorrect measurement action by a first-order sensor, consider a temperature sensor. The example is fully worked through in Coughanowr and Koppel (1965), so only the results need be given here. A thermometer with a time constant of 6 s (that is, for its use in a defined application; it is not a feature of the thermometer alone) is placed in a bath to detect bath temperature variations of $\pm 1\,^{\circ}\mathrm{C}$ amplitude that are sinusoidal at around three cycles per minute. Because of its inherent frequency response, these cycles would be indicated to be half their real magnitude, the sine wave output being of the same frequency but now delayed by some 4 s.

A second example is found when considering the mechanical pen recorder. When adjusted for critical damping, the response of a plotter can be regarded as being essentially of first-order character. If the recorder response is inadequate, it will plot signals at reduced amplitude. If the signal of one channel is of lower frequency than the other but of the same amplitude, the recorder will not record a true indication of the amplitudes and phase existing between the two signals being recorded.

For similar reasons, filters added to smooth out noisy signals (in any energy regime), may also lead to similar inaccuracies when more than one frequency component exists in the forcing function, that is, any complex continuous signal. The response can be found by making use of superposition, which is applicable when the system is linear. This allows each component to be evaluated separately for magnitude and phase values, the set then being added to obtain the total response. A worked example for a forcing function with two components is given in Doebelin (2003).

Complex signals will not, therefore, give exactly the same normalized responses as are given in Figure 4, but they will always produce attenuation and phase shift as τ and ω increase. It can be seen that a square wave, being a set of sine wave components, will produce a response in which each cycle follows a step response profile as the square wave rises and falls, the starting point of each new transition depending upon the level to which it rose, or fell, in the previous cycle.

As has already been mentioned, the time constant used must be the effective value of the combination present when the stage is interfaced. It will not be the same value as that of the stage in isolation, unless the input source and output load added to the stage do not interact through loading mechanisms. For example, a simple electrical low-pass RC stage will have, in isolation, $\tau = RC$. When the input source impedance and the output load impedances are connected, they each modify the effective value of resistance because the load resistance is added in parallel with C and the source resistance is added in series with R.

This situation has been described in Section 1, where the mercury-in-glass thermometer was considered; in that example, the properties of the fluid can greatly vary the effective time constant experienced.

It might be thought that the type of a stage can be recognized uniquely from the shape of the step response. However, this is not necessarily a unique indicator because systems of any order can, if suitably conditioned, exhibit somewhat similar transient responses. This occurs when the time constants of the respective order contributions are such that the components producing them effectively work in phase. As the order rises, however, the shape of the curve changes more noticeably enabling the nonconformity to a first-order response to be more easily recognized.

5 EXAMPLES OF FIRST-ORDER MEASUREMENT SYSTEMS

The suitably thermally lagged thermometer has already been discussed. From that example, it is possible to recognize that a first-order system results when there exists a significant energy storage mechanism and the inability of that stored energy to discharge through a dissipative element in a relatively short time. The direct combination of these two system properties decides the all-important time constant.

As the dissipating property (often called *the loss*) decides how well a response is damped (assuming, in such cases that a fixed level of energy storage capacity exists) this is often called *the damping property*. The simplest form, mathematically, is that in which the rate of damping is fixed independently of the rate of the signal. In mechanical systems, this is called *Coulomb friction*. Almost always, however, it will be found that the damping property in a system is dependent upon influence variables, such as temperature. Friction that is proportional to the velocity of the signal is termed *Newtonian*. Add to these two the fact that the friction coefficient for static systems is generally much higher than for those after breakaway has occurred (nonlinear friction), it will be seen that practical use of linear systems theory is a much-simplified version of reality. Although expressed in now deprecated units, the practical information on damping is contained in a classic statement. Drysdale and Jolley (1924) is very relevant to fine mechanical systems.

In electrical systems, the obvious first-order example is the *RC* combination, such as is met in a low-pass filter stage. Cascading first-order stages raises the order of the system producing a different result from that obtained by the same components arranged to produce the same time constant as a single stage.

In fluid systems, first-order stages occur in tanks of fluid being drained, the resistance to outward flow and the capacity of the tank forming the time constant pertinent to level of the fluid. Chemical systems provide this order action when solutes are mixed into solution. In acoustics, an air enclosure having a baffled (resistance to airflow) output port, as is used in some speaker enclosure designs, is another fluid regime example. The same applies to a similar situation met in pneumatic instrumentation; much of pneumatic equipment, however, is not linear in operation. First-order systems are also referred to as providing, or being, an exponential lag stage.

Further details of practical examples are to be found in Atkinson (1972). Coughanowr and Koppel (1965), Olson (1943), and Shearer, Murphy and Richardson (1967). Other works that may be found to be useful are Oppenheim *et al.* (1996), Hsu and Hse (1996), Nise (2000).

6 SPECIFYING FIRST-ORDER SYSTEMS

First-order systems require the following features to be given when specifying their response:

- system type is of the first order
- amplification factor
- time constant, usually in seconds.

1 DESCRIPTIVE EQUATIONS FOR SECOND-ORDER SYSTEM AND AN EXAMPLE

Second-order systems can arise when two energy-storage mechanisms exist in a system and act with some degree of interaction. They must also be able to act with a 180° phase shift between them, for example, a capacitor and an inductor in an electrical system but not two inductors or two capacitors. They need not be of the same energy type, for energy conversion mechanisms make them mathematically and practically compatible. Dissipative qualities are, again, important as this is the factor that decides the damping of responses.

A most noticeable feature of second-order systems is that they can overshoot final values, even providing oscillation (when sufficiently small damping exists).

Characteristics of a second-order stage will first be derived, followed by the study of its response to step, ramp, and continuous sine-wave forcing functions.

The second-order system is described by the nonhomogeneous ordinary linear differential equation:

$$a_2 \frac{\mathrm{d}^2 y}{\mathrm{d}t^2} + a_1 \frac{\mathrm{d}y}{\mathrm{d}t} + a_0 y = x(t) \tag{1}$$

Taking Laplace transforms for $f(0) = 0$ (where the system is initially in the steady state) gives

$$a_2 s^2 Y(s) + a_1 s Y(s) + a_0 Y(s) = X(s) \tag{2}$$

Rearrangement into the transfer function form gives

$$G(s) = \frac{Y(s)}{X(s)} = \frac{1}{a_0} \frac{1}{(a_2/a_0)s^2 + (a_1/a_0)s + 1} \tag{3}$$

For this expression, three parameters of practical implication can be defined. They are

- $K = 1/a_0$ transduction constant, the DC gain or conversion constant.
- $\omega_n = (a_0/a_2)^{1/2}$ the angular natural frequency (with zero damping present); it has time dimensions.
- $\zeta = a_1/2(a_0 a_2)^{1/2}$ damping ratio, a dimensionless number relating, in practice, the magnitude of actual damping to that at $\zeta = 1$, called *critical damping*.

These parameters occur as the result of interpretation of the solution of the above equations that show that the system is oscillatory in nature and that the level of damping present, due to losses, controls the degree of oscillation. Being properties of the stage and not of the stage coupled to any

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

ISBN: 0-470-02143-8.

particular forcing function, they can be used as descriptors of a second-order block.

The period of the natural angular frequency of the system can be expressed instead of the angular frequency as its 'reciprocal' and can be given the symbol τ. This is done by some authors and is adopted here. It must be made clear that τ is not used in the same context as it was for the first-order system nor is it exactly the period of the oscillating waveform (it is only for a zero damping situation).

Using these alternative symbols enables the transfer function to be expressed either as

$$G(s) = \frac{K}{(1/\omega_n^2)s^2 + (2\varsigma s/\omega_n) + 1} \tag{4}$$

or as

$$G(s) = \frac{K}{\tau^2 s^2 + 2\varsigma\tau s + 1} \tag{5}$$

both forms of which are commonly used.

As the denominator of the transfer function is a quadratic function, it can be factored into a form that shows that the system could be formed by using two suitable first-order systems placed in cascade.

Note that the natural frequency and damping ratio are interdependent, each also being functions of the transducer constant. Thus, gain changes and damping-ratio changes can alter the natural frequency.

Changes of K matched by appropriate changes to the damping ratio can retain a given natural frequency.

The implication of these constants becomes clear when the step response of such a system is studied.

2 RESPONSE OF SECOND-ORDER SYSTEM TO STEP FUNCTION INPUT

Forming the output expression in Laplace form from the Laplace transforms of the transfer function given above and the unit step function yields

$$Y(s) = \frac{1}{a_0}\frac{1}{s}\frac{1}{(a_2/a_0)s^2 + (a_1/a_0)s + 1} \tag{6}$$

This reveals that the response will be one involving roots of a quadratic. As the actual working is not needed to understand the output response and because it is fully presented elsewhere, such as in Coughanowr and Koppel (1965), the method of solution only needs to be considered.

Forming the partial fractions and inverting the Laplace expressions gives the time-domain solution. The solutions can only be obtained mathematically as three separate regions, these depending upon the nature of the roots of the quadratic. The damping ratio ζ is the dominant factor here. The roots are complex when $\zeta < 1$, real and equal when $\zeta = 1$, and real when $\zeta > 1$. These three regions are termed *underdamped* or *oscillatory, critically damped*, and *overdamped* or *nonoscillatory* for the three regions respectively.

It must be clear that the response range itself passes through a gradual gradation from the under to the over-damped response. It is a need of the mathematical method of solution, not a property of the real physical system, that dictates that there are three different regions. The performance characteristic is a smoothly varying effect, not having sudden changes of behavior as the equations might suggest happens.

A family of response curves is presented, in a normalized manner, as in Figure 1; these show the response as the damping ratio is altered from zero to around 5.0. Note that at large damping ratios, the response curve takes on a similar form to that of a first-order system, the two being slightly different in shape at the origin.

It can be seen that second-order system response can overshoot the final value, and if inadequately damped, it can continue to oscillate after a step is applied. It can be seen that the second-order system, with zero damping, acts as a sinusoidal signal generator if the losses are truly zero or are actually supplied to the system.

A step function is the most severe form of input-level change that can be applied. In practical systems, this rate of rise may be unrealistic, and in such cases, a step input would produce a response that is considerably more oscillatory than what reality might yield. The transient is sometimes called *ringing*. A slower rate of rise, as would be simulated by a ramp that reached a terminated level at given amplitude, would often be more reasonable to apply. This

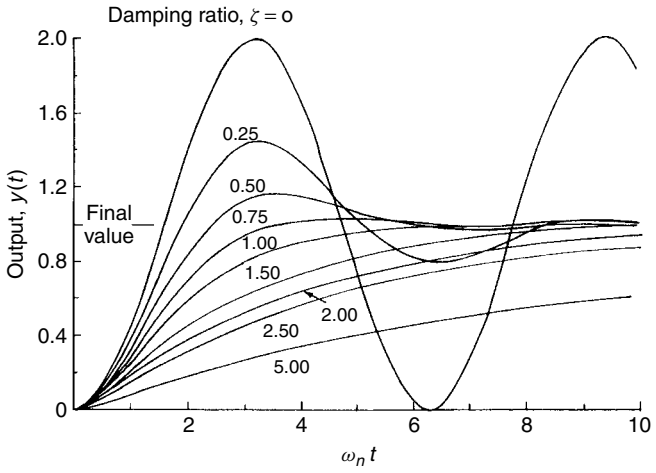

Figure 1. Normalized response of a second-order system to a unit step function.

situation is worked through in Doebelin (2003) to show that with a terminated ramp forcing function, the underdamped ($\zeta < 1$) response can be made to be virtually error free if the natural frequency of the system is large compared with the reciprocal rise-time duration of the ramp applied, this also applies for virtually zero damping. Doebelin makes the point that this means that stages having little damping may be satisfactory if they have high natural frequencies and are not excited in use by rapid rate of rise steps. The example cited in such a case is the piezoelectric accelerometer, when it is used to measure responses of relatively low-pass mechanical functions.

The general relevancy of the step response for many practical systems has given rise to several descriptive terms that relate to the underdamped responses given in Figure 1.

Overshoot is defined as the, less than unity, ratio of the magnitude to which the first overshoot rises over the final-value line to the magnitude of the final value. Numerically, this is given by

$$\text{overshoot} = \exp\left(\frac{-\pi\varsigma}{\sqrt{1-\varsigma^2}}\right) \tag{7}$$

and is, thus, decided only by the damping ratio. Note that the half magnitude of the overshoot cannot exceed the final value.

Decay ratio is defined as the, less than unity, ratio of successive amplitudes of decay cycles. Mathematically, it happens to be the square of the overshoot function given above.

These two expressions enable the damping for a given system to be calculated from a given record or the overshoot to be estimated from the tail end of a record, as occurs when phase delay loses the first part of a record in an oscilloscope.

Their behavior with varying damping ratio is plotted in Coughanowr and Koppel (1965).

Rise-time does not follow the same simple relationship with the defined τ as it did in the first-order case. It is quoted here as the time for the signal to rise from zero to the first crossing of the final value.

Settling time, defined in **Article 61, First-order System Dynamics, Volume 1**, applies with the same meaning to these waveforms. It is also called *response time*.

The period of oscillation, T, the time duration from one peak to the next of the cyclic transient, is not given directly by τ when damping is present, but it is found from

$$T = \frac{2\pi\tau}{\sqrt{1-\varsigma^2}} \tag{8}$$

the term τ being the period of the undamped second-order system. As suggested earlier, the natural frequency of the system is a function of the damping ratio. As damping increases, natural frequency falls according to

$$\frac{\omega}{\omega_n} = \sqrt{1-\varsigma^2} \tag{9}$$

As with first-order systems, although these factors appear to define the system as a stand-alone unit, they are subject to modification by the terminations used. For example, the damping ratio that would be used when studying the response of a high-speed plotter would depend upon the damping added by the plotter to the system of interest.

Impulse response is not covered here, the reader should refer to Coughanowr and Koppel (1965) and Doebelin (2003) for worked derivations and normalized response curves that match those given in Figure 1. A somewhat similar oscillatory response, described in identical terms, results.

Although the treatment has covered the response in a general manner, many texts include worked examples of specific practical systems of mechanical, electrical, electromechanical, acoustical, and pneumatic nature. In the discipline of physics, it is covered most usually under the titles of wave motion and simple harmonic motion. It is also dealt with in many texts on the mechanical-design aspect. Closed-loop control systems often result in second-order open-loop transfer functions and can sometimes be regarded more simply as a stage with this form of response, instead of needing to be seen as a closed-loop stage.

3 RESPONSE OF SECOND-ORDER SYSTEM TO RAMP FUNCTION INPUT

The response of the second-order system to a ramp forcing function is derived by the same procedure as was used for that of a first-order system. It is worked through in Doebelin (2003) and Atkinson (1972).

The response is similar to that of a first-order system fed with a ramp, the exception being that now the system might oscillate about the final ramp line during the initial transient portion of the response curve. Again, there exists a step function component that delays the output ramp by an amount decided by the damping ratio ζ and natural angular frequency ω_n. The resulting steady state time lag and error are both reduced by increasing the natural frequency and reducing the damping ratio. Doebelin (2003) provides a normalized chart of how deviation error varies with varying damping ratio as the transient solution dies away.

4 RESPONSE OF SECOND-ORDER SYSTEM TO SINUSOIDAL FUNCTION INPUT (FREQUENCY RESPONSE)

The forcing function here is that used to establish the second-order frequency response. The methodology used is that given in **Article 61, First-order System Dynamics, Volume 1**. A solution is needed for the Laplace form of the resultant function:

$$Y(s) = \frac{A\omega}{s^2 + \omega^2} \frac{K}{\tau^2 s^2 + 2\varsigma\tau s + 1} \tag{10}$$

This involves solution of the roots of two quadratics. This solution is worked through in several texts (Beckwith and Buck, 1969; Coughanowr and Koppel, 1965; Shearer, Murphy and Richardson, 1967). The resulting time-domain parameters of phase and amplitude are obtained from the output expression:

$$Y(t) = \frac{AK}{\sqrt{[1 - (\omega/\omega_n)^2]^2 + (2\varsigma\omega/\omega_n)^2}} \sin(\omega t + \phi) \tag{11}$$

where

$$\phi = -\tan^{-1}\left(\frac{2\varsigma}{\omega/\omega_n - \omega_n/\omega}\right) \tag{12}$$

or in the form where $\tau = 1/\omega_n$,

$$Y(t) = \frac{AK}{\sqrt{[1 - (\omega\tau)^2]^2 + (2\varsigma\omega\tau)^2}} \sin(\omega t + \phi) \tag{13}$$

where

$$\phi = -\tan^{-1}\left(\frac{2\varsigma\omega\tau}{1 - (\omega\tau)^2}\right) \tag{14}$$

These expressions show that the output is a sine wave of the same frequency as the input signal but that the magnitude can now be greater, or lesser, as the frequency rises. When $\omega = \omega_n$, the amplitude can rise to a theoretical infinity magnitude, the magnitude being decided by the damping ratio.

The phase component of the equations shows that it lags from zero to a maximum while approaching, but never quite reaching, -180° if the damping ratio approaches zero. It is -90° at the natural frequency, ω_n. The expressions are plotted in normalized form as the two plots of Figure 2. In this regard, second-order systems are quite different to first-order stages. These curves are plotted in a particularly accurate manner in Shearer, Murphy and Richardson (1967).

Because the system can produce output signals larger than what is provided to it, it has the ability to provide signal gain or amplification; the output amplitude variable is, therefore, termed the *magnification ratio*.

Whether magnification is to be deliberately adopted or not depends upon the application. In some detection systems, a second-order sensor is purposefully designed to ring (by virtue of absence of damping) at its natural frequency so that magnification is gained. In other systems, it may be desirable to keep the frequency response flat for as wide a bandwidth as possible.

The degree of resonance can be described in terms of the Q-factor, a quality factor or figure of merit. It can be shown (Shearer, Murphy and Richardson, 1967) to be

$$Q = \frac{1}{2\varsigma\sqrt{1 - \xi^2}} \tag{15}$$

or, for low levels of damping, it approximates to

$$Q \simeq \frac{1}{2\varsigma} \tag{16}$$

Alternatively, it is defined in more direct terms of the 'peakiness' of the resonance curve as the bandwidth at the half-power points (where the power level has dropped to half that at the peak), divided into the resonant frequency. Both methods give the same result; direct measurements on the amplitude–frequency response curve can be used to determine the damping ratio.

A word of caution is needed here. In many second-order systems, resonances need time to develop when fed with a swept frequency forcing function. Response curves swept too rapidly may, therefore, yield resonance peaks below their final value if given sufficient time to build.

5 SELECTIVITY ISSUES FOR SECOND-ORDER SYSTEMS

The factor Q is also a measure of the selectivity of the system. This usage applies when the system is used to deliberately detect signals near the resonant frequency, this being achieved by attenuating all others with respect to that small bandwidth.

Quotation of flat-response bandwidth is usually achieved by specifying the range of frequencies over which the response remains within the maximum and the half-power (3 dB) points. From Figure 2, it can be seen that the widest flat response is obtained with a damping factor of around 0.5. By comparison with the frequency response curve

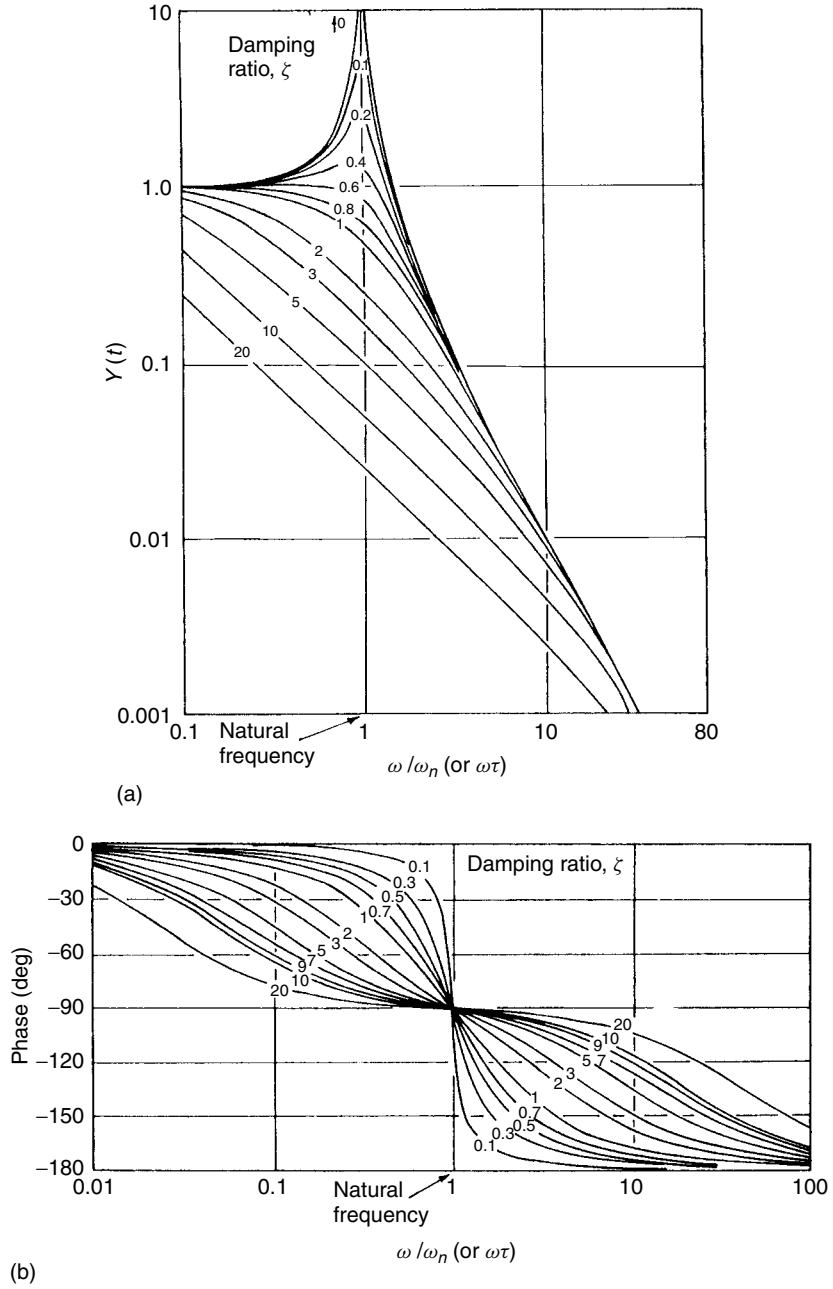

Figure 2. Normalized response of second-order system to sinusoidal excitation: (a) amplitude; (b) phase.

of the first-order system **Article 61, First-order System Dynamics, Volume 1**, it can be seen that a second-order system will provide a flat response of similar bandwidth but the first-order system will not fall off as rapidly. Additionally, the phase shift of each might be important. At the 3-dB point of each, a first-order system introduces approximately -60° shift, while the second-order stage introduces some -110° of lag.

Complex signals fed to a second-order stage can be treated as the sum of sinusoids. If the original character of the signal is to be preserved, then each frequency must be transmitted through the stage without attenuation or phase shift.

6 SPECIFYING SECOND-ORDER SYSTEMS

Second-order systems require the following features to be given when specifying their response:

- system type is of the second order
- magnification ratio at DC
- damping ratio
- resonant frequency.

Other sources of detail on second-order systems are Oppenheim *et al*. (1996), Hsu and Hse (1996), and Nise (2000).

1 DEFINITION OF SYSTEMS THINKING

Too often designs for a system are generated from the 'bottom up'; the core need is hastily matched against an apparently suitable technical solution that appears to fit the need. As the detailed design progresses, it becomes clear that other factors should have been allowed for and that it is by then getting expensive and time consuming to change things.

On the other hand, the more aware and experienced designer will carry out the design from the 'top down' finding appropriate solutions much later when the full requirements have been established. This article and **Article 64, Executing A Measuring System Design, Volume 2** provide the background information to become a 'top down' designer, who rarely needs to make drastic redesign changes.

Systems thinking is a mental attitude to problem solving that intuitively assists one allow for issues of the 'whole' – this is the holistic mode of consideration.

Its implementation is done by application of Systems Engineering (SE) principles that, in turn, leads to the detailed engineering design that is well developed in academic curriculum; systems thinking and systems engineering are seldom developed in an overt didactic manner. The material given here is extracted from Sydenham (2004) where the issues of modern engineering design are covered in detail.

A simple definition of Systems Engineering starts development of this thinking. QinetiQ, UK, staff has developed this conveniently short description of SE:

> 'A set of activities which control the overall design, implementation and integration of a complex set of interacting components or systems to meet the needs of all users.'

This clearly recognizes that engineering design tasks have to include numerous interacting issues (often not properly allowed for in engineering design) in order to obtain a sound solution to the customer's needs.

SE makes use of a set of principles and processes that efficiently apply resources to optimize a development project's progress toward a sound solution of a customer's product or service need. The definition of SE also highlights the fact that it deals with more than the physical energy/mass relationships that are covered by detailed engineering work.

Application of Systems Engineering is not a case of applying a set of rules, but more a way of thinking that extends conventional engineering design practice.

Where the memory requirement needed to track the many issues that arise exceeds one person's 'brain-full'

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

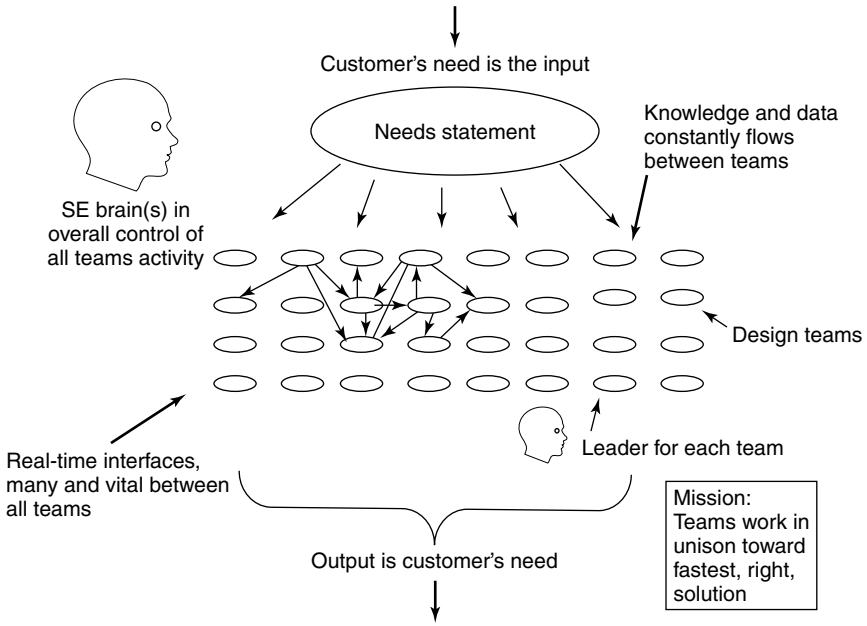

Figure 1. Teaming in an engineering development.

it becomes necessary to employ commonly understood and agreed recorded processes and activities. This helps ensure each person designs the 'right' thing as their part of the whole.

Application of systems engineering is about deciding, for the technical aspects of a project, what should be done by whom, and by what time?

This kind of management task differs from that of office, corporate, or project management; however, the distinctions are not always black and white. Figure 1 provides a simple model of the human teaming aspect of the engineering of a systems task; it represents the overall situation taking place in a development.

All teams must be efficient in their duty in order that the whole set of teams delivers the 'best practice' design needed. Note that numerous interactions will take place between the teams as the project outcomes pass from 'customer need in' to 'satisfactory system out'. An individual must work as a team player; a design team leader is needed to help the process along.

Applying SE to the measuring system design task is a matter of being able to recognize what kind of activity is appropriate to be done at any particular time. This ability is developed by reading, taking courses, working with experienced practitioners, and using every opportunity to bring fresh and better solutions to design situations.

Underpinning the professionalism of SE is an appreciation of Systems Thinking. An appreciation of how engineers and physical scientists go about their thinking is needed at this point.

In the seventeenth century, Descartes suggested that problems are handled by successively breaking down a problem until a level is reached where sufficient understanding exists. This paradigm for problem solving is known as 'reductionism'. It is the basic thinking methodology of science and engineering and has been applied with great effectiveness.

Taking this reduction idea a step further suggests that a system rebuilt from a set of subsystem solutions must be a sound overall solution. This is, however, not necessarily so. Small deviations in subsystem solutions can, all too easily, propagate upward leading to major errors in the final performance.

Difficulty in not meeting requirements is also due to the fact that the traditional limited engineering detail viewpoint often cannot cope with the complexity of real systems. Reductionism needs to be supplemented with other kinds of thinking.

In the reductionism design approach, a closed model of the design situation has to be realized to complete and close the design boundaries. Care is needed in setting up these boundaries – *see* **Article 68, Setting the System Boundaries, Volume 2** and **Article 64, Executing A Measuring System Design, Volume 2**.

Many engineering design situations contain issues that do not lend themselves to reductionism thinking. The ability to recognize the nature and scope of these limiting parameters needs skill in design team operations. Seeking to force reductionist ideas to fit where they are not appropriate can lead to project failure.

Systems Thinking includes attention to

- human activity systems, not just the inanimate physical objects that make up the whole;
- operational readiness and suitability, that is, will it do the job when called upon and will it continue to perform its task for as long as expected?
- systems of all levels and types.

Key statements have been published on Systems Thinking by engineers involved in major projects; Hitchins (1992) is worth visiting for its mind-opening views.

Key tenets of Systems Thinking are as follows:

- It is concerned with the concept of 'whole' and its properties.
- It needs systemic thinking (i.e. including all of the issues) as well as systematic thinking (i.e. being methodical in tackling the problems).
- Systems consist of hierarchies that relate to each other through numerous interfaces, each having their own kind of requirement.
- All parts of the whole are interconnected (*interface* is an alternative term) to a varying degree, some being very dominant and thus having greater influence on the behavior of the whole.

The various methods and parts of Systems Thinking are illustrated in Figure 2.

A model of the layers of system openness starts with the outer total shell that includes everything thought to be of relevance to the problem that the diagram represents.

Inside this layer is placed the study of how the different systems viewpoints are expressed. This has two thinking aspects – philosophical systemic thinking that is often hard to apply, and the various pragmatic working areas that the various kinds of thinking need to advance their problem solving.

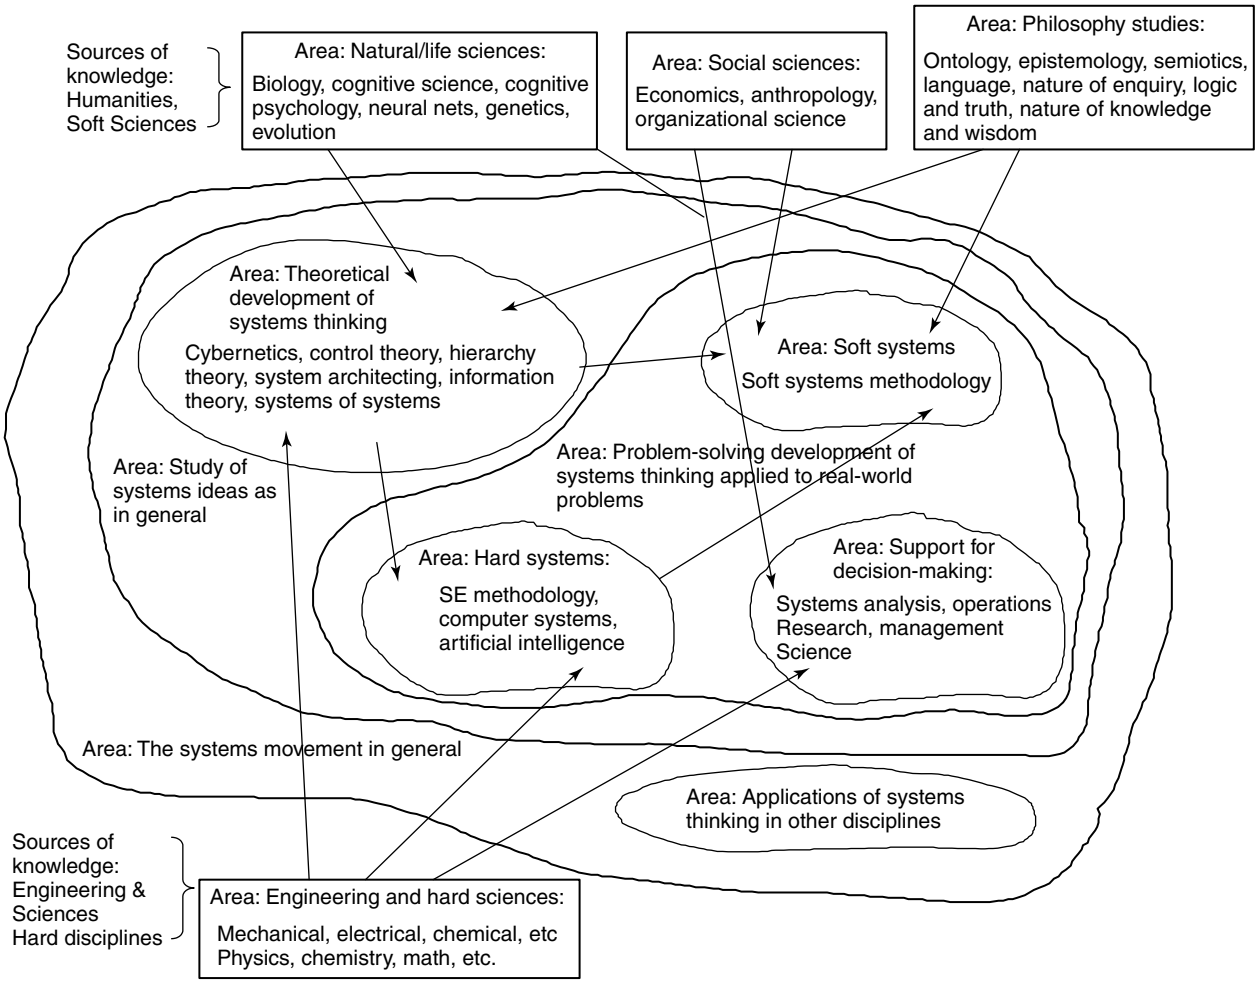

Figure 2. Representation of the relationships of the key disciplines.

Engineering can be seen there to make use of all of the domains shown in Figure 2 with the exception that the application of the soft kind of systems is not well developed – see Section 3.

2 REDUCTIONISM VERSUS POSTMODERNIST THINKING

Reductionism has served engineering and science well, but it cannot provide all of the solutions to systems design – see Section 4. Design engineers overly seek to use the reductionist approach because it is the main method in their design toolbox. They are not as well equipped to find sound solutions for systems involving human activity.

In the 1970s, an engineer in charge of major engineering projects in the United Kingdom was dissatisfied with the fact that the reductionist engineering approaches were not working well enough. He developed a methodology for these situations that is now known as the Soft Systems Methodology (SSM), Checkland (1981), Checkland and Howell (1998). SSM recognizes that not all disciplines make use of reductionist thinking.

In the humanities, it has long been recognized that the human machine has two aspects. The physically existing 'body' part can be explained through the laws of physics. The cognitive 'mind' part, however, cannot – yet they form the same whole. There is currently no meeting of the minds on this dual body problem; it continues to provoke philosophical debate.

This has led to the humanities disciplines solving problems differently to how they are tackled in the hard science disciplines. Their phenomenological approach – often called the *postmodernism approach* – is not as precise as reductionism but it can make progress in soft science situations.

3 SOFT SYSTEMS THINKING

Figure 3 shows the flow of activities for finding and implementing a solution to a system need in a 'soft' situation.

The SSM process begins with the problem being identified as unclear and lacking an obvious reductionist solution. The need is then expressed in writing as that helps clarify the situation.

Purposeful activities are identified and conceptual models generated. These are compared with the starting point of the real situation. Extreme differences are rectified in the model and the implementation adjusted to make it acceptable to the people involved in the change.

This process is repeated until the best available plan results. Considerable iteration may be needed to reach an acceptable situation.

Success cannot be assured with the soft system methodology, but it is one of the few ways known to seek design solutions for problematic system designs. Here the solution solver 'gets inside the problem' making a considered intervention to see what happens.

In sharp contrast, the hard engineering solution path develops a separated model of the whole through metaphorically dissecting that which identifies its subsystem. This set of component subsystems, and their interrelationships, are then simulated using a computer to investigate the

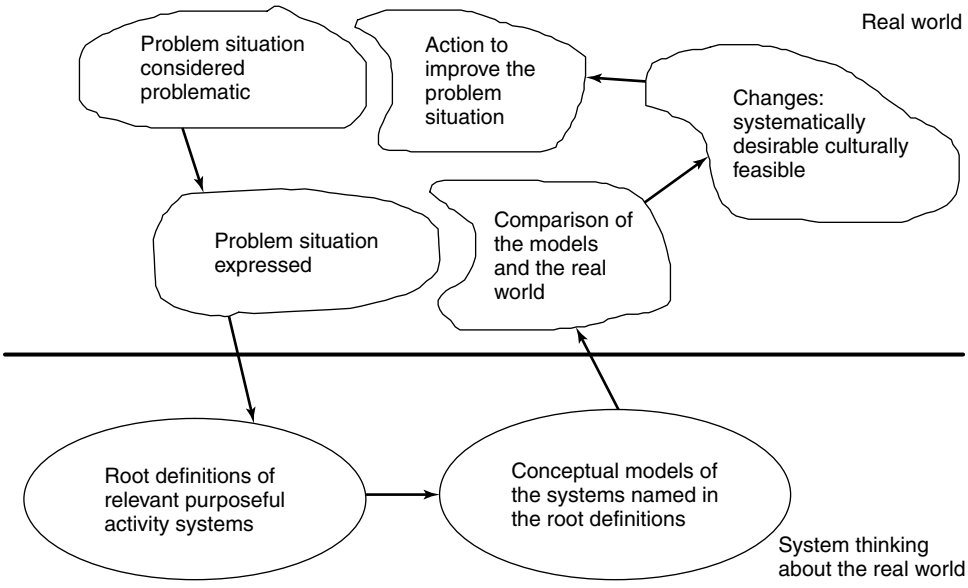

Figure 3. Flow of activities in finding and implementing a solution in a soft system situation.

sensitivities of the various critical issues. Optimization methods are applied to facilitate beneficial changes to the model.

When the right model and its parameters have been realized, the real system is rebuilt to form a new system; altered parts are put back into place to see if the whole works as intended.

Humans cannot be adequately understood as technical machines alone. People within systems can be slow and reluctant to respond to the direct process of change. Changing organizational cultures can take a long time to achieve. It has been summed up as trying to 'herd cats'.

It is often, however, the engineers trained in reductionism who are expected to develop solutions for systems with which they are not well versed, and for which there is often low chance of clear-cut success, as measured in hard science ways.

The design team leader needs to recognize the kind of system class in which the design team is involved and set up appropriate team membership.

When designing measuring systems, any human element present needs careful treatment to ensure it will operate properly. This arises when generating the needs statement in order to establish what should be measured, and for what purpose. This stage – *see* **Article 64, Executing A Measuring System Design, Volume 2** – usually involves thinking in the soft regime as customers develop their ideas. The operational regime of measuring systems – the knobs, dials, panel layouts, handling properties, colors, and emitted sounds – all involve soft thinking as the human factors – *see* **Article 94, Human Factors Engineering, Volume 2**; **Article 95, Human–Machine Interface, Volume 2**; **Article 96, The Domains of Human Factors Integration, Volume 2**; and **Article 97, Design Methodology, Volume 2**.

4 HIERARCHY OF SYSTEMS

Representing the whole of all systems activities and relationships would be a massive task; there are too many issues and variations to cover. Instead, a collection of thought provoking models is used that develop insight into aspects of the whole.

Three different models are now given, each revealing different characteristics of the same generalized whole.

The first relates the groups of people involved, the sciences, and their thinking, Figure 4.

Three key kinds of interrelated activities are shown – the natural world, the sociopolitical system, and engineers and scientists at work. The needs of all three must be met for a system design to be successful. Engineering, until recently, largely neglected the other two; today sociopolitical and natural world aspects must be taken into account. Installing a measuring/detection system can sometimes seriously impact people's perceptions producing disastrous outcomes, as did the 'Star Wars' missile protection system program.

Each of the three regimes is represented by a triangle. At the base of each triangle sits the scientific, formal, quantitative thinking workers. Moving up each triangle, the thinking style used changes from essentially quantitative to almost entirely qualitative, for at that level it is taking in people's feelings and emotions.

Engineering and science disciplines operate best in the lower areas.

The middle ground is where the use of Systems Engineering finds effective application. At the top, all manner of

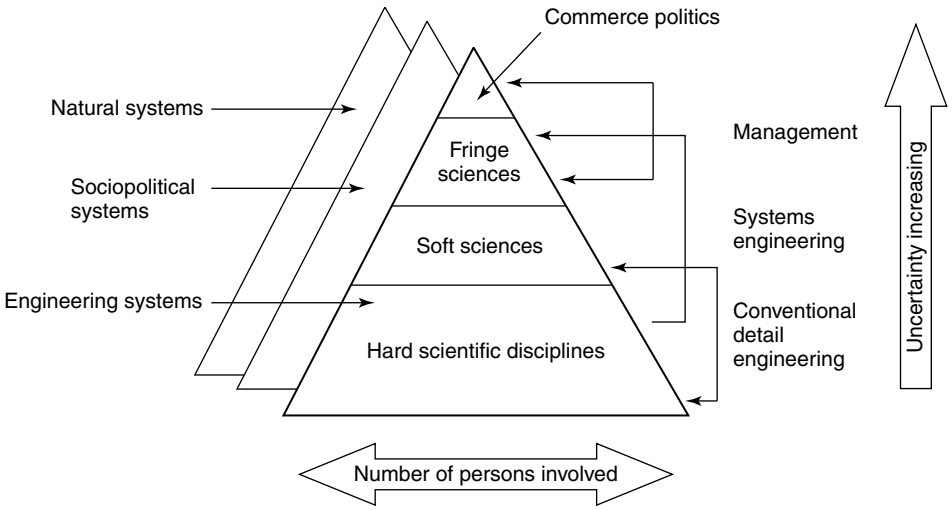

Figure 4. 'People and Science' model of a systems activity.

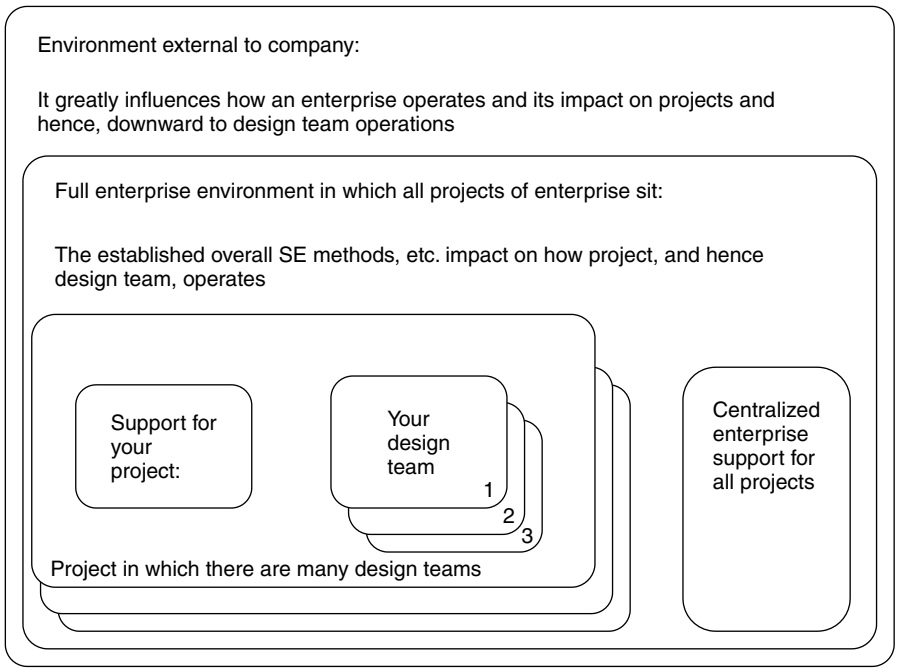

Figure 5. Environment layers in which a design team works.

often inexplicable decision-making takes place, not because of lack of skills but for lack of any formalized way to do it better.

The width of the triangle at any given level crudely indicates the number of people involved. It is interesting to note that as little as one person at the top can decide how the many people below use their resources and skills; large groups of designers are involved in taking the ideas of a few to fruition. A designer generally has little influence over the top-level needs and has to work within given requirements.

The second model, Figure 5, shows how the design team works within a multilayered set of quite different environments. For overall success, a project must make allowances for the nature of the limitations and controlling factors that exist for the type of enterprise in which the design team works. These issues vary greatly. For example, a private organization does not have to disclose as much information about its processes to the public as does a government institution. To get on top of many problematic issues, it pays to appreciate the higher layer affairs that are impacting on a design's situation.

The third model given in Figure 6, after Boulding (1956), assists appreciation of the classes of types of system design that can arise. It helps a designer identify what kind of difficulties the design team might expect to encounter.

This model is based on mapping the various kinds of systems that exist onto a modeling space represented by two variables – the degree of disagreement on systems

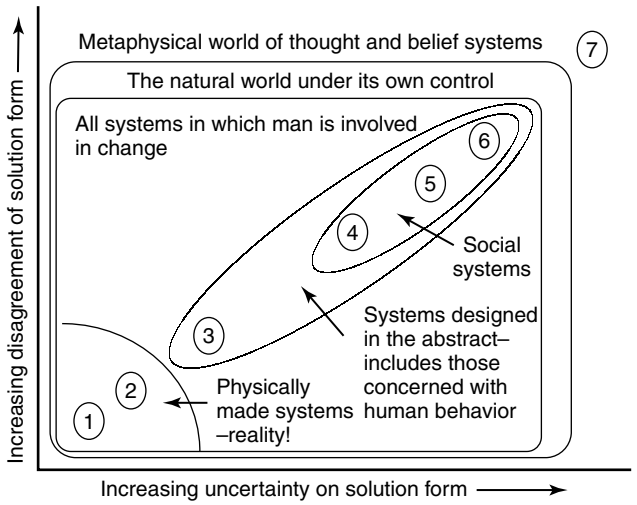

Figure 6. Diagrammatic representation of a hierarchical classification of systems.

issues that exist versus the degree of uncertainty of their characteristics.

The types of systems shown in the diagram are

1. straightforward technical design tasks that inherit considerable know-how and have low risk in execution if done by experienced experts;
   (Examples: simple road bridge; electronic amplifier board; weighing platform)
2. technical tasks with a modest degree of design change, thus including a clear degree of risk;

(Examples: original network for 3G mobile phones; major automobile model change with advancing functionality such as moving to all-wheel drive from dual wheel drive, measuring instrument using novel principle of detection)

3. engineering systems involving considerable human control and intervention in their operation, but not so much in the overall organization;
   (Examples: production line manufacturing systems instrumentation; transport systems)
4. systems where their major subsystems components are associated heavily with human organization; here engineering risk issues are low compared with the risks of understanding the human behavioral aspects;
   (Examples: building detection and evacuation systems; flight control systems; educational support systems)
5. systems where human attitude is dominant and largely unpredictable;
   (Examples: change management taking place in a factory; speed control on roads; engendering professionalism. Improving the quality of the design of measuring systems)
6. systems that are as complex as man thinks he can build and so often attempts to make;
   (Examples: fighting wars, peace making, societal policy systems. Government's economic measurement models.)
7. systems that can only yet be represented by abstraction in the thinking world of science fiction and theology. (Examples: Utopian worlds; Godlike abilities of design.)

As the risks rise and the systems nature becomes more problematic, it becomes increasingly impossible to be certain about numerous critical systems issues. Those involved are increasingly unable to agree on what kind of solution to use. Without clear definition of the critical issues it is problematic for a sound engineering solution to be achieved – *see* **Article 3, Measures and Metrics; Their Application, Volume 1**.

Most commercial projects sit in the lower two classes of 1 and 2 because they tend to exploit proven technologies and because they need to work in relatively low-risk areas.

The measuring system engineering detail design team is usually working, by necessity of delivering a reliable and low-risk outcome, in the high-certainty and low-disagreement area with respect to their design solutions.

However, they can sometimes get involved in the execution of tasks in many of the classes shown. As the magnitude of the position number increases, the detail engineering design component becomes of lesser importance compared with execution of the whole as it, in itself, is unable to provide solutions to the problems.

It is important to be able to recognize the class of system in which a design task is working; the surrounding climate of thinking can make a large impact on progress and on the type of solutions that will be accepted.

5 INTRODUCTION TO THE 5-LAYER SYSTEMS ENGINEERING MODEL

The various holistic levels of a project task have been identified by Hitchins and are reproduced here from his Web site www.hitchins.net, where it is free to download.

Overall human system endeavors fit into levels as follows:-

Level 5: Socioeconomic Engineering, what constitutes regulation and government control at national and international operation.

Level 4: Industrial Systems Engineering, or engineering of complete supply chains/circles. Many industries make a socioeconomic system. A global wealth creation philosophy.

Level 3: Business Systems Engineering – many businesses make an industry. At this level, systems engineering seeks to optimize performance somewhat independent of other businesses.

Level 2: Project or System Level – many projects make a business. Western engineer managers operate at this level, principally making complex artifacts.

Level 1: Product Level – many products make a system. The tangible artifact level. Many engineers and their institutions consider this to be the only 'real' systems engineering

The design of measuring systems is most likely to fit into Levels 1 and 2. Detail of the factors of each of the layers, provided on the Hitchins Web site, provide appreciation of the kind of problems, and thus the boundary limits that a particular development needs to consider.

6 LIFE CYCLE CONCEPT

The popular way to provide a representational foundation for systems development uses the system life cycle model. Development and use of all product or service systems follow the same generic sequence of life cycle activity stages.

While various specific expressions of this life cycle exist they follow the generic one illustrated in Figure 7. The phases (stages) are the following:

- conceptual formation of ways in which the task might be solved;

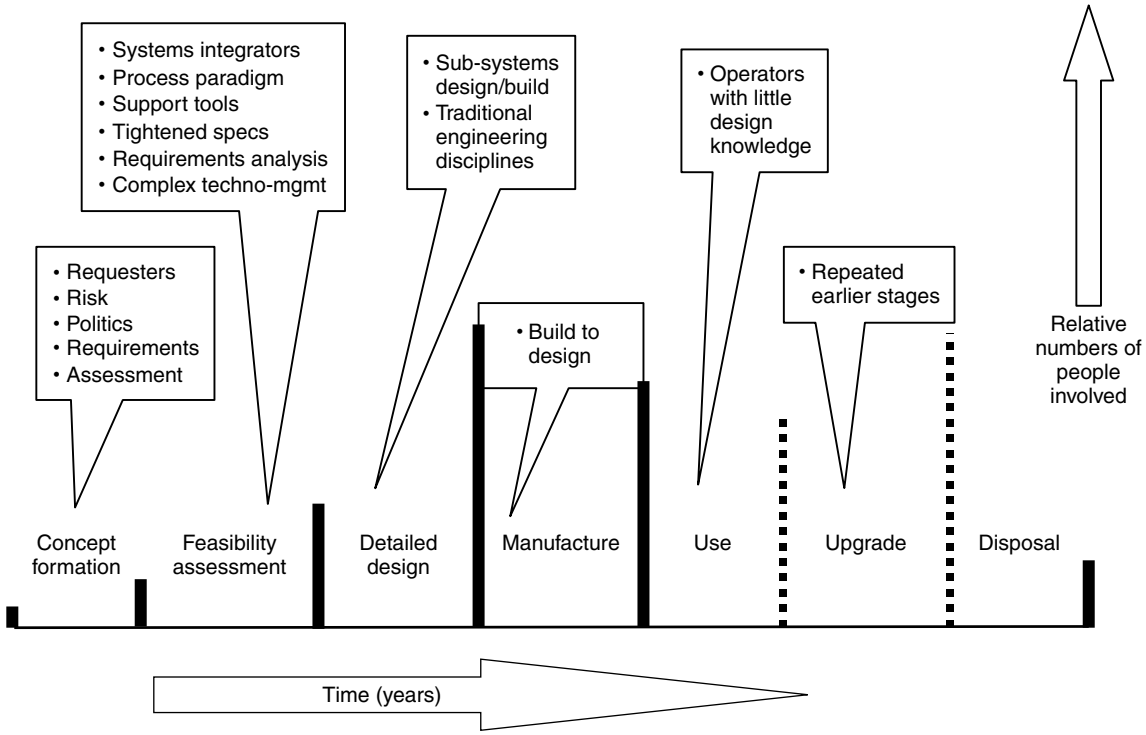

Figure 7. Life cycle stages of a product or service development.

- feasibility assessment of selected, apparently sound, design ideas;
- detailed design of the component parts of the chosen design;
- manufacture of the real system based on detailed engineering design, using physical or digital model prototypes to prove the design;
- use in the application for which the system was designed;
- upgraded for further use with improved or different requirements;
- disposal after use, to follow regulations, and so on.

Good design and effective application of systems thinking are key issues within the tasks of all of the stages. Each is not a stand-alone stage and all need some level of consideration from commencement of a project. To appreciate the differences consult **Article 66, Phases of System Life Cycle, Volume 2** and **Article 65, Life Cycle Concept, Volume 2**.

7 EMERGENT PROPERTIES

Parts of the whole will have their own important 'emergent properties'. These are key performance parameters that may, or often may not, have been expected as the result of implementation.

They can exert a great influence on the other systems with which they interface. Unexpected, nonbeneficial, emergent properties can become very apparent once the system is nearing, or after being put into service.

For example, it might have been decided to use a microminiature wireless telemetry system to communicate temperature data from inside the flying suit of a pilot, only to find after commissioning that it causes the flight navigation system to be inaccurate. Today, this is an obvious design factor to expect, but that was not always the case or we would not have to turn off mobile phones in hospitals and in aircraft.

8 SYSTEMS OF SYSTEMS

As man has learned how better to organize and design technical systems they have grown in size to an enormous extent. Many of today's major man-made systems have evolved by progressively combining systems to form very large conglomerates.

For example, the first railway system in Britain created emergent requirements for engine water and fuel supply depots, spare parts provision, hotels en route, signaling, track rules, special tools for making parts, training schemes, and so on. What might have been overlooked as it was developed was the effect it would have on the existing water

canal transport system that it replaced, and the impact it would have on the nature of the industrial revolution taking place at that time.

In recent years, such complex and extensive systems were seen to be too large to be considered as suited to the usual methods of management and design. The name Systems of Systems (SoS) has been coined for such systems.

A main driver for SoS developments has been in defense systems. These evolved as the following:

- First there existed the personal weapon system.
- Then came team use of weapons combining the various forms of firepower with behind the lines support logistics and intelligence inputs.
- This was followed by many kinds of platforms combined with the necessary command and control needed in a campaign structure.

The sophistication and number of cooperating systems has continuously increased in defense, civilian commercial, and government systems, and in the search for solutions to societal and humanitarian problems.

It became obvious that the former paradigm of first building general utility platforms (the ship, the airframe, the armored vehicle, etc.) on which are then mounted control and command systems, weapons, and other systems, all as separate entities, was inadequate. It needed the SoS approach. Similar thinking is essential in such systems as civil aircraft control systems that now span countries, and in integrated power grid operations.

So, what are the differences between Systems Thinking and SoS thinking? This is a matter of degree. SoS is an extension of general holistic considerations and has the following characteristics:

- High complexity comprising relatively independent systems that can each be regarded as a sophisticated system in its own right
- Continuously evolving as the emergent properties of each system interact
- No obvious start or end-point goals for their existence
- Parts are often geographically distributed
- Viewed as a set of interacting, separate, systems
- Component systems retain much of their independence, pursue their own goals, and have independent management
- Systems Engineering activity is dispersed and loosely controlled
- Understanding the behavior of constituent systems needs transdisciplinary (each is learning from the other) approaches, not just multidisciplinary approaches (each does its own thing usually with an insufficient number of disciplines)
- Measuring systems are unlikely to form into SoS units in their own right but their common nature and universal methodologies will be used across those systems comprising an SoS assembly.

9 APPLICATION OF SYSTEMS THINKING TO MEASUREMENT SYSTEMS DESIGN

Applying the systems thinking culture is a case of 'being a specialist at being a generalist'.

When a design team is part of a large systems provider house, a person will usually be appointed who is responsible for organizing the systems support for all teams. In such situations, teams usually will be provided with the following:

- a company specific SE Process Manual;
- a computer-based support tool system and support tutors;
- special development facilities as are needed according to the project;
- sound archiving and communications for design records and the configuration management system;
- safety control process;
- design controls;
- sources of advice and mentoring for junior staff;
- in-house training and more.

As a guide, design team leaders need to be familiar with the basics of systems thinking and the culture of systems engineering. They need to have on hand copies of foundational books on SE practice such as Blanchard and Fabrycky (1998), Sage and Rouse (1999), Sydenham (2004) and they need to refer to these for concepts and methods to employ as project problems arise. A sound source of SE knowledge is found in the general pages, and also in those of the technical committees, of the International Council on Systems Engineering, INCOSE (2004).

The US DOD Military Handbook on Systems Engineering MIL-STD-499B, USDoD (2004), although being comparatively old as SE standards go, is still an excellent source of ideas for use at the various stages of the life cycle. Other works giving various views of Systems Engineering are Stevens *et al*. (1998), Buede (2000), Westerman (2001), Faulconbridge and Ryan (2003).

An issue that will arise in the design of measuring systems is how much of the SE process should be carried out when executing the systems engineering for a project. Some design tasks are so small as not to need any ordered process. Some, like that for flight-testing an aircraft where

over 100 000 test points might be set up, will need to adopt the complete best practices of SE.

Overhead costs of an SE support process are not always easy to justify because the benefits of its use are abstract in nature, cover long-term issues, and appear not to produce easily measured value-adding components to a project. For this reason, SE activities are often seen as costly luxuries by those who control the project budget.

They are, however, as important to project success as accounting and management activities in that they assist in

- controlling the final performance obtained;
- providing early detection and control of design error.

Who in their right mind would make a development journey without sound assurances that all design work is on track and that the design is moving forward in the right direction?

The design team leader has to use personal judgment in setting the scale of use when applying the techniques or support mechanisms of SE. A single team comprising a dozen or so staff working in a start-up company will probably not be able to devote the time to writing a dedicated SE manual. They might instead simply align with an SE standard. The team leader in that case, however, still needs to apply SE principles as part of routine technical management. Article **Article 64, Executing A Measuring System Design, Volume 2** moves this discussion on to show how a project should progress.

1 UNDERSTANDING THE WHOLE

Having introduced system thinking in **Article 63, Outline of Systems Thinking, Volume 2**, it will be clear that a sound design of a measuring system begins with a general appreciation of many system issues before a commitment is made to firm design parameters.

Obviously, the main aim of a design exercise is to produce a system that satisfies the need. Getting to that state needs systematic activities that drill down from the top of the situation.

The whole process will pass through several life-cycle stages such as

- formation of some suitable solution concepts
- assessment of two or three likely candidate concepts
- detailed design of the chosen concept that has become more defined by now
- manufacture of the measuring system
- installation and commissioning of the system
- operation by obtaining the desired measurements
- removal from service when useful life has expired.

The first step is to obtain a sound briefing of the need from the customer or their representative. Sounds easy! Customers are not always experienced enough in stating a need in terms that clearly lead to design parameters. Do not expect a swift resolution of this issue. Usually it requires a lot of patience as both the designer and the customer undergo a joint learning process. Development of the requirement is a journey of discovery; more on that later.

It is very important to glean as much as possible about the need and its influencing factors as the starting point to success.

Issues to be explored are

- the overall statement of customer need, in customer's terms;
- purposeful requirement – what capability is to be fulfilled;
- operational requirements – how well, and in what circumstances it is to be operated;
- the extent of the limits of influencing issues in the technical, social, and legal arenas;
- the key critical issues that were introduced in **Article 3, Measures and Metrics; Their Application, Volume 1**;
- personnel that will operate and maintain the system;
- decide when it is needed.

It is necessary to appreciate the role of the various types of players in the development. Figure 1 shows their relationships as the project progresses.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

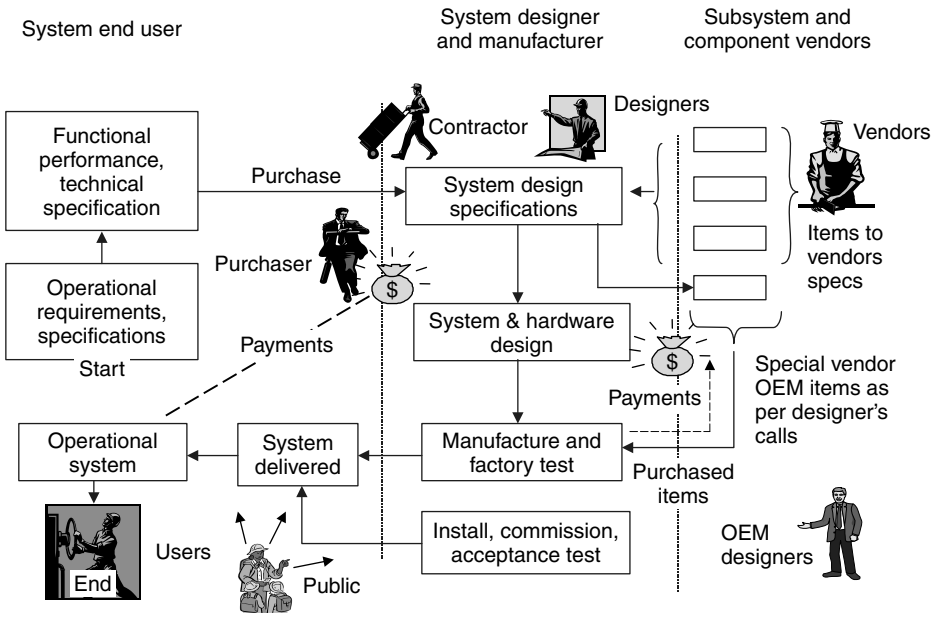

Figure 1. Role of the various players in a system development.

Each player – customers, users, designers, contractors, vendors and the public – has different reasons for participating. Their incentives are different, and the designer needs to appreciate these differences, Sydenham (2004).

2 CLOSED-SYSTEMS DESIGN

Begin with a general assessment of the type of design situation, using the tenets of Systems Thinking given in **Article 63, Outline of Systems Thinking, Volume 2**. Ask the following questions and reflect on the findings.

- Is it going to easily lead to a closed-system design?
- What is the level of system in the layered Boulding model given in **Article 63, Outline of Systems Thinking, Volume 2**?
- Does the degree of human activity suggest a reductionist approach that will need the use of a Soft System Methodology (SSM), as described in **Article 63, Outline of Systems Thinking, Volume 2**?
- What is the impact of the characteristics of each lifecycle stage? For example, is there a serious disposal problem?
- What is the useful lifetime likely to be and will it need upgrading?

After obtaining an appreciation of these issues, start building an overall contextual systems model of the situation. This will help clarify matters and provide material for briefing others who are associated with the project.

This does not need to be that complex to start with – include just enough detail to portray the overall situation. Figure 2 shows such a model for a measuring system being set up for monitoring an oil refinery system.

Just how the system will finally look is still to be developed. For example, the sensors may well be connected on a circular digital bus instead of the star configuration shown. At this stage, do not rush to start the detailed design; the specifications need to be well developed before that commences.

A good way to develop a concept is to develop a Concept of Operations (ConOps) – *see* **Article 67, Principle of Concept of Operations (ConOps), Volume 2**. This is a case of working through the things that need to be done to achieve the right outcomes for the system in use. Figure 3 shows one developed by Ring (2000) for a program to train systems thinking design engineers.

While this particular ConOps is developed for a system in which humans are the subject, the same rules of development apply for purely physical or mixed systems; apply the main rule – what is it that happens to the flowing entity as it migrates from an input to an output?

At some stage, the overall system architecture becomes clear enough to define the boundary limits of the whole. This can depict the extent to which influencing effects will impact the system, for good or bad. Figure 4 shows such a diagram set up for a temperature measuring system operating in a high hazard situation. The influence parameters that will heavily impact the actual sensor system are defined.

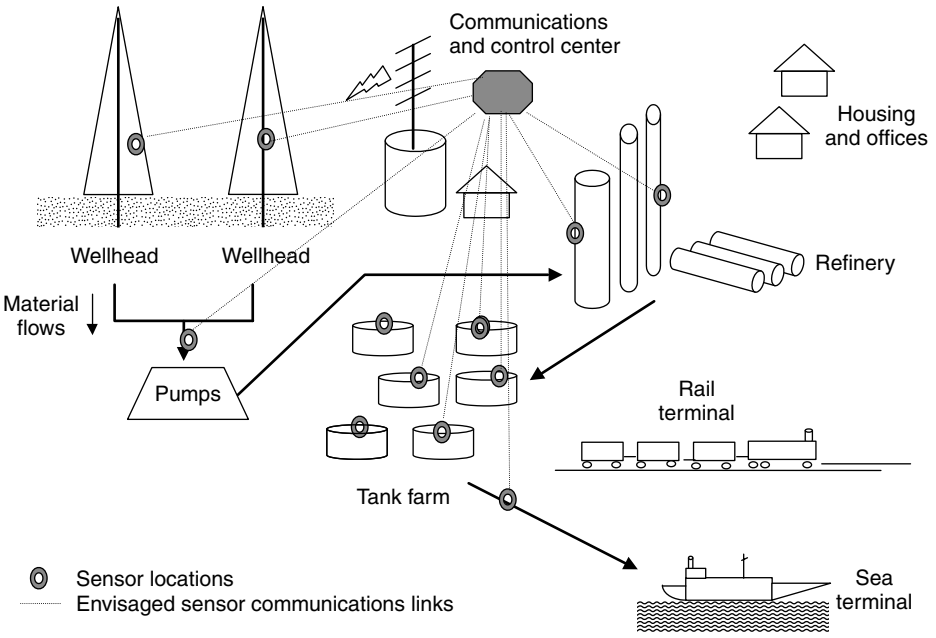

Figure 2. First cut measuring system layout.

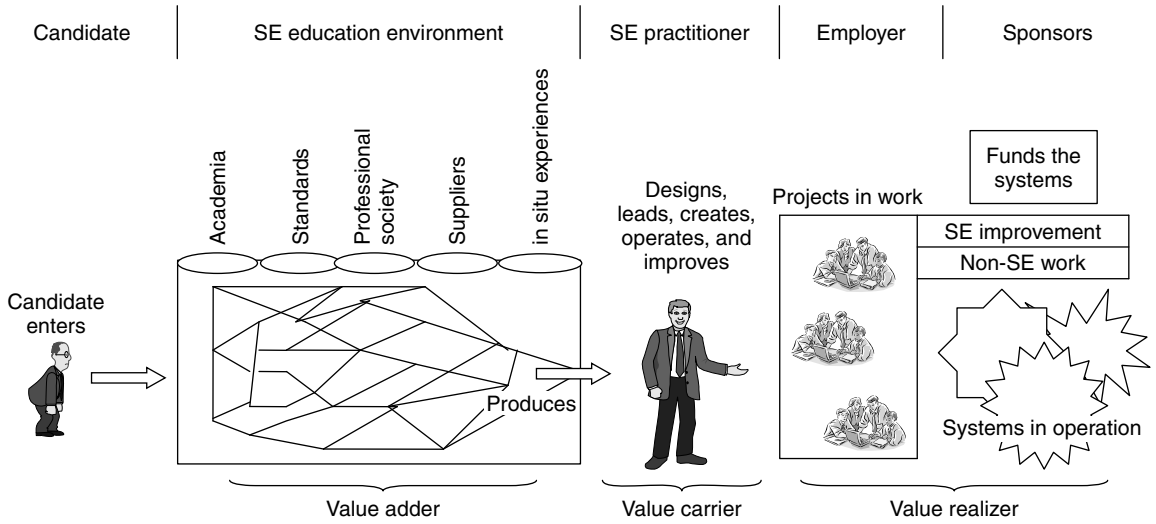

Figure 3. ConOps developed to train engineers.

It is useful to form a matrix of the likely influence parameters as the design proceeds. For each parameter, list the

- parameter name
- effect by which it arises
- likely magnitude, frequency, and phase of the influence signal
- likely effect on the output signal in terms of error
- suggested means for its sufficient reduction.

It will not be possible to fill in all of the details of these various mechanisms until after the requirements have been well established. They, however, need to be understood as the requirements are developed; they settle down as investigation proceeds.

3 THE OPEN-SYSTEM CHALLENGE

If humans are involved, the task can be considerably complex to design. After gaining oversight of the whole system, and its working environment, prepare a list recording where human activity is likely to be needed in the construction, installation, operation, and the maintenance of the measuring system.

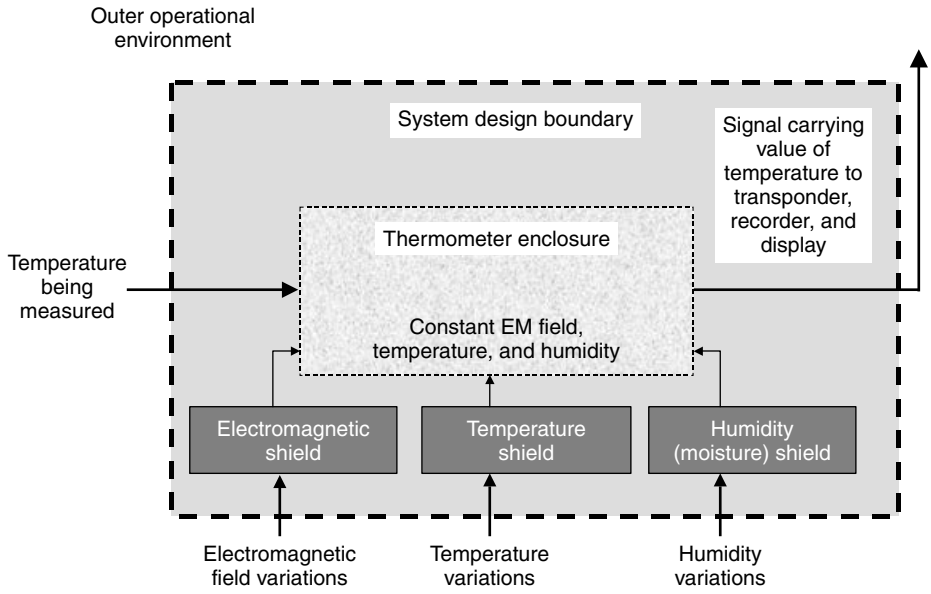

Figure 4. Simple closed-system diagram for a small sensor system.

Each of these human situations will need human factors (HF) consideration – *see* **Article 94, Human Factors Engineering, Volume 2**; **Article 95, Human–Machine Interface, Volume 2**; **Article 96, The Domains of Human Factors Integration, Volume 2**; and **Article 97, Design Methodology, Volume 2**.

Assess whether the situation is suitable for reductionist methods by testing it for the following:

- Is it only concerned with energy or mass flows and not people activities?
- Can a truly closed system be modeled?
- Will *all* elements be able to be modeled with formal models?

If the system boundaries are not clear, then it is of little value to advise the client that the system has no clear-cut solution. The design has to proceed with the fuzzy boundaries that are modeled as best as one can as things progress. Where they are fuzzy, application of the soft systems methodology is suggested – *see* **Article 63, Outline of Systems Thinking, Volume 2**.

Explore how the boundary might be limited to a closed system by employing risk reduction measures, such as reducing human involvement, or by circumventing a difficult area with bypass type of solution.

Areas of design uncertainty must not be ignored as they have a habit of showing up at the wrong time. Also, make sure they are recorded so that they are not overlooked.

To this point, little detailed engineering design has been undertaken, but what to do is becoming clearer.

It will also become clear as to what type of life-cycle development model should be used – *see* **Article 66, Phases of System Life Cycle, Volume 2** for a description of the alternatives. This has to be decided early as it dictates what process is needed to develop the early SE (systems engineering) items and specifications.

4 SPECIFYING THE NEED

If not already familiar with design, this is the time to consider the engineering design process. It has the same elements as the SE life-cycle process but it is expressed as a flowchart of tasks with key feedback paths incorporated – shown in Figure 5 as links back to (1). Detail designers usually view the design process as shown in Figure 5.

There may seem to be too much process management needed, but it is imperative to follow the general thrust of the flowchart or serious design errors can appear late in the process. Design errors are expensive to fix if not picked up early. For example, a resistor in an electronic circuit that does not have a sufficient power rating will be hard to replace once the circuit boards have been manufactured, for the following reasons:

- too little space is then available for the larger packaging needed;
- there may be overheating of adjacent components;
- a board change will be needed that entails removal from service, freight, replacement, and testing cost.

To change the design at the early design stage, the cost will be as little as a dollar, but once in service, it shoots up to hundreds/thousands of dollars if it gets to the recall situation.

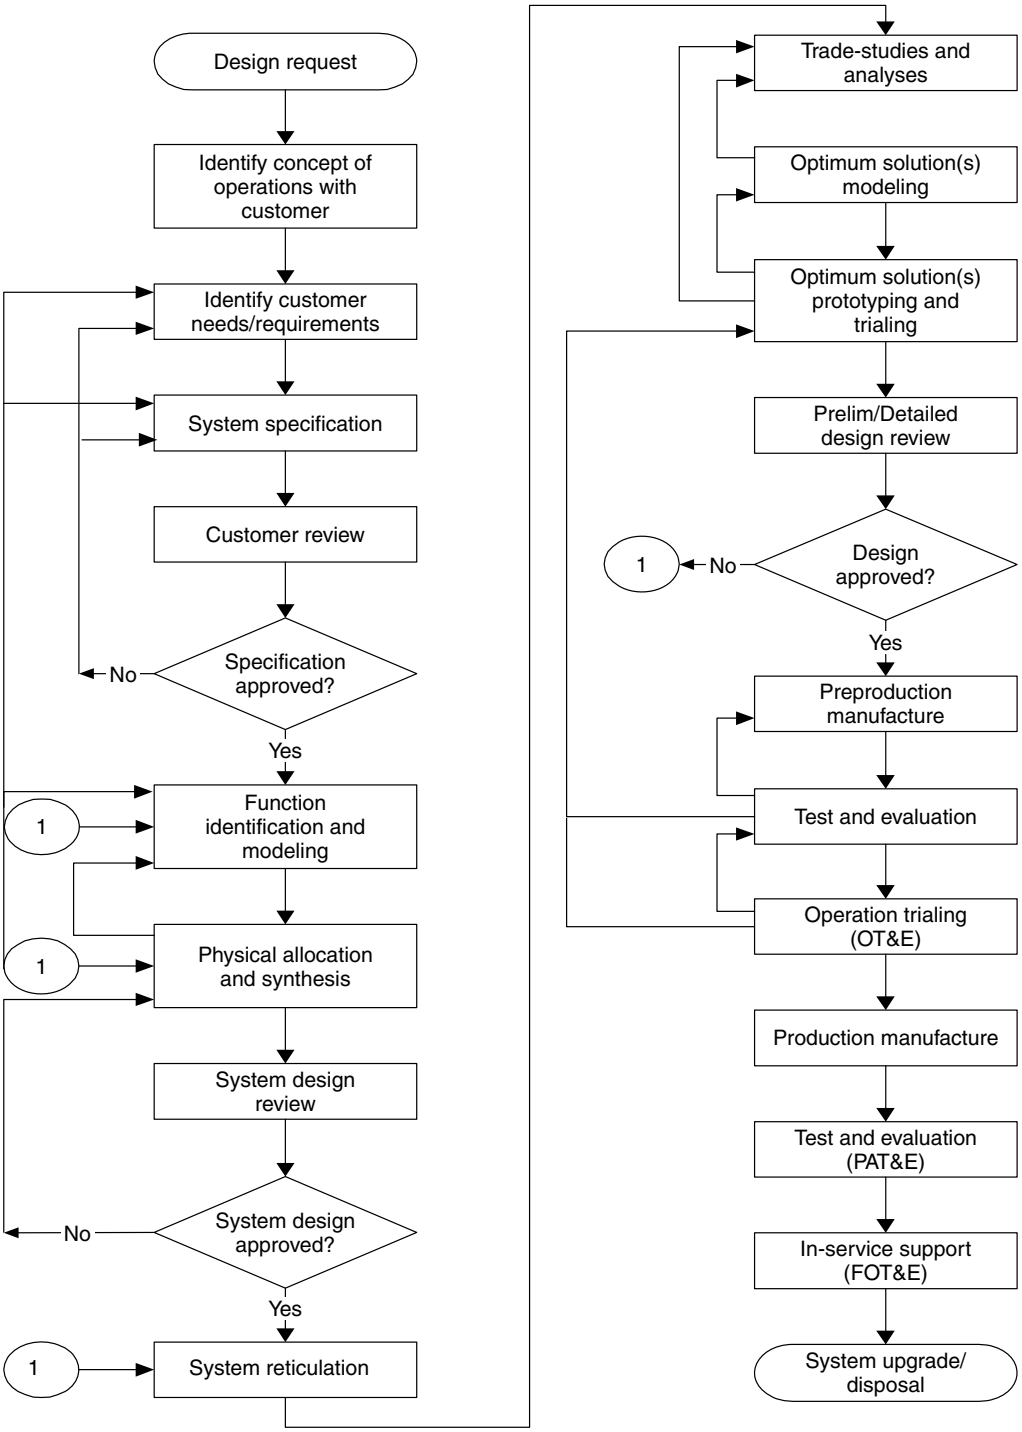

Figure 5. Flowchart of the design process (Courtesy: Tim Welburn).

Getting a design 'right' requires considerable effort in the early phases of the life cycle. As a guide, considerable design resource should be placed into this front-end loading (FEL). Figure 6 indicates the differences in FEL.

The area under the curve is an indication of total cost. It will be seen that while the large FEL at the start seems to have more resources than needed – at least that is too often the perception of senior managers – the total is less overall.

There is little doubt that allocating the right level of FEL expenditure is a wise move; but there are many forces at work against proper allocation.

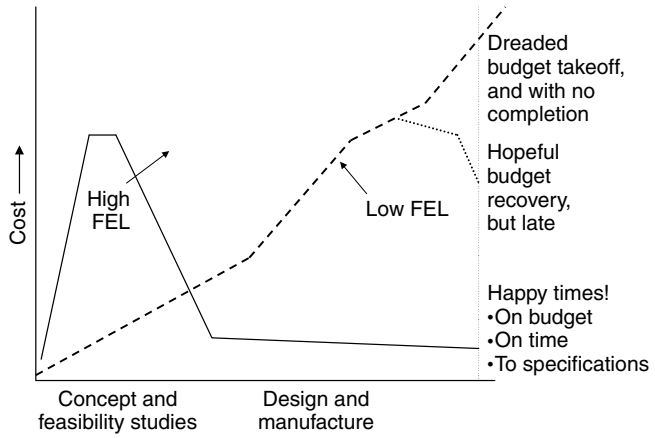

Figure 6. Effects of different FEL in project outcomes.

The first difficulty is that most situations are operating in a fixed financial supply climate. This means, overall, managers will tend to opt for more project starts by cutting the FEL budget on each in order to allocate funds to more new starts. When the project overruns the forecast time and budget expectations, the lack of the earlier FEL budget is not seen as the culprit.

High FEL can be interpreted by some as a luxury situation wherein designers will waste the funding by doing too many unnecessary things, at too slow a pace. If the senior managers have little faith in use of high FEL, they will probably also feel that they are not keeping back sufficient funds to fix the system errors that always seem to arise in projects around delivery time – a circular argument that leads to failure all too often. Early planning is needed to avoid the risk of late errors.

5 REQUIREMENTS GENERATION

Determining a sound set of specifications is one early task that needs appropriate resources. The requirements extraction activity generates the inputs for System Specifications, which in turn, establishes design requirements.

Establishing the set of requirements for a project needs patience, understanding, and experience. It can take a considerable time to assemble a sound set of issues that characterize the customer's need. They must be set up carefully and completely.

This section can only give an introduction; more detail is found in several texts and standards on the topic and in numerous published papers and standards documents such as IEEE (1993), Sage and Rouse (1999), Bray (2002), Hull, Jackson and Dick (2002), INCOSE (2004), and Sydenham (2004).

Requirements need to cover much more than the operational task that the measuring system has to meet.

Need should be based on real deficiencies, that is,

- the current system is inadequate, is
- unavailable or unsupportable, or is
- too costly to operate.

The statement of need should be presented in specific qualitative and quantitative terms, as sufficient detail is provided to allow the systems engineering process to proceed in functional terms.

Requirements extraction is just that – extraction of hopefully 'hard' objective detail from what is initially often quite abstract thinking. It is usually necessary to provide assistance to the customer to transform the initial expressions of need into the format and knowledge content needed to later flow down tasks to the detailed engineering activity stage.

Customers are not often experts at this task and would not have usually approached it by establishing their need on well-structured lines that suit those who follow. To get a project approved, they would have been working in a different direction to the designer's need, perhaps coming up, instead, with a business plan or budget bid that makes its case differently to the needs of requirement extraction.

Requirements extraction starts with the formulation of the key factors – often called the *Critical Issues* (CIs) – via a process of discovery, Sage and Rouse (1999). A representation of the steps of the complete development process is given in Figure 7.

Although the customer will usually provide a written needs statement, it is the contractor that prepares the first requirements list. This developing document needs to be regularly checked with the customer to ensure whether this is what is needed. In this activity, it is important to ascertain that the customer is doing a sound job of verifying suggestions; they may well be distracted by other more urgent internal matters.

Always keep in mind that this is a most critical step in the life-cycle process; this is where directions of effort of many people are decided.

A client needs a system that

- provides operational capability, that is, does the right task;
- possesses adequate operational suitability, that is, does the above tasks when needed, for as long as needed;
- meets certain cost conditions for ownership and ongoing operation;
- fits within a host of legally required environmental conditions;
- meets appropriate health and safety regulations.

To provide this large list of 'must haves', it is necessary to tease out a long set of requirements. A sound way to

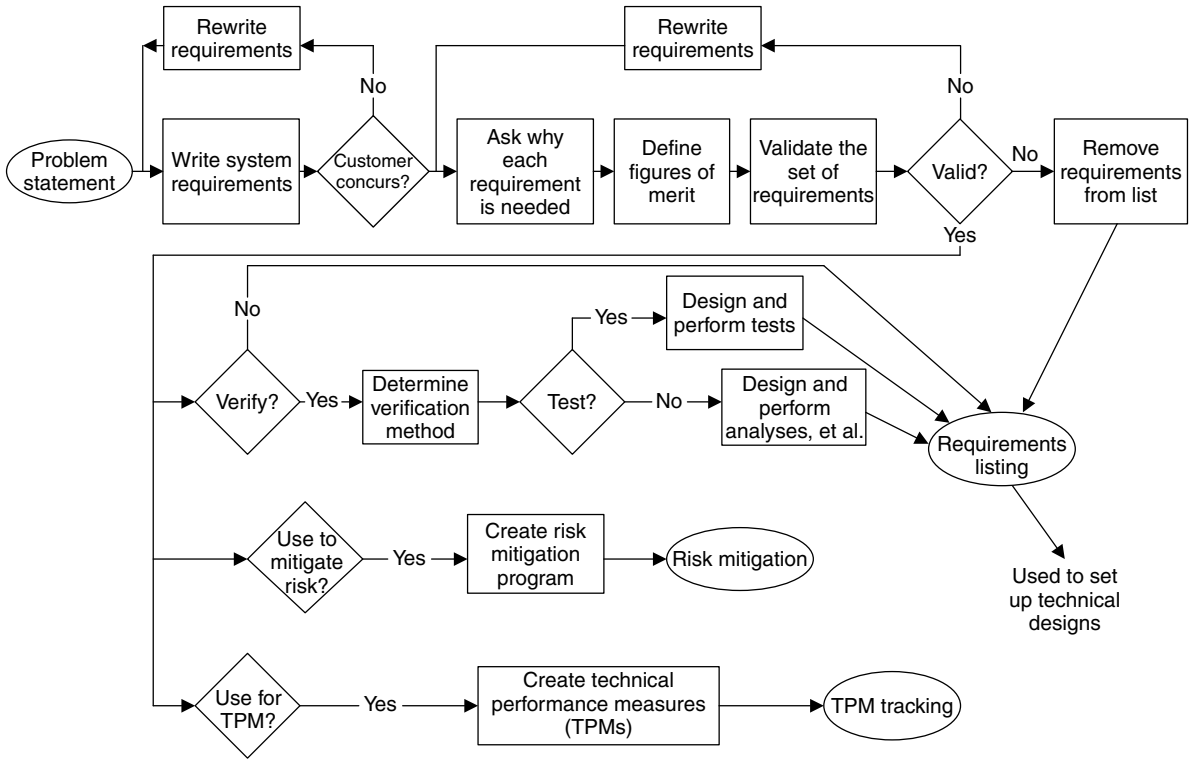

Figure 7. Requirements development process. (Reproduced from *Handbook of Systems Engineering and Management*, Sage and Rouse, Copyright © (1999), Reprinted with permission of John Wiley & Sons, Inc.)

get started is to generate an operational concept or ConOps document for the project, as is discussed in Section 2.

After becoming familiar with every statement about the project that is then available, the next step is to explore the nature of the problem to be serviced. Key issues to address are as follows:

- Why is this measuring system needed?
- What role does it fulfill?
- Is it a new system with few precedents or is it an updated copy needed to give the customer a place in a market or to suit an enhanced operation?
- How does it provide for that need?
- Is it that a major activity will be needed to push forward the technical edge?
- Is it a new innovative use of existing largely proven technology, such as a new-generation digital measurement and control system?

Differences realized here will highlight many requirements issues. This is also the time to make a short study of the type of system needed in terms of its hierarchical and organizational natures as discussed in **Article 63, Outline of Systems Thinking, Volume 2**. The kind of development it will be will then emerge, revealing the generic kind of engineering solutions that might be applicable.

This activity is looking for directions as well as for specific engineering needs. Engineering design must start into its detail only when the needs and constraints are adequately appreciated. It should not leap off with a specific solution at this early stage, but be top-down driven from a sound requirements extraction.

A situation assessment should be developed. General approaches to apply here are as follows:

- What should it be?
- What are the factors that matter over time?
- What to do and how to do it?

An important aim of requirements development is to lead to the recommendation of some candidate solutions. The most likely approaches need their performance, effectiveness, maintenance, and logistic support to be made clear.

This critical identification step is all too often jumped into using ‘intuition’ alone to start an investigation of requirements. This may well start to motivate the mind, but its outcomes must be followed up with analytical assessment of the findings.

It will not be feasible to address every issue that is discovered. Concentrate on the Critical Issues (CI); large systems will identify hundreds of CIs. Learn from similar past projects from which many CI definitions and metric units may be reused.

CIs group into four kinds; these have to do with the following:

- Operational task (What is to be done?)
- Suitability (Will it perform when needed?)
- Political, social, legal, and environmental (What are the key constraints?)
- Programmatic ability (How well will the contractor perform in the development?).

Being able to provide adequate operational service when needed is as important for a system design as is making sure that it does the right job. Ability of a system to successfully fulfill its mission objective is highly dependent on the effectiveness of the support infrastructure provided by the design. This is variously called the R&M (*Reliability and Maintenance*), 'ilities' or 'special functions' aspect, Sydenham (2004).

Life-cycle costing could be a major consideration at the requirements extraction stage.

A Maintenance Concept should therefore be developed that leads to a maintenance plan.

Requirements are best prepared as descriptions of the operation of the system under development and do not state any design solutions – they emerge later. Avoid writing any requirement that dictates a technical solution.

Small measuring system projects can maintain a simple hard-copy record of the requirements. However, when the number of individual requirements exceeds a few hundred, it becomes essential to use a computer-based requirements management tool. All these are based on the creation of a tree structure by intelligently generated functional decomposition activities, starting out with the CIs. Caution is needed. As tools allow rapid generation of statements, it is easy for poorly stated requirements to be entered. What happens later depends on these statements being well thought through.

Detailed design should only start after a careful study of the requirements has developed a sound set of requirement statements that have been fully validated with the customer. Pointers on the features of a good requirement have been published, Sage and Rouse (1999) or Sydenham (2004).

6 CONVERSION INTO A SYSTEM DESIGN

With the requirements in place, it is now the right time to put effort into detailed design. Each requirement statement will outline something to be done and what it is to. It will not describe how to achieve it; that is the technical designer's task.

From the requirements statements, the technical specifications (also called *technical requirements*) are identified that say how the design will be approached. Specifications of many kinds are prepared from these.

Many types of specifications are used in a project. Table 1 gives a summary of the essential types that are usually involved in the larger projects. USDoD MIL documents are given as examples as many of them are available for free download. There exist numerous others. The ones to use are those mandated for a project in its SE Plan or elsewhere.

Other kinds of specification are for

- documentation
- installation
- packaging and transport
- standard items
- modified items
- special subcontracts
- incoming inspection
- use of vendor specifications in projects
- service and maintenance
- safety
- security.

The specifications that are to be used in a project are usually designated in the Systems Engineering manual for the project. Clearly, small projects will roll these together, or often not have them! The list does give an idea of the aspects that a design project has to address. Standard specifications are also useful reference works, for they often embody practical methods and workable ways of proceeding.

7 PARTITIONING

As the initial ideas develop for a concept design solution, there arises the need to break down the whole into parts, each of which is then broken down again. This is called *system partitioning*, *box cutting* or *system reticulation*. This activity concerns the physical association of component parts and how their interfacing is done in the real world and in the design meta world.

A single sensor measuring instrument can be simple, its breakdown being into a serial chain of blocks – *see* **Article 71, Modeling Methodology, Volume 2**. In these cases, the partitioning is reasonably obvious.

As the number of subsystems that interface grow, just how they are grouped is crucial.

For example, development of a multiple sensor monitoring system for an agriculture project will involve sensors, processors, communication channels, central processing, maintenance, calibration, training, and spares replacement.

Table 1. Essential types of specifications, Sydenham (2004).

Specification type	Description	Example format
Operational requirements specification	A specification describing the requirements of the proposed system in terms of user needs, its relationship to existing systems or procedures, and the way in which it will be used and maintained.	MIL-STD-498 DI-IPSC-81430 'operational concept description'.
System/subsystem specification	A specification describing the requirements to be satisfied by the system and the methods to be used to verify that the requirements have been satisfied. The SSS is used as the basis for design and verification of the system.	MIL-STD-498 DI-IPSC-81431 'system/subsystem specification'.
Interface requirements specification	A specification describing the requirements associated with a system that defines its interface(s) with other systems. Interface requirements may be defined as part of the SSS or as a stand-alone IRS.	MIL-STD-498 DI-IPSC-81434 'interface requirements specification'.
Subcontract manufacture/quality specification	A specification identifying requirements and standards of workmanship for items of a system supplied by a subcontract agency. Such requirements may be identified in a subcontract Statement of Work (SOW) as part of a contract or the SOW/Contract may refer to the suggested stand-alone specification.	MIL-STD-498 DI-IPSC-81431 'system/subsystem specification', tailored to identify requirements associated with safety, system quality factors, and design and construction as well as other SOW-style clauses associated with the manufacture and quality of items.
Acceptance test specification (subcontractor, factory, field)	A specification identifying the criteria for acceptance of system requirements described in the SSS. The specification may be tailored to address acceptance criteria for requirements verified by a subcontractor, at the facilities of the contractor, prior to delivery to the end customer or in the field (i.e. when the system is delivered to the end customer).	N/A
Installation specification	A specification identifying requirements associated with the installation of the system in its target (end-use) environment.	MIL-STD-498 DI-IPSC-81431 'system/subsystem specification', tailored to identify requirements associated with installation of the system in its end-use environment only.

If the system development is divided to have all sensors being developed as one kind of subsystem and maintenance as another set of activities, there could well be the need to call all sensors in to carry out the maintenance. Alternatively, they could be designed with the sensor and preprocessing, with maintenance being done for each sensor unit. An example of this going wrong was seen in a fighter plane for remote airfield use that needed 20 plus different maintenance kits, each with different training needs. The project folded when the airfield maintenance staff made it clear that such a division could not be supported in the field.

8 INTERFACE DESIGN

A physical interface is where signals, components, or subsystems connect together. The same interface concept applies to software modules. It also applies to design activities wherein the design of an item needs the data of another item's design to be completed and also the data on where the activities of operation link up.

This means a design exercise always progresses with numerous information interfaces. Each one is a high-risk design-error situation.

For example, the design of an aviation electronic amplifier will need to interface with the packaging, weight, power supply, cooling, and shielding designs. The design requirements of all must be satisfied simultaneously.

Practice has shown that in design activity, there will be almost as many interface design links as there are available interfaces, this can be a huge number.

If the many interfaces involved are not well thought through, prohibitive mixes of activities can arise. There was

once a space telescope that was designed in its testing and calibration functions such that it could only be designed and built when the complete system was assembled and the unit placed into a flight simulation chamber. Any thing found to be wrong at that late stage could only be fixed by iteration back to the very roots of the design.

By partitioning the system in different ways, the number of interfaces can be kept to a minimum. Another way to regard this is by seeking a high degree of isolation of design items. There exists a formal way to investigate this using the n^2 matrix method.

For example, in the design of a sensor, it is sound practice to combine the preamp, supply voltage regulation, conversion, and shielding packaging in one unit sending a high-level signal over the communication system.

A poor design situation was one in which a television-set maker used resistors as a support to wind inductor windings with the insulation set up to deliberately incorporate capacitance – very ingenious but hard to troubleshoot as components could not be isolated for testing or even be seen.

9 TEST AND EVALUATION

The three drivers for all systems developments are cost, time, and performance – the CTP factors. Improvements in all three are always necessary. At first sight, optimizing all three together seems to be impossible. Process improvements and improved design support systems have, however, actually improved all of these in many projects.

As projects are always set up using normal business practices, it is reasonable to assume that the control of cost (accounting) and time (project management, PM) will be in place for a project.

Management of performance, however, is often left to the design engineers to implement on an ad hoc informal basis – *see* **Article 3, Measures and Metrics; Their Application, Volume 1** for an overview of the use of measures and metrics.

This general area has been called *Test and Evaluation* (T&E). Too many people think of this only as testing, that is, measuring a Technical Performance Parameter (TPP) without appreciating T&E is really about evaluating the performance of a system as it develops to ensure it delivers the expected performance throughout its life.

Implementation of sound through-life T&E practices can provide ongoing data on the maturation of the system's CIs. These can be used to tell managers, designers, clients, and financiers that the development is moving toward completion on time, within budget, and with the performance required. T&E should be regarded as a whole-of-life process, not just as a set of tests made at strategic times.

The need for T&E is summed up by asking three key questions of a system development to see if they are in place:

- What are the system's development teams trying to achieve?
- How will those concerned know when the performance objectives are reached?
- Who has the responsibility for a satisfactory performance outcome?

A well-run project will not be using testing as an experiment to find out what has been developed but to verify that the performance of the system is where it is expected to be. A 'no-surprises' project situation should be the aim – T&E is a key mechanism to achieve that condition.

As such, the first text on T&E seems to be the one by Stevens (1989). The case for T&E to be given more status in systems development and operation has been well made in Crouch (1992) and Reynolds (1996). There is, however, little other published material on this topic. It is quite surprising to see project after project being done without sound T&E.

Investing more resources in T&E for a project has the potential to prevent cost overruns and failed systems. Unfortunately, all too often, the T&E budget component is the first to be pruned when overruns arise.

T&E is often practiced in an ad hoc informal manner as a band-aid activity to find out things when a project is not going well. In this form, it has the following deleterious features:

- No adequate traceable or recorded control process exists.
- Success relies on the various designers' abilities to know when and what to test, after which they often have no adequate records addressing the three T&E questions given above.
- There is a real chance that the system elements that the various design teams are developing will not integrate without considerable rework. This situation can arise, not because of lack of competency in performing a good detail design but by simply designing the wrong thing.
- Omitting the overhead of planned T&E activity can indeed save short-term cost. Doing this, however, can increase the risk of not obtaining final success. T&E expenditure can save wasteful rework later by detecting early design errors.
- Last-minute decisions are often made on what to test. This can lead to poor testing as the materials and equipments, not being planned ahead, are often not available.

- There exists too much flexibility in setting up tests and in how to process the data for evaluation purposes. This leaves things very open for biased tests to be implemented to obtain an apparently satisfactory result.

An important thing to recognize is the need to plan T&E activity from the commencement of a project, not at the end of a development stage. A suggested methodology for implementing T&E is given in Sydenham (2004). A T&E Master Plan is essential. This outlines the what, how, and when of the T&E activities to be done.

Three main planning needs of a successful T&E program are as follows:

- Ensuring that scarce test resources efficiently address the project's CIs. Every possible system parameter cannot be tested, there are far too many of them.
- Ensuring that those that need to know can observe how well the CIs are maturing according to well thought through expectations.
- Providing information on the plan and its maturity to all who need to know about these issues. For example, those who plan the use of test resources need considerable lead time for organizing availability of test objects, observers, test equipment, test suite programming, and so on.

As development moves through its stages, the CI determinations should, by tight design control, gradually trend toward the target value, with their uncertainties reducing to acceptable values by the required time.

With such a system available, the project managers and design team leaders can see how the CIs are maturing toward their goals. Time trend graphs can show the current state of performance maturity compared with the target value. Severe deviations can then be given more design attention to bring a particular CI back on track. An openly observable system such as this also exposes errors early, where it can be less expensively corrected with less impact on the careers of the staff.

10 APPLYING SE TO A PROJECT

When a measuring system design team is working within a large systems provider house, there will be a person responsible for organizing systems engineering support for all teams. In such situations, teams usually will be provided with a

- company-specific SE process manual
- computer-based support tool system and support mentors
- special development facilities as are needed according to the project
- sound communications
- effective design records archiving
- configuration management system
- safety control process
- design controls
- sources of advice and mentoring for junior staff
- in-house training
- key documents library.

As a guide, design team leaders need to be familiar with the basics of systems thinking and the culture of systems engineering. They need to have at hand copies of foundational books and standards on SE practice and refer to these for concepts and methods to employ as project problems arise.

Finally, when executing SE and T&E practices for a project, there is the question of 'how much is enough'.

Overhead costs of a support process are hard to justify when the results of that process are of an abstract nature, cover long-term issues, and do not appear to produce easily measured value-adding components to a project. SE and T&E activities are often seen like this – as costly luxuries. They are, however, as important to success as are accounting and project management in that they also assist early detection and control of design error. Who in their right mind would make a major development journey without sound assurances that all design work is on track and moving the design forward is in the right direction at the right speed and within budget?

The design team leader has to use personal judgment in setting the scale of use when applying these techniques or support mechanisms. A single team comprising a dozen or so staff working in a start-up company will probably not be able to devote the time to writing an SE manual. They might instead simply align with an SE standard. The team leader in that case, however, still needs to apply SE principles as part of routine technical management. It is a matter of judgment. First, you need to know what is at stake, then, what tools are available to assist, and then to have the experience to reflect on what to do.

1 CONCEPT OF THE LIFE CYCLE OF A SYSTEM

The life of a system is modeled by its *life cycle*. In the case of engineered systems, systems that are built using the principles of engineering, the word life cycle is synonymous with *process model*, and it refers to the processes by which the system is conceived, specified, designed, built, deployed, and retired. We will see that life cycles may be quite generic, or quite detailed. A detailed life cycle is shown in Figure 1 for an arbitrary large, complex system. Use is also made of other life cycle models, *see* **Article 66, Phases of System Life Cycle, Volume 2**.

Everything that is divisible into parts can be considered to be a system. It is often said of systems that *'the whole is greater than the sum of its parts'*. This means that there are attributes or properties of the whole that did not exist or that were not manifest in the collection of parts from which the system was assembled. These attributes may be properties of the structure, function, or purpose of the system. Such attributes are called *emergent properties* of the system. It is the study of emergent properties of systems that is the principal subject of *systems engineering*.

Emergent properties of systems, when they are sufficiently well understood and properly managed, provide both solutions and constraints that directly influence designs. On the other hand, unanticipated emergent properties can cause products to fail to meet structural, functional, or purposeful requirements of the system. It is well known that system defects, which require rework of the product specifications, are much less costly to correct when the problems are anticipated – detected and corrected early – rather than later in the design after the product system, and perhaps the production and delivery systems, systems developed to enable the production and delivery of the product as well, have already been built.

The development of a system has both a positive and a negative aspect. In the negative sense, it is in the nature of engineering a system that every design decision, beginning with the development of the initial concept, forecloses options for the structure, function, and purpose of the product. A poorly considered decision early in the design could, in theory, eliminate excellent design alternatives before they are ever considered. Engineering a system is *subtractive – each decision subtracts the options not selected from the total option space* – when viewed in this way, since every decision reduces the size of the option space. The positive aspect will be discussed in the next section.

2 THE SERIAL NATURE OF THE LIFE CYCLE

In the previous section, it was noted that the development of a system has both a positive and a negative aspect;

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

DEFINITION

1. Elicitation of requirements
2. Classification of requirements
3. Analysis of requirements
4. Prototyping of requirements
5. Requirements documentation and specification
6. Preparation of transition documents: request for proposal and a proposal, containing a statements of work, a systems engineering management plan, a work breakdown structure, and negotiated list of other deliverables

DEVELOPMENT

1. Creation of a system architecture and an organizational structure consistent with the system engineering management plan
2. Establishment of configuration control
3. Identification of subsystems
4. Production of subsystem specifications and subsystem test requirements
5. Specification of subsystem components
6. Design of subsystem components
7. Fabrication and testing of hardware components
8. Coding and unit testing of software and firmware components
9. The development of environments and test equipment for hardware testing and scaffolding for software unit testing
10. Integration of components into subsystems
11. Integration testing of each subsystem
12. Validation of the built and tested subsystems
13. Integration of subsystems into a system
14. Integration testing of the system
15. System validation against the system specification
16. Integration test procedures
17. Provide product information to planning & marketing
18. Preparation of transition documents and other aspects of preparing to deliver the system, such as installation materials and procedures, training manuals and special training equipment, maintenance equipment and manuals, and user's guides

DEPLOYMENT

1. Delivery and installation of the system
2. Acceptance testing of the system
3. Operational testing and evaluation of the system
4. System acceptance by the customer
5. Formal maintenance agreement with a contractor that includes a maintenance plan, maintenance test plans, and maintenance test procedures
6. Trade-off study to compare options for continuing to support the business process
7. Decision to decommission the system
8. Provide current system description to requirements team (linkage to new cycle)

Figure 1. A thirty-two step life cycle. (Reproduced from *Handbook of Systems Engineering and Management*, Sage and Rouse, Copyright © (1999), reprinted with permission of John Wiley & Sons, Inc.)

and the negative aspect was explained. In the positive sense, it is also true that each decision opens up a new set of viable options, prompting yet another decision. The sequence of options and decision from concept to product can be represented as a decision tree, which can provide a useful record to support subsequent developmental efforts, provided enough information is captured. Engineering a system is additive when this viewpoint is adopted, since each decision leads to more options, which lead to more decisions, ad infinitum. Neither point of view is altogether correct or incorrect. However, in both cases, the importance of early decision in constraining or creating later decisions is self-evident. For this reason, systems engineering places strong emphasis on the earlier design decisions, those upon which later design decisions are based.

In all this, there is the concept of growth. A given system begins as an embryonic entity: a concept, idea, vision, or the like. Through the repeated application of the process of deciding among options as described above, the system grows in size and maturity, perhaps changing state several times, until the system is realized as a product. The different states may include the mental image, a written concept, a drawing, a prototypephase, subsets of the total development process that are relatively complete, or self-contained, with respect to their structure, function, or purpose.

In broad terms, the simplest life cycle of any system can be described in terms of

- a definition phase,
- a development phase, and
- a deployment phase.

This is referred to as the *DDD* model, shown in Figure 2.

The *DDD* framework facilitates understanding of the resource requirements needed by the system during the various stages of its existence. The *DDD* model is recursive, in that any of the *D*s may be further broken down into steps by application of the *DDD* model to it (Patterson, 1999).

The utility of this approach to engineering a system is found in the ability of the management to treat each phase or subphase as a self-contained project, with discrete inputs and outputs, and with its own schedule and cost profile. As we shall see, the phases are arranged serially, such that the output from any phase represents the starting point for the successor phase; and the input for any phase is provided by its predecessor.

3 LIFE CYCLE VERSUS TEAM WORKING MODEL COMPARISON

It has been pointed out that the systems engineering life cycle provides a simple, useful management tool for estimating, allocating, and accounting for resources during the life of a system. It is an oversimplification to say that phases of the life cycle are self-contained from the standpoint of engineering the total system.

The life cycle concept is a growth model that embodies the concept that early design decisions determine options for later design decisions throughout the life of the system.

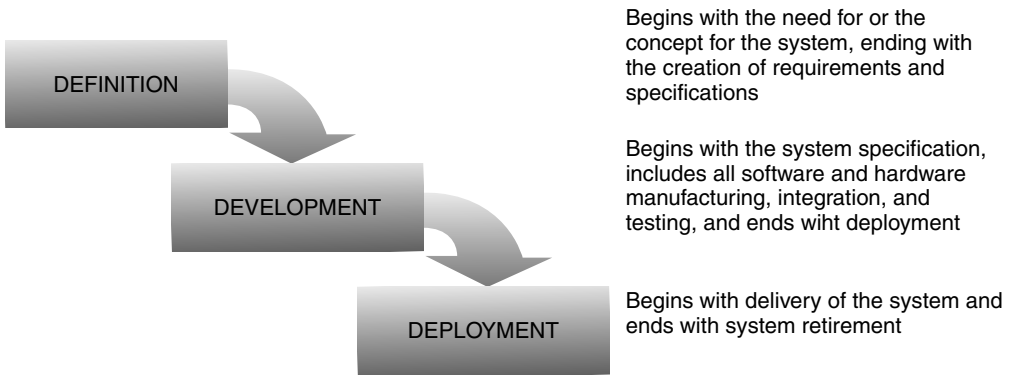

Figure 2. The DDD life cycle. (Reproduced from *Handbook of Systems Engineering and Management*, Sage and Rouse, Copyright © (1999), reprinted with permission of John Wiley & Sons, Inc.)

It follows that no subset, including a life cycle phase, can be entirely self-contained. While it is true that certain very well-defined and well-understood parts of the work effort can be considered to be miniprojects, these parts are always subject not only to verification against a specification, but also to validation in the context of the system of which it is a part.

A common error is to define subsets of the system with nontrivial or poorly defined interfaces to other parts of the system or with insufficient acceptance criteria to ensure the successful validation – testing of the system with the goal of determining whether the customer's expectations have been met – of the miniprojects. It is very difficult, for example, to imagine that one group of engineers can write a set of requirements for a system and deliver the requirements to a different group of engineers for development of a design with the expectation of success. While such an effort may pass a verification test (for example, a design may meet each and every one of a set of written requirements), it is much more difficult to imagine that such a design could be validated against the expected result.

From the standpoint of the engineer, it is much more important to create, communicate, and develop a common vision of the system than it is to attempt to create or to follow a perfect specification. Because documents, drawings, and other design representations have a very low information content relative to the amount of knowledge carried by an engineer who has participated in the design process, various strategies have been proposed to avoid the loss of experience and information through the introduction of new people. Such strategies typically involve the formation of a *system team*, charged with the responsibility of communicating the common vision to the group. The system team remains with the project throughout its lifetime.

Because difficulty of communication varies with the size of a project team and also with the amount of data that one needs to communicate, large teams with large projects

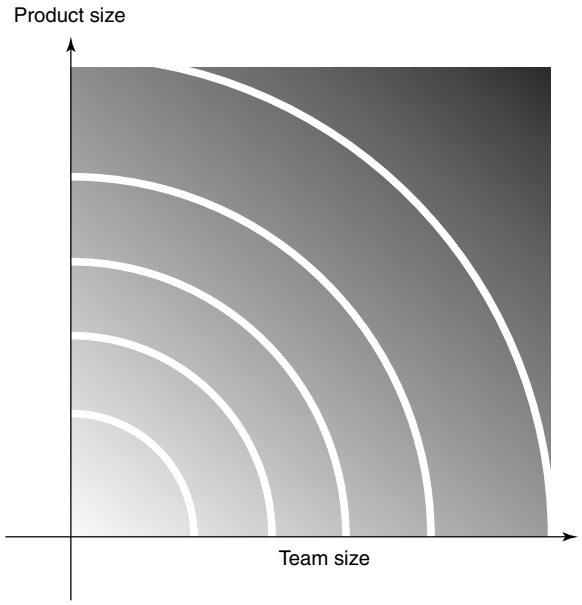

Figure 3. Relationship of project risk to product and team size. (Reproduced from *Handbook of Systems Engineering and Management*, Sage and Rouse, Copyright © (1999), reprinted with permission of John Wiley & Sons, Inc.)

or products experience much more risk – the probability of loss of time, money, or quality – than small teams on small projects. This is depicted in Figure 3, where darker shading indicates more risk.

Organizations organize themselves around processes according to some partition of the enterprise. Their strategic plan is much enhanced by introducing a life cycle model with proven success for the domain. An ad hoc organization will occur – this is the message of Stogdill – if not templated – provided with a structural pattern – especially if the organization is involved in an enterprise with which it is unfamiliar. Introducing the systems engineering life cycle template saves much time and helps to assure success.

4 TYPICAL LIFE CYCLE FOR A MEASUREMENT SYSTEM

The life cycle of a system begins when there is sufficient need to motivate the formation of a concept. The life cycle ends when the system is decommissioned, the *DDD* model can be applied to a measurement system in a very straightforward way. Recursive application of *DDD* yields increasingly detailed descriptions of the activities that compose the effort that is to be managed. It is worth noting here, before discussing the Figure, that the Figure is only a partially complete illustration. The effort required to develop a life cycle that is custom built for the development of system is repaid in many ways. It is a necessary operational framework that needs to be reinvented for each new system development project.

Figure 4 depicts a partially completed life cycle for a generic measurement system, dividing the life cycle into three phases, definition, development, and deployment. At this point, it is appropriate to articulate the expectations for each of these three phases, especially the inputs and outputs.

The input to the definition phase is a need for a particular measurement system that has a well-defined purpose and, perhaps, other success criteria in terms of the structure or function of the system, and any known constraints on the design. The output of this phase is a well-researched and analyzed list of attributes or properties to be measured by some means.

The list of attributes is the input to the development phase, where metrics and measures, which may be qualitative or quantitative, are proposed, validated, and packaged as a metrics framework for use. Thus, the deployment phase can be concerned with using the metrics framework as a tool for actually measuring attribute levels in the data – *see* **Article 3, Measures and Metrics; Their Application, Volume 1**.

In Figure 4, the *DDD* model has been reapplied to each of the three phases to yield subphases as illustrated by the color coding. To further illustrate, the definition subphase of the definition phase has also been refined. This recursive descent into greater levels of detail may be continued until further detail yields no further useful information.

Further information on systems engineering and the life cycle model application is found in the part on '**Part 5, Measuring System Design, Volume 2**'.

1 LIFE CYCLE APPROACH TO THE ENGINEERING OF SYSTEMS

Systems engineering necessarily takes a life cycle approach. It views the end from the beginning and considers carefully everything in between.

1.1 Standards and life cycle variations

The life cycle for each product or system varies according to its function and market. You tailor the life cycle approach to fit the product; a medical device could emphasize the US Food and Drug Administration (FDA) Design Control Guidance, whereas an electric food mixer will focus on manufacturability to reduce final cost.

Standards for specific markets drive the life cycle processes: software for avionics, for instance, requires very closely defined procedures and methods and, in the United States, follow the stringent requirements of the Department of Defense (DoD) DOD-178B standard; military devices might follow, instead, DoD STD 2167; finally, commercial companies often adhere to the International Standards Organisation (ISO) ISO 9000 standard for producing sytems. Each one of these standards has different specific requirements but they all have similarity, if not the exact same terminology, in their phases. These phases are described in detail below.

1.2 Development processes

Development can move through these phases in several different ways. You can use the top-down or waterfall method to layout and build your system (Figure 1); its premise is that the requirements completely specify a design and the development follows precept upon precept. Alternatively, you could build from the bottom up using the prototyping method (Figure 2); you take a basic idea, add some features to it, and try it out. Finally, you can combine the waterfall and prototyping methods into a spiral development (Figure 3) where requirements and development occur incrementally (Fowler, 1996; Sydenham, 2004).

Each stage of the waterfall process, Figure 1, aligns closely with the phases described below. The waterfall process is the original model for life cycle development. It may be the most well understood but it fails to accurately portray most development. It does not account for major changes in requirements without starting over. It assumes that iteration can only happen between adjacent phases of development, which is not typically the case. Problems in one stage, such as manufacturing, may force you to go right back to revisit the requirements and change some of them.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

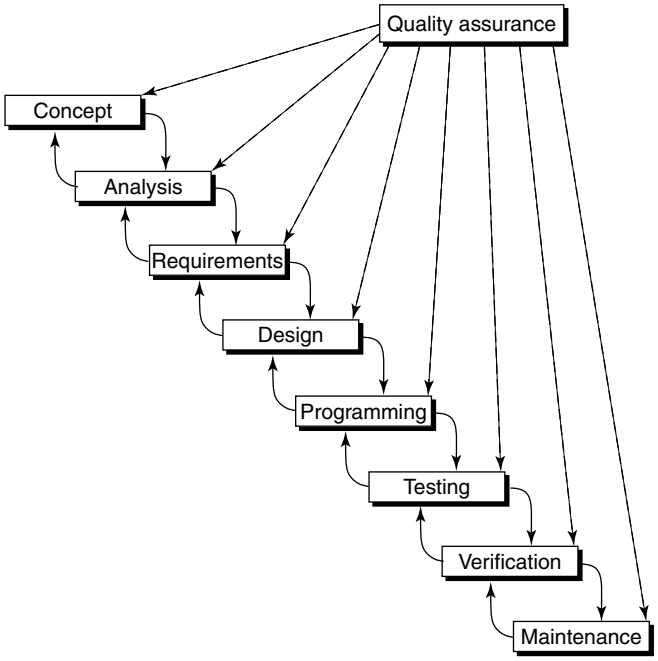

Figure 1. Waterfall method of development. (Reproduced from "Electronic Instrument Design: Architecting for the Life Cycle", Fowler K.R. Copyright (1996) © Oxford University Press.)

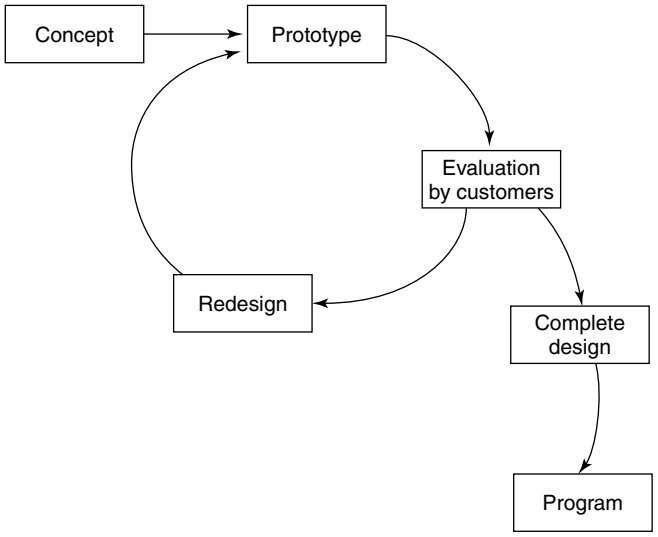

Figure 2. Prototyping model of development. (Reproduced from "Electronic Instrument Design: Architecting for the Life Cycle", Fowler K.R. Copyright (1996) © Oxford University Press.)

The prototyping method, Figure 2, often suffices for proving a concept, but it does not have the rigor to transfer sufficient information and knowledge for manufacturing and deployment. Its utility resides in one-of-a-kind systems and custom development.

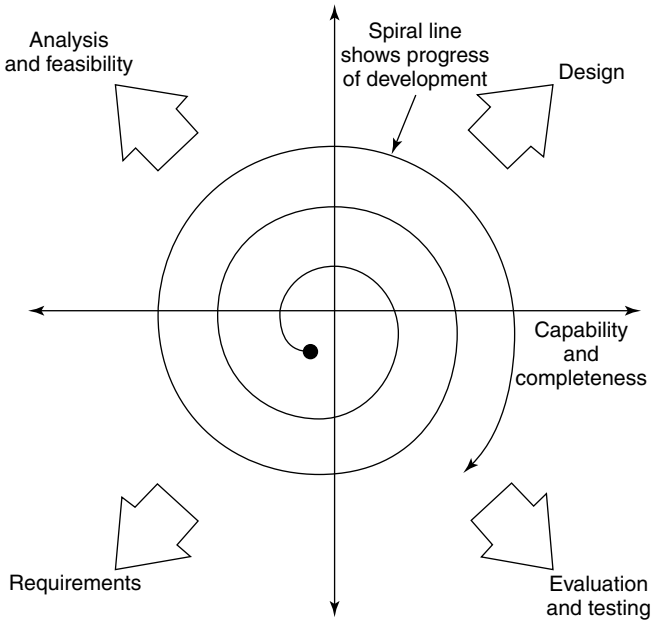

Figure 3. Spiral model of development. (Reproduced from "Electronic Instrument Design: Architecting for the Life Cycle", Fowler K.R. Copyright (1996) © Oxford University Press.)

Spiral development, Figure 3, evolved from the perceived strengths of the other two methods to supersede their shortcomings. It takes a basic set of requirements and develops a workable system with a reduced set of desired features. This allows you to understand more fully the interactions between critical components and subsystems early in development. You then add more requirements that lead to additional features and proceed around the spiral to integrate, test, and prove greater functionality. It is often favored in software development.

1.3 Judgment

Understanding the principles of systems engineering and applying the appropriate life cycle development are not enough to ensure an optimal solution. These are necessary but not sufficient conditions for success. Most final products are a suboptimal set of compromises and trade-offs; a fighter aircraft, for example, is never a perfect solution – it trades off many concerns, such as threat, mission, speed, maneuverability, range, weapons loads, and reliability. Most products and services of a mature and new kind will be of this nature.

Ultimately, good judgment, based on knowledge, experience, and wisdom – some call it refection – will do the most toward guaranteeing a good result. We can only get there by learning and applying, which means that we need

to risk some elements of failure. Learning should perfect your engineering judgment, and the only way to get there is through experimentation, iteration, and failure. 'No one wants to learn by mistakes, but we cannot learn enough from successes to go beyond the state of the art' (Petroski, 1985).

2 CONCEPT PHASE

The life cycle begins by defining the problem. You have a number of sources for understanding the problem better; they include the following:

- customer objectives (which are not necessarily the users),
- user needs (users are not necessarily the paying customer),
- mission (defines the regions of operation),
- constraints from physical processes and environment,
- government regulations,
- commercial standards.

The real brilliance in setting requirements is to see what people *do*, not what they *say*. Only by doing this can you really understand the true need (Christensen, 1997). People do not necessarily understand the capabilities of technology and innovation, so they do not often express their true needs. They tend to express their desires, clouded as they are with misconceptions and misperceptions. Setting up the need is usually a journey of discovery for both the client and the designer.

2.1 Requirements

Requirements generate the '*what*' to which designers then prepare the detailed descriptions (schematics, source listings) that give the '*how*'. A sizable portion of time is devoted to generating requirements in the Concept Phase. Requirements may include some or all of the following: performance, reliability, maintainability, availability, human factors, safety, fault tolerance, operation regimes, environment, and logistics. *See also* **Article 69, Requirements Allocation, Volume 2**.

2.2 Analysis

After defining the problem, you enter an iterative cyle of analyses to refine the possibilities toward a potential solution. Functional analysis defines basic operations and then breaks them down into successively more detailed functional components. These functional blocks or components eventually specify *who* does *what*, and *when* and *where* they do it. This kind of analysis is much like tracing the roots of a tree down to finer and finer rootlets. It can be an exhaustive but worthwhile exercise to understand all the possibilities and interactions.

Once you define the functional components, you then model the problems and their solutions through mathematical analysis, simulation, and prototyping. Mathematical analysis can be tedious and limited in its efficacy, but it often can give bounds or constraints to the problem and its solution. Simulation provides insight into the interactions between components and allows 'what if' type of studies. Prototyping produces a subset or subscale model that allows indepth studies of functionality without committing to a complete production cycle – *see also* **Article 72, Mathematical Methods of Optimization, Volume 2**. These methods and techniques allow you to characterize the potential solutions, which then enter the feasibility analysis.

Typically, a CoDR or Conceptual Design Review completes this phase of development – *see also* Concept of Operations in **Article 67, Principle of Concept of Operations (ConOps), Volume 2**.

2.3 Feasibility

Feasibility is the evaluation portion that refines the potential solutions. Typically, you will iterate several times through definition and refining requirements, functional analysis, modeling, and feasibility analysis (Figure 4). As a problem grows more complex, the analyses become more detailed and time consuming.

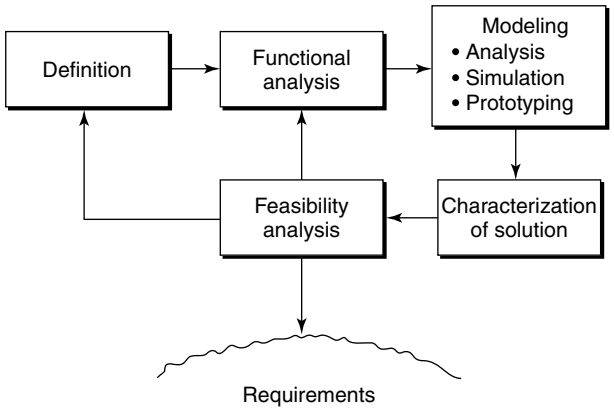

Figure 4. The iterative nature of concept development and feasibility analysis. (Reproduced from "Electronic Instrument Design: Architecting for the Life Cycle", Fowler K.R. Copyright (1996) © Oxford University Press.)

Feasibility has several categories, business, physical, and risk, which can overlap in their outcomes. The business case looks for the best outcome, most likely to maximize revenues or profit. The physical case evaluates whether the proposed solution violates any physical principles and other needs such as safety and legal issues. Finally, risk analysis evaluates the potential problems and margins of tolerance; these can include Fault-Tree Analysis (FTA) and Failure Modes Effects Analysis (FMEA) – *see also* **Article 101, Assessing and Demonstrating Safety, Volume 2**; **Article 100, Safety Analysis Methods, Volume 2**; and **Article 99, Safety Organization, Volume 2**. These two types of risk analysis are complementary. FTA takes each identified potential fault in the system and traces the cause(s) down to the possible originating components or interactions. FMEA hypothesizes a failed component or interaction and then traces the effects of its failure up through the subsystems to its ultimate manifestation at the system level.

3 DETAILED ENGINEERING DESIGN

Detailed engineering design takes the *'what'* from requirements and molds it into an integrated whole. In other words, design synthesizes the *'how'* of the system. Detailed engineering design follows after the Concept Phase and feasibility.

For many complex systems, detailed engineering design splits into two design phases: preliminary design and critical design. Typically, you complete each of these phases after a formal review that satisfies all open action items or concerns.

Design, and indeed all development, should follow a simple, iterative cycle: plan, execute, review, and report. Every activity should follow this process. Even the overall phases should follow this general pattern. It is a useful habit to inculcate.

3.1 Documentation

The primary output from detailed engineering design is documentation. Documentation includes source listings from software, schematics of hardware, plans, and procedures, checklists, memos, messages, manuals, reports, and reviews. Documentation records the plans, the execution, and the reviews and tests. These components of documentation become the directions and instructions for manufacturing, producing, and using the product or system.

Documents need version control to record an accurate historical picture and to maintain a contiguous string of updates. Version and configuration control has been manual until the recent past, software and systems now exist that assist control of versions and archive documents.

3.2 Execution

Execution is the actual design work but it is usually a very small portion of the total effort. This is the creative part of development where coding happens or schematics originate. You should maintain a disciplined habit of keeping a detailed engineering notebook, or its equivalent in software; it becomes indispensable when problems arise or modifications are needed in the future. The notebook needs to provide clues and reasons for your work.

3.3 Review

Review has a variety of forms. It may be formal, such as a design review. It may be informal, where you consult with a colleague about a problem. Formal review can include some or all of the following specific instances:

- Peer review – a process of examining a module or subsystem, particularly software that evaluates the implementation for soundness. Usually four or five people take part – a moderator (best being a person not too close to the project) to facilitate the review, the author/designer, two colleagues to do the review, and sometimes a note taker to record comments and action items.
- CoDR – conceptual design review, which typically completes the Concept Phase. It evaluates the basic approach and the feasibility.
- PDR – preliminary design review, which completes the Preliminary Design phase. It evaluates the basic approach and the initial designs.
- CDR – critical design review, which completes the Critical Design phase. It evaluates the final design and approves the production go-ahead.
- Manufacturing transfer or production hand off (PHO) – this is an additional step that follows a CDR in a volume production scheme. It evaluates the manufacturing issues and gives final approval for production.

3.4 Test

Tests usually begin during the detailed design phase and evaluate the individual components, modules, and subsystems. Tests can cover one or a variety of concerns, such as

performance, failure modes, and environmental tolerance. Examples of tests include the following:

- Software white box testing – where knowledge of the code leads the tester to exercise all reasonable paths of operation (white box for where only internals are known).
- Software black box (for where only externals are available) testing – where the tester exercises the module in all the anticipated operations without knowledge of the code operations.
- Hardware thermal testing – cycling the circuitry through cold and hot temperatures to find potential areas of operational noncompliance.
- Vibration and shock – testing the circuitry and mechanical hardware for potential problems and stress points.
- Integration – exercising the system as subsystems are attached for functionality and correct operation.
- Verification – testing for conformance to the metrics in the requirements. These metrics may originate in performance, electromagnetic compatibility (EMC), fault tolerance, reliability, and maintainability.
- Validation – testing of the system for apparent fulfillment of the customer's or users' desires. Usually, you exercise the user interface or graphical user interface (GUI) for operational responsiveness, utility, and ease that leads to user satisfaction.
- Field-testing – is a combination of integration, verification, and validation. It can accurately portray the environment and functionality of a system in actual use. These types of tests are extremely valuable but tend to be the most expensive; they also often require a completed system, but today the trend is to make use of a sophisticated model of the system.

4 MANUFACTURE

Manufacturing is an entire field of study unto itself. Concerns for manufacturing should be addressed during the previous phases of concept and detailed engineering design. You should consider design for manufacture, where fewer, simpler parts are almost always better than greater complexity. Another area for consideration is design for test; this will help you and those who follow you to also diagnose problems more quickly and efficiently as well as show compliance.

One particular manufacturing concern that you should consider is building the system in-house or outsourcing the work. If you have the assets and resources in the company, which are available and which can be efficiently and wisely used (meaning keep them busy full time for most situations), then in-house production is reasonable. Otherwise, outsourcing the production effort is a worthy consideration, particularly if your company does not have the expertise to manufacture the product. It does, however, pass control out and thus the supplier has to be reliable.

5 OPERATION

Just designing and building something is not the end of the matter. You need to see it into operation and ensure that it functions reliably. This means that you need to consider the effort to install the equipment, train the operating personnel, and provide technical support.

One area of this that is continually overlooked is the user manual. Successful operation requires a good manual, training, and access to appropriate information. For more complicated systems, a troubleshooting and repair manual is essential.

Once operational, you need to consider the logistics and inventory. What are the consumable resources that your system needs – fuel, lubrication, batteries, or auxiliary supplies, for example, paper for printers? Then there are maintenance and repair, which are two completely separate activities. Maintenance involves periodic care for the equipment – labor, spares, inventory, and equipment downtime are all factors. Repair is the fixing or replacement of a failed component; here the same concerns as maintenance, such as diagnostics, prognostics, and test equipment accompany additional issues.

6 UPGRADE

If your system operates with some degree of success, then invariably someone will want to upgrade its capabilities in the future. You need to consider this when you do the initial design. Prepare design hooks in the original design. These are openings or attachment points for potential upgrades. Careful coding of software can make the addition of new modules and capabilities easier in the future. Providing a margin in memory, performance, size, weight, and power will ease the addition of future hardware.

Designing a system for expandability does add complexity to the system. It generates new possibilities for unforeseen circumstances and interactions. Consequently, complete and correct documentation is absolutely essential. Necessary documentation includes

- software source listings,
- hardware schematics, and
- design documentation that explains the theory of operation.

The engineering notebook can be indispensable for upgrades. It provides the reasons for why and how things were done. It can also help with explaining the theory of operation.

7 DISPOSAL

Environmental concerns for disposing off equipment that is no longer in use are rising. You need to consider, during the early phases of concept and detailed engineering, how to dispose of your system. Plan for recycling of the materials, particularly of the enclosure and packaging aspects. Reuse of components may be an avenue for disposal as well. Toxic compounds, such as heavy metals used in solder, circuit boards, and components, are becoming an environmental crisis; think about how you might reduce their use in your products.

8 CONCURRENT DEVELOPMENT

The life cycle of development necessarily involves parallel streams of effort. Someone must evolve the hardware designs as someone else designs and codes the software. A different group must prepare the mechanical mechanisms and packaging alongside the circuits and software. This is the business of systems engineering oversight.

One principal concern is the definition of interfaces within the system. These interfaces will control the architecture and the eventual operation of the system; they also affect the concurrent development of the system. A general philosophy of interface coupling, whether loose or tight, will help define the architecture.

Loose coupling means that the interface is straightforward with the minimum in communications between modules. It tolerates changes and tends to be more robust. Loose coupling can reduce rework and redesign and can increase reuse. It aids concurrent and independent development, can adapt to the market, and ease the test burden. The disadvantage with loose coupling is that it tends to produce a bigger, heavier system.

Tight coupling optimizes performance or size by spreading function across interfaces. Its advantage is that it can reduce the initial cost of manufacture with more optimized structure or smaller form factor. Concurrent development, however, is much more difficult and testing is more extensive at the system level. Redesign is more difficult because it affects the entire system; changing one component more readily affects others within the system.

9 EVOLUTION OF THE LIFE CYCLE

The concept of the life cycle has evolved into various forms from its origins in the 1950s and 60s. The waterfall model gave way to several different models including the prototyping and spiral models that better fit actual development. Complex systems, for example, a fighter aircraft might use a combination of approaches – first it is built to a set of requirements that provides a major subset of functions (basically a waterfall development), then it goes through extensive flight tests that determine other capabilities. These flight tests are iterative and can cause changes to requirements, now development looks more like the spiral method.

The facility provided by the Internet is forcing further evolution of systems design and life cycle development. Embedded systems are gaining Internet ports so that software upgrades may occur quickly and easily in the field. These kinds of upgrades significantly reduce downtime and allow more frequent tuning of operation within embedded systems. The capability of the Internet can now combine field-testing with operation; successive versions of the software can be far more numerous. This type of life cycle development strongly resembles prototyping but it is much faster. The iteration time is much shorter. The problem with fast field upgrades is that people will be tempted more than ever to release 'buggy' code that does not work quite right to make market deadlines and hope to 'fix' the problems later through field upgrades.

Engineering knowledge and judgment is the one area over which you have some control during your career. You should be continually learning, monitoring, optimizing, and improving what you do and how you do it. Your experience can lead to changes and improvements in the life cycle of development. There is much more to engineering than the design itself!

1 DEFINITION OF A CONCEPT OF OPERATIONS (OR OPERATIONAL CONCEPT)

A Concept of Operations (ConOps) describes how an observer intends to use a contemplated measurement system in a specific actual or anticipated situation. It is the starting point for engineering a measurement system – *see* **Article 63, Outline of Systems Thinking, Volume 2** – and other articles on that topic.

In the vein that 'understanding the problem is 90% of the solution', a ConOps purposefully treats the intended measurement system as a black box. ConOps authors describe the operational situation – what the users need to accomplish and how a measurement system can help make sure that the right issues are reached. Authors must studiously avoid making any assumptions about the internal content and structure of the eventual measurement system.

The ConOps focuses on both the stimuli to which the measurement system is expected to accommodate and the user-visible responses to such stimuli. Further, the ConOps describes the effect the responses are intended to have on the operations situation. This latter facet sets the stage for the Measures of Effectiveness (MOEs) by which the eventual measurement system will be judged.

A ConOps describes why a measurement system is needed, how the measurement system will be used, and the consequent value of such a system. The user's mission objectives and goals regarding the phenomenon to be measured are mapped to measurement system capability scenarios. It tells a story about the expected behavior of the phenomenon to be measured and about a day, week, month, or other episode in the life of the users of such measurements and thus of the desired behavior of the contemplated measurement system.

A ConOps is not the same as an Operations Concept. The ConOps describes the usage of the intended system by articulating 'we need a system that will enable us to do the following: "The authors are standing in problem space looking out"'.

The other view, the Operations Concept or Concept of Operation, describes the operators view of a system as designed or produced. The authors are standing in solution space looking toward the problem space.

This subtle distinction is very important because it emphasizes an understanding of the operational need without the clutter, confusion, and complexity of implementation ideas.

For example, a ConOps says, 'here's what we need to measure about the weather and how we intend to use those measurements'. In contrast, an Operations Concept document says 'given that we have designed this ocean temperature, salinity, and current flow system, here is the way it should be deployed, operated, and maintained'. Accordingly, the Operations Concept is a response to the ConOps, not an alternate name for the same thing.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

A good ConOps may reflect 'out-of-the-box' thinking and is not concerned with immediate perceptions of implementation feasibility. Because a ConOps describes a measurement system yet to be designed, it is necessarily speculative – a vision, though hopefully not a hallucination.

To many readers and especially to system designers and developers, a ConOps can be irritatingly vague, presumptive, or unrealistic. However, a ConOps should be judged solely on how well it describes the situation in which the measurement system is to be used.

A ConOps is not the same as a Use Case. The ConOps is a big picture scenario of the total usage envisioned, whereas a Use Case presumes to describe what the system will do internally to serve each user. Use Case Scenarios are similar to Operations Concepts rather than to ConOps.

2 THE CONCEPT OF OPERATIONS APPLIED TO SYSTEM DEVELOPMENT

A ConOps often serves to converge multiple stakeholders toward a common understanding regarding the usage and value of the desired measurement system. This should be accomplished before getting into details about what the measurement system will look like, what technologies it will employ and what its cost and development schedule are expected to be. In other words, it is not about implementation detail.

The ConOps description included all of the stimuli and responses to be monitored by the measurement system. These include all interfaces between the intended measurement system and the User, Phenomenon System, and all collateral systems. Interface types must be specified. Examples are as follows:

- Coexist = two or more entities in contact.
- Compete = two or more entities in tension regarding contact.
- Connect = two or more entities structurally involved.
- Conduct = two or more entities passively exchange energy.
- Communicate = two or more entities passively exchange data.
- Cooperate = two or more entities change behavior in order to exchange energy or information (usually as function of energy or information).
- Collaborate = two or more entities change structure or content in order to exchange energy or information (usually as a function of result being pursued).

This level of information enables an analysis of the effect of all the responses relative to user objectives and goals. These effects are the basic Measures of Effectiveness. Next, the acceptable performance levels for each MOE are decided. These are the basis for the measurement system acceptance criteria.

The design contract for the measurement system should be based on the ConOps and the MOEs. Of course, this is what Customer Oriented, Voice of the Customer, and similar ministrations in a variety of business publications have meant for the last 10 years.

Products can fail in the marketplace because the contract document was based on the Specification for the System rather than on its value to the system users.

Time and again, marketing and prospective customers collaborate to describe the problem that exists and how they would like their world to be, and even the tolerable therapies they will endure to get there only to watch as engineering people proceed to reexpress the intent in the form of requirements, then 'manage requirements'. In response to this, they can fend off corrections with threats of cost and delivery time explosion.

After consensus is reached on the ConOps, MOEs, and acceptance criteria, the system development process can proceed to draft Use Cases about each of the stimuli (and their sources) on the system. These begin to reveal the system requirements.

3 ALLOCATIONS OF MEASURES OF EFFECTIVENESS TO THE CONOPS MODEL

Although a measurement system may have to handle hundreds of stimuli and generate responses for each, it is necessary that the MOE is the minimum set that adequately characterizes the effect of the measurement system on the user situation. Some call these the system's critical issues (CI) that then can be analyzed to reveal its MOEs – *see also* **Article 14, Hierarchical Aspects of Measurement Systems, Volume 1**.

The generic MOEs for a measurement system each address and include the following:

Adequate: The system must measure and report enough attributes of the phenomenon of interest to satisfy the user needs. For example, if the phenomenon is a single event, then the measurement of that event is adequate. However, if the phenomenon is the popularity rating of a politician, then dozens of attributes may have to be measured as well as the demographics and psychographics of those interviewed.

Accurate: The inherent precision and uncorrectable disturbance error in each measurement are important as is the frequency of measurement and duration of observation.

Timeliness: This factor concerns the time lapse from (a) occurrence of the phenomenon to (b) the availability

of the measurement in useful form. A highly accurate measurement too late is not valuable to the user.

Interoperability: This factor concerns the behavior of the measurement system with respect to other systems in the operational situation. This goes beyond mere existence of interfaces to consider the interoperation scenario (e.g. control vs. slave and multiple modes of interoperation).

Resilience to operator error(s): Often called the *ease of use*, which is too ambiguous; the better term is the *effectiveness factor* of the measurement system's resiliency to disturbances caused by operator error, and especially to a scenario of errors.

Operational Availability index: This factor describes the likelihood that the measurement system will be operational at all times it is required to be operational. The operational availability (OA) index is a combination of reliability, maintainability, and operations calendar. An important subfactor is the calendar date for the first intended use of the measurement system. This, of course, is an attribute of the measurement system development project rather than of the measurement system itself, but the OA index goes to zero if the measurement system is not delivered on time when it is needed.

Total cost of ownership: Total cost of ownership (TCO) is important even if the cost is not the direct responsibility of the user.

The use of Standards of Acceptance is illustrated in Table 1. For each MOE (generic ones are used here), the acceptable values for each are specified. The 'X(i)' values indicate the capability of the system if it is to be of maximum value to the users. The 'Y(i)' values indicate the effectiveness level that the users will find acceptable. Because the TCO of the system typically increases with the level of system effectiveness, a measurement system can be judged acceptable while significantly below the Max Value Threshold.

Table 1. Relationship of MOE factors to quantified level of each MOE.

MOE	Max Value Threshold	Acceptance Threshold
Adequate	X1	Y1
Accurate	X2	Y2
Timely	X3	Y3
Interoperability	X4	Y4
Resilience to operator error(s)	X5	Y5
Operational availability index	X6	Y6
Total cost of ownership	X7	Y7

4 DOCUMENTATION

The ConOps is often produced as a file document but the better ConOps is formed as an executable model (or a model and simulation) such that the dynamic interaction of the ConOps factors can be observed.

Regardless of form, the following checklist of ConOps content should be used:

1. Mission of the Measuring System (MS).
2. Scope/context of the MS.
3. Anticipated phenomenon system (content, structure, behavior, pertinent exogenous attributes, pertinent endogenous attributes, persistence, variability, glint, scintillation, position, etc.).
4. Anticipated User objectives and resulting needs for a measurement system, such as

   - the existence of something, both the exogenous attributes and the endogenous attributes;
   - the location of something, including the related factors;
   - the persistence of something, including the related factors;
   - the variability exhibited by that something (such as range of values, the rep rate of pertinent changes, the least count of observations).

5. Desired observation and interpretation scenario (regardless of implementation feasibility). Includes usage of the measurements, such as

   - surveillance,
   - metrication,
   - alarm,
   - control.

   Also describes the roles, accountabilities, authorities interfaces and responsibilities of the operations personnel.
6. The boundary of the MS (and what is not MS such as the transport system that positions the MS or the reference standards that enable calibration of the MS.
7. Any technology constraints or opportunities consistent with operational considerations.
8. The permissible support and maintenance scenario for ensuring OA of the MS.
9. Test capability the MS must provide or endure.
10. Operator readiness capability the MS or a supporting subsystem must provide.
11. The preferred or permissible Cutover scenario.
12. The MS evolution that must be provided for within the OA timeline.

13. The interoperability with related systems (communicating, cooperating, collaborating, coevolving).
14. Permissible environmental impact considerations.
15. Permissible societal impact considerations.

Effort expended in developing a sound ConOps can save the existence of late errors that are costly to fix. Errors are far less costly when fixed early.

1 BOUNDARY PERSPECTIVE OF MEASUREMENT SYSTEMS

The wider system, within which a human–machine system is embedded, is sometimes referred to as *the supersystem* (McGhee, Henderson and Sankowski, 1986; McGhee *et al*., 1996).

Since each of the subsystems, described in **Article 6, Substructure of Human–Machine Systems, Volume 1**, may also be considered as systems in their own right, this means that the human–machine system is the supersystem in which each is embedded. Hence, it can be seen that measurement systems, which may be considered as subsidiary blocks of the information system, cannot exist in isolation.

The human–machine system environment, or supersystem, within which they function, regards them as subsystems of itself. Hence, the bilateral impacts of this linking must be considered.

Instruments perform a purposeful function. They also possess an opaqueness and obscurity of structure, characteristic of complexity. This functional complexity of the combination of the associated components justifies treating them as systems. An exemplary aspect of the systems approach is the totality of the considerations that are taken into account.

A basis for highlighting all of the effects impacting on a measurement system may be adapted from the boundary view of human–machine supersystems, given in McGhee, Henderson and Sankowski (1986), in McGhee *et al*. (1996), and in **Article 6, Substructure of Human–Machine Systems, Volume 1** where it has been shown that this boundary perspective indicates the importance of a detailed consideration of all impacts in measurement systems. It also allows a distinction to be drawn between the three groups of inputs and outputs as shown in Figure 1, where the systems engineering approach, described in **Article 5, Humans in the Real World, Volume 1**; **Article 2, Organization of Instrument Science, Volume 1**; and **Article 6, Substructure of Human–Machine Systems, Volume 1**, can be applied fruitfully by visualizing a boundary view of an instrumentation system.

In the same way as for human–machine systems, as described in **Article 6, Substructure of Human–Machine Systems, Volume 1**, the three types of input and output may be grouped as Resources, Information, or Contamination.

These inputs and outputs in measurement systems may appear in any of the COMETMAN energy forms described in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. The principal resources in measurement systems are the energy forms involved in supporting the flow of information.

In the case of a measurement system, there is no need to emphasize the presence of a resource output since the information output is also the resource output.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

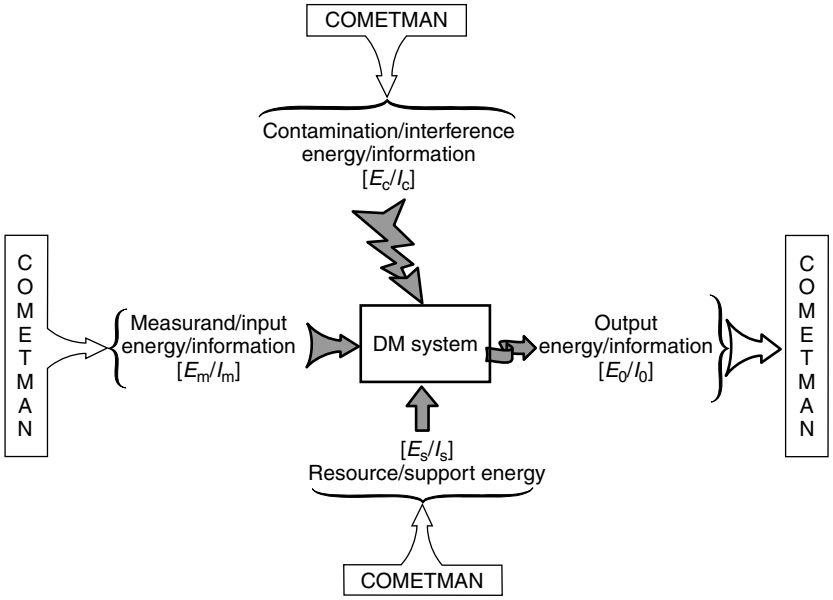

Figure 1. Boundary impacts in an instrumentation system.

Contamination, which is also known as an *influencing input*, or simply as interference, consists of disruptions, impurities, and disturbance power flows. Although not shown in Figure 1, it is generated at the output of the, say, digital measurement (DM) system represented in this figure. It may also appear as interference in other information carrying channels. Disturbance power flows are the primary source of deviations and errors in measurement systems.

2 EXTRINSIC AND INTRINSIC BOUNDARIES

It is also important to distinguish whether the sources of contamination occur from inside or outside the measurement system. The systems approach uses the principles of recursion and reticulation (or subdivision) of systems. Consistent with this view is the possibility of distinguishing between extrinsic and intrinsic system boundaries. The reticulation, or breaking down, is based upon the methods of taxonomy described in **Article 2, Organization of Instrument Science, Volume 1**.

Consequently, a boundary may be visualized between the measurement system and the human–machine supersystem. This boundary may be referred to as an extrinsic, or external, boundary (McGhee, Henderson and Sankowski, 1986; McGhee *et al.*, 1996) as represented in Figure 2. Impacts from outside the instrument penetrate the extrinsic boundary and cause effects within the system. These external interference sources distinguish the extrinsic boundary from the intrinsic, or internal, boundary.

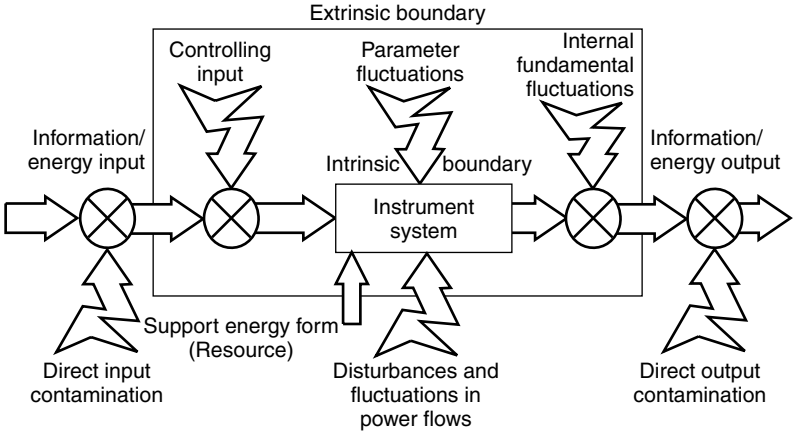

Figure 2. Extrinsic and intrinsic boundaries in instrument systems.

Linking the extrinsic boundary with another boundary called an *intrinsic boundary*, as shown in Figure 2, provides a way of classifying different extrinsic or intrinsic interference sources. Taking an intrinsic boundary into account allows a separation and distinction between the various impacts within the system from those outside the system.

Thus, modeling instruments using the extrinsic and intrinsic boundaries illustrated in Figure 2 is essentially the same as modeling, for example, an operational amplifier. The real operational amplifier is enclosed within an imaginary extrinsic boundary. An idealized noise and drift-free operational amplifier is contained within its intrinsic boundary. The internal noise and drift in the real amplifier are accounted for by including appropriate models for these effects within the space between the intrinsic, or internal, boundary, and the extrinsic, or external, boundary. Proposing extrinsic and intrinsic boundaries allows a separation and distinction between effects in the system due to external or internal causes. It should be noted that inputs and outputs in Figure 2 could be in any of the COMETMAN energy forms. They have not been included for the sake of clarity. The COMETMAN acronym is explained in **Article 109, Structure and Energy in Sensor Systems, Volume 2**.

3 APPLICATION OF BOUNDARY CONCEPT TO SYSTEMS IDENTIFICATION

Systems Identification (Eykhoff, 1984; Ljung, 1985; Söderström and Stoica, 1988), which has special importance in model building for control engineering purposes, is essentially a problem in high precision inferential measurement (Finkelstein, 1994). It is shown in **Article 5, Humans in the Real World, Volume 1** that inferential measurement is one of the two classical problems in measurement.

It is concerned with inferring the physical properties of a system, which characterize its physical ability to store, dissipate, transmit, or transform energy. The close symbiosis between Systems Identification and Physical Measurement, which is manifested in their many and diverse similarities, gives the identification problem a predominant relevance in measurement.

This example provides a convenient means of demonstrating the importance of a boundary perspective for systems. This view is especially appropriate, as the systems' context of identification highlights the importance of the holistic aspects of the Systems Engineering approach when applied to Instrumentation Systems (McGhee, Henderson and Sankowski, 1986; McGhee *et al*., 1996). From the vantage point provided by this view, it is possible to propose that Figure 2 is a general representative model of a process system. It is also valid to look upon this as a representation of an identification channel.

In the case of identification, the extrinsic boundary of Figure 2 may be appropriately called the *identification boundary*. Impacting upon this boundary are the demand input and the contaminating influences. These interferences can affect the system in a direct manner at input and output. Alternatively, they may be distributed throughout the system. An important class of extrinsically arising interference is that caused by disturbances and fluctuations in the various types of power flow.

4 INFLUENCES ON A REAL SYSTEM

As systems operate in a real environment, they are subjected to the full range of influences, which this environment can exert. The boundary perspective provides an important aid to the visualization of these impacts, which may be from energy or information sources. Energy can be classified in a number of different ways, as described more fully in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. The classification of energy using the COMETMAN acronym, which may be regarded as complementing other energy classification schemes (*see* **Article 109, Structure and Energy in Sensor Systems, Volume 2**), is useful because it is a good memory aid. It may also be conveniently extended to the measurement system shown in Figure 2.

The inputs then become the energy and signal form of the input, the resource energy form supporting the flow of information, and the energy and signal form of the contamination. Thus, the resource and contamination classes have a possible total of eight energy form inputs each. The signal at the output of the identification channel has captured information about the ability of the system to store, transmit, transform, or dissipate energy. This information is the resource output of the channel.

The intrinsic boundary is subjected to two kinds of internally occurring disturbance or interference.

The first of these gives rise to inevitable fundamental limits, which are important in all information handling systems. If the information handling operation is measurement, then a fundamental measurement limit exists. Fundamental fluctuations occur as a result of the equipartition of energy between the thermodynamic state and the states of the other energy forms.

In mechanical systems, this is manifested in Brownian motion, while Nyquist or Johnson noise occurs in electrical systems, and temperature fluctuations occur in thermal systems – the latter being also the result of mechanical molecular motion. Although the fundamental fluctuations

have been shown at the output of the system in Figure 2, in practice they are more likely to be distributed throughout the system.

Components used to build systems are not everlasting. Aging of the elements gives rise to a change in their properties, which can affect performance. If burnout failure occurs, then a disruption of the operation of the system occurs. Parameters of the sensor system, which are instrumental in determining the performance of the system, give the system some level of parameter sensitivity. Parameter sensitivity is caused by the inexorable aging of all of the components that make up the system structure.

All of the above sources of interference, in whatever energy form they manifest themselves, must be considered in data measurement systems. Any synthesis or analysis of measurement systems that does not take them into account will almost certainly have very serious shortcomings. Interfering influences, which arise from inside the measurement system, are due to either parameter sensitivity or internal noise.

External interference is caused by disturbance power flows or by other forms of direct contamination. Highlighting the various sources of contaminating inputs exposes the limits of the ultimate resolution of a measurement system in executing its primary function.

1 INTRODUCTION

Design is information-processing activity resulting in the creation of an object. An early design stage is referred to as *conceptual design* (Pahl and Beitz, 1988) – *see* **Article 64, Executing A Measuring System Design, Volume 2** and **Article 66, Phases of System Life Cycle, Volume 2**. In conceptual design, design requirements are transformed into a functional and then physical description. At an early design stage, requirements are formed and then allocated to functions. This article covers the methodology.

To date, relatively little research has been done in the area of design specifications. Kota (1990) developed a function-decomposition hierarchy to identify a set of basic design building blocks. Qualitative functional specifications and synthesis for conceptual design of microelectromechanical systems are presented in Crary and Kota (1990). A methodology for hydraulic circuit synthesis based on functional and structural design building blocks is presented in Kota and Lee (1990). Kannapan and Marshek (1990) presented procedures for specification and synthesis using algebraic and logical transformation rules. Rinderle and Finger (1990) used a graph-based language to describe the behavioral specifications of a design as well as the behavior of the available physical components. Morrell (1988) described the concept of quality function deployment (QFD) applied to improve product quality based on customer requirements.

2 REQUIREMENTS FORMING

Design *requirements are* 'demands' and 'wishes' that clarify the design task in the space of needs (Pahl and Beitz, 1988). They provide an abstraction of the design task from the most general demand (the overall requirement) to more specific demands (subrequirements). A design *function* indicates the behavior that is required for the device to satisfy a given requirement (Kota and Ward, 1990). Requirements and functions are domain specific and represent part of the knowledge base of the design system. A designer, as the needs or his/her design experience changes, can also add them.

A design task is given overall requirements that are domain dependent. They are further decomposed into a set of subrequirements. The number of levels of requirements depends on the complexity of the design task.

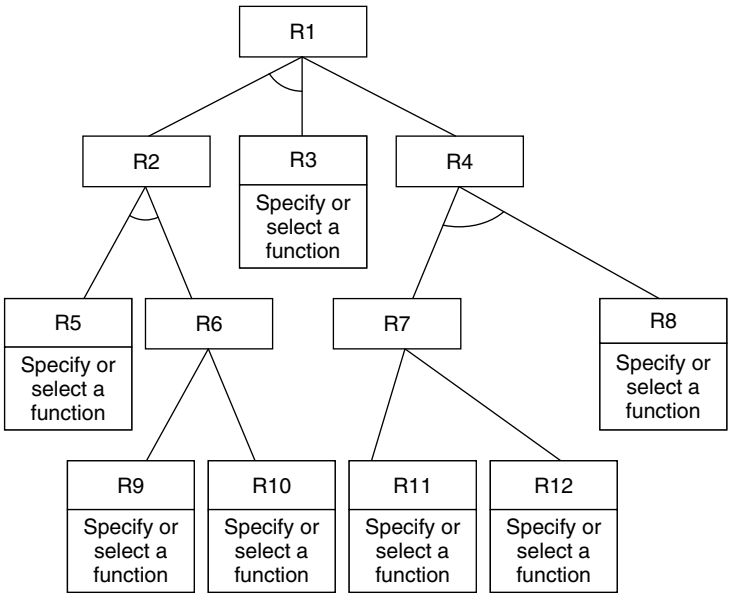

Figure 1. Decomposition of requirements.

Figure 1 shows the overall requirement R1, its decomposition into subrequirements, and the corresponding functions (Kusiak and Szczerbicki, 1992).

An arc between nodes of the tree in Figure 1 represents a conjunction. A node without an arc represents a disjunction. In the example presented in Figure 1, the overall requirement R1 is satisfied by each of the following four sets of subrequirements:

1. {R11, R8}
2. {R12, R8}
3. {R10, R5, R3}
4. {R9, R5, R3}

Each of the above sets may lead to a different conceptual design. Some such designs are discussed in Kusiak (1999).

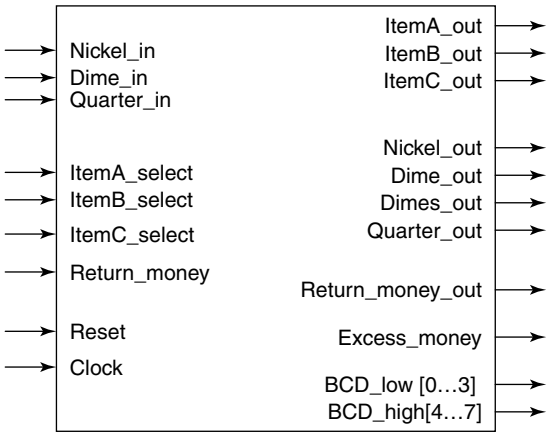

Figure 2. Model of a vending machine controller.

3 DECOMPOSITION

Decomposition is useful in analysis of requirements and functions (Kusiak 1999). It reduces the complexity of the problem at hand. The application of decomposition will be demonstrated here using the design of a vending machine controller. The controller of a typical vending machine has 9 inputs and 11 outputs as shown in Figure 2.

The vending machine needs to be designed for purchasing items, for example, A, B, C, by a providing a change and then selecting an appropriate button to get the item. If the change exceeds the price of the item selected, the vending machine returns the difference. If the Return_money button is selected, the controller will return all the coins deposited since the last transaction (Return_money_out will be activated). The machine accepts the money only up to 95 cents. If more change is inserted, then the Excess_money output variable activates a bypass chute and extra change inserted is routed directly to the change return. Two 4-bit binary coded decimal code combinations represent the current amount of money (in cents) the user has deposited in the vending machine.

4 SOLUTION APPROACH

Having formed the design requirements for the vending machine, the next step is to analyze the various Product Functions. The main functions are now discussed.

1. **Coin counting**
   The function 'count coins' of the vending machine is illustrated in Figure 3.
2. **Money return**
   The vending machine returns change if the button of Return_money is selected (see Figure 4).
3. **Excess money**
   The excess of 95 cents is returned (see Figure 5).
4. **Item selection**
   When the customer selects an item and the amount deposited in the vending machine is equal to or greater than the price of the selected item, the item is delivered (see Figure 6).
   Note: Item_select includes itemA_select, itemB_select, itemC_select.
   Item_out includes itemA_out, itemB_out, itemC_out.
5. **Change calculation**
   If the customer drops in more money than the price of the item selected, the change needed is calculated. The change equals the total amount deposited in the vending machine minus the price of the selected item (see Figure 7).
6. **Change out**
   After the vending machine has calculated the amount of change, the proper change amount is returned to the customer (see Figure 8).
7. **BCD indicator**
   The vending machine needs to indicate the current amount of money (in cents) the user of the vending machine has deposited with two 4-bit BCD code combinations (see Figure 9).

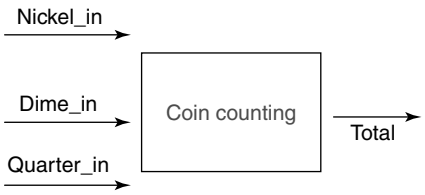

Figure 3. Coin counting.

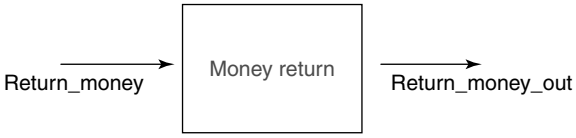

Figure 4. Return money.

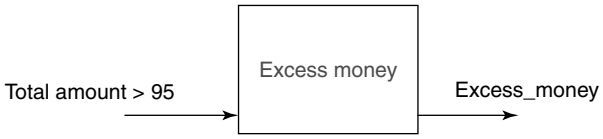

Figure 5. Excess money.

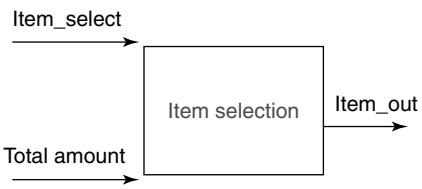

Figure 6. Item selection.

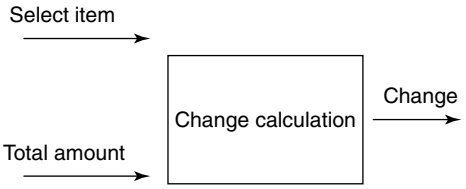

Figure 7. Change calculation.

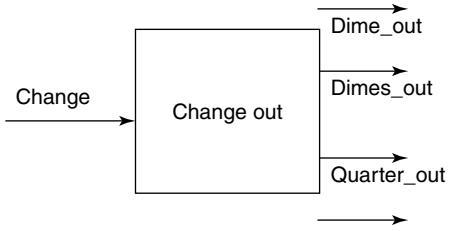

Figure 8. Change out.

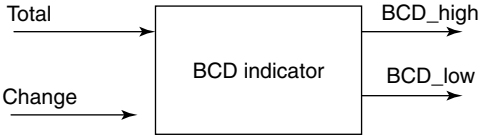

Figure 9. BCD indicator.

5 STRUCTURAL DECOMPOSITION

On the basis of the functions defined in Figure 2 through to Figure 9, the function-input/output matrix is formed (see Figure 10).

Each "*" in Figure 10 indicates a relationship between the corresponding function i, $i = 1, \ldots, 7$ and input/output j, $j = 1, \ldots, 16$.

A list of functions is obtained from the rows in Figure 10:

1. Coin counting
2. Return money
3. Excess money
4. Item selection

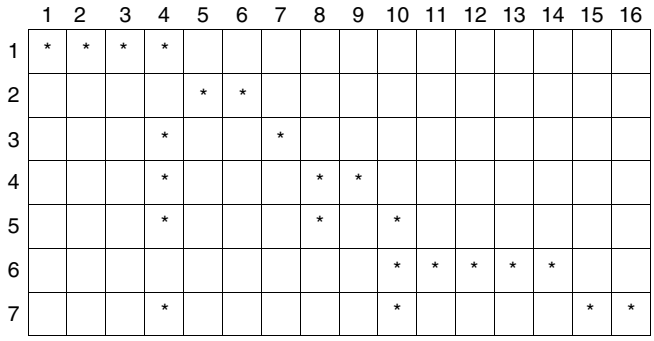

Figure 10. Function-input/output incidence matrix.

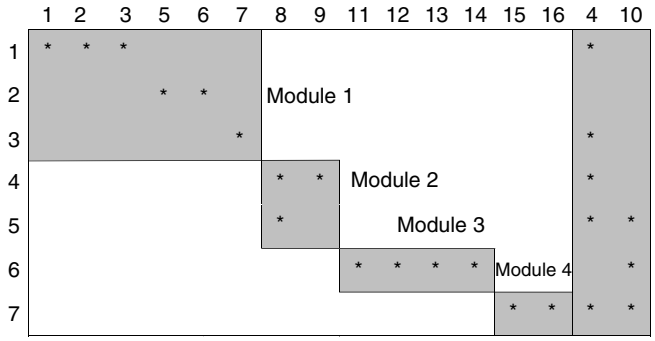

Figure 11. Function-input/output matrix of vending machine clustered with the branch-and-bound algorithm.

5. Change calculation
6. Change out
7. BCD indicator.

List of inputs/outputs (columns in Figure 10):

1. Nickel_in
2. Dime_in
3. Quarter_in
4. Total_amount
5. Return_money
6. Return_money_out
7. Excess_money
8. Item_select (includes ItemA_select, ItemB_select, ItemC_select)
9. Item_out (includes ItemA_out, ItemB_out, ItemC_out)
10. Change
11. Nickel_out
12. Dime_out
13. Dimes_out
14. Quarter_out
15. BCD_high
16. BCD_low.

Clustering the matrix with the branch-and-bound algorithm (Kusiak, 2000) results in a new matrix (Figure 11) that is more suited to design allocation. Four groups of functions – {1, 2, 3}, {4, 5}, {6} and {7} – and four groups of inputs/outputs – {1, 2, 3, 4, 5, 6, 7}, {8, 9}, {11, 12, 13, 14} and {15, 16} – are visible in Figure 11. Inputs/outputs 4 and 10 interact with more than one function.

Introducing redundant inputs/outputs for performing the functions allows decomposition of Figure 11 into the four mutually separable submatrices shown in Figure 12 (for details see Kusiak (1999)).

6 MODULE DESIGN

The four function modules are introduced to fulfill the requirements from Figure 12. VHDL logic is now used to describe the behavior of each module (Perry, 1994).

Module 1: Coin handler

A coin handler counts coins, calculates the total amount, returns money, and handles excess money according to the VHDL logic presented next and the function illustrated in Figure 13.

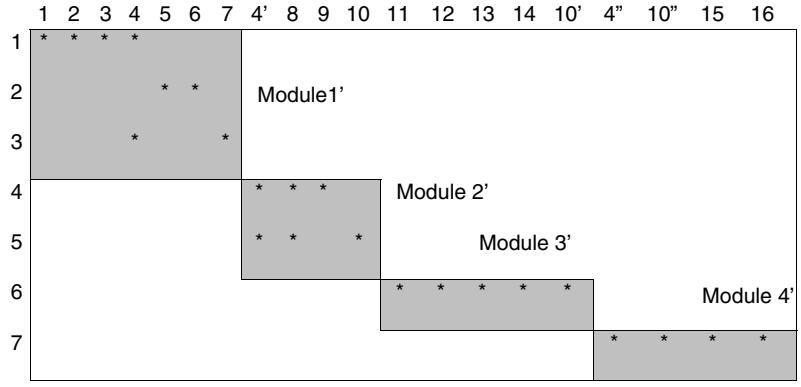

Figure 12. Structured function-input/output matrix of vending machine after introduction of redundant inputs/outputs.

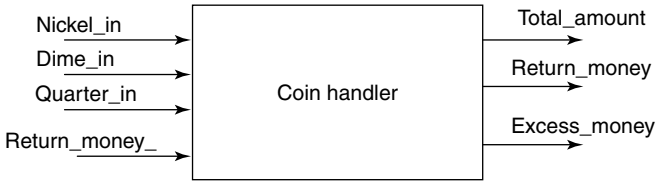

Figure 13. Coin handler.

1. **Count coins**

```
IF nickel_in = '1' THEN
  total_amount := total_amount + 05;
END IF;
----------
IF dime_in = '1' THEN
  total_amount := total_amount + 10;
END IF;
----------
IF quarter_in = '1' THEN
  total_amount := total_amount + 25;
END IF;
----------
```

2. **Return money**

```
IF return_money = '1' THEN
  return_money_out = '1';
END IF;
```

3. **Handle excess money**

```
IF total amount > 95 THEN
  excess_money = '1';
END IF;
```

Module 2: Item processor

The Item processor accepts purchase requests and determines if the money entered is enough to purchase an item (see Figure 14).

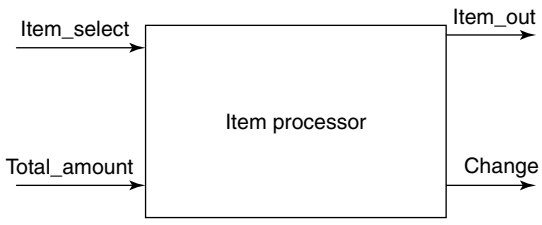

Figure 14. Item processor.

Item	Price(cents)
A	55
B	65
C	75

Figure 15. Item price list.

The price of each of the three items A, item B, and item C is listed in Figure 15.

1. **Select Item A**

```
IF ItemA_select = '1' THEN
 IF total_amount >= 55 THEN
  ItemA_out = '1';
  Change := total_amount −55;
 END IF;
END IF;
```

2. **Select Item B**

```
IF ItemB_select = '1' THEN
 IF total_amount >= 65 THEN
  ItemB_out = '1';
  Change := total_amount −65;
 END IF;
END IF;
```

3. **Select Item C**

```
IF ItemC_select = '1' THEN
 IF total_amount >= 75 THEN
  ItemC_out = '1';
  Change := total_amount −75;
 END IF;
END IF;
```

Module 3: Change maker

Change maker outputs provide change to the customer (see Figure 16).

The input/output of the change maker is shown in Figure 17:

The following VHDL statements illustrate the process of handling a change of 35 cents.

```
IF change = 35 THEN
  Nickel_out = '1';
  Dime_out = '1';
  Dimes_out = '1';
  Quarter_out = '0';
  Total_amount := 0;
  Change := 0;
END IF;
```

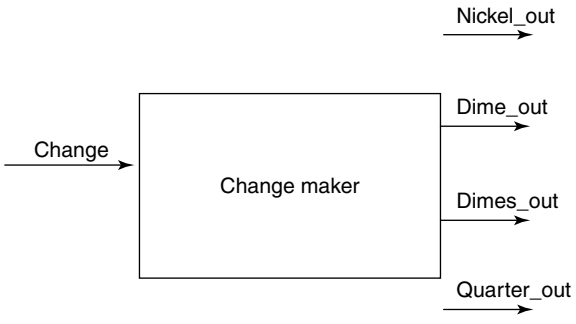

Figure 16. Change maker.

Change (cents)	Nickel_out (5 cents)	Dime_out (10 cents)	Dimes_out (20 cents)	Quarter_out (25 cents)
0	0	0	0	0
5	1	0	0	0
10	0	1	0	0
15	1	1	0	0
20	0	0	1	0
25	1	0	1	0
30	0	1	1	0
35	1	1	1	0
40	1	1	0	1

Figure 17. Input/output table of the change maker.

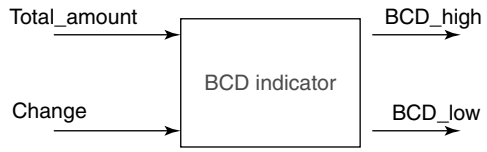

Figure 18. BCD indicator.

Module 4: BCD indicator

Two 4-bit BCD code combinations represent the current amount of money (in cents) the user of the vending machine has deposited. Before purchase, the amount equals the total amount, after purchase, the amount equals the change (see Figure 18).

The input/output of change maker is presented in Figure 19.

Suppose the amount is 35, the following VHDL sequence is used:

```
IF amount = 35 THEN
  BCD_LOW = ''0101'';
  BCD_HI = ''0011'';
END IF;
```

7 SYSTEM DESIGN

7.1 Module interaction

From Figure 11, it was determined that input/output 4 (total amount) and input/out 10 (change) interact with multiple modules. The relationship of the modules is obtained from Figure 11 and shown below. Thus, the inner connections of modules are established (see Figure 20).

Amount (cents)	BCD_high	BCD_low
0	0000	0000
5	0000	0101
10	0001	0000
15	0001	0101
20	0010	0000
25	0010	0101
30	0011	0000
35	0011	0101
40	0100	0000
45	0100	0101
50	0101	0000
55	0101	0101
60	0110	0000
65	0110	0101
70	0111	0000
75	0111	0101
80	1000	0000
85	1000	0101
90	1001	0000
95	1001	0101

Figure 19. Input/output of BCD indicator.

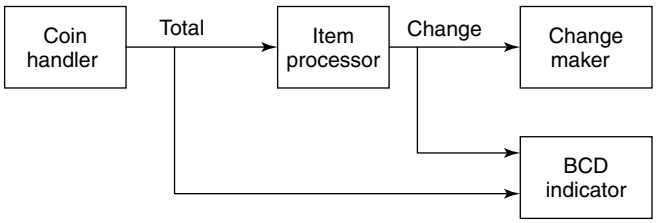

Figure 20. Inner connections of modules of vending machine.

8 VENDING MACHINE CONFIGURATION

After the module design is finished and the inner connections established of modules, the top-level vending machine configuration is obtained. Clock and Reset are added to synchronize the operation of each module (see Figure 21).

This process has systematically worked its way through the many options. By reorganizing the relationship matrix, several units have been identified that have less interfaces to other units than was first developed. With less interfaces, the chance of system failure is reduced and design made simpler. Measuring systems can similarly be broken down in this manner. More information on the nature and scope of requirements is found in Sage and Rouse (1999) and Sydenham (2004).

1 MEASURING SYSTEM DESIGN TASK

The design of a measuring system is the transformation of knowledge about the measurement task to be performed into a specification of a system that can perform the required task in such a way that the system can be realized.

The methodology of measuring system design is determined by the fact that measurement is an information process, measuring instruments are information machines, and that measuring instrumentation can be treated for the purposes of analysis and design as a system.

To discuss the principles of design of a measurement system, it is convenient to do so on the basis of a simple model of such a system – see Figure 1.

Measuring systems are invariably a subsystem of a large system. The measuring system consists of a number of subsystems. There is firstly the system under measurement (also called the *system under test* SUT). This is connected to a sensor system and acts on the sensor by a flow of matter or energy.

The sensor converts this flow into a signal, maintaining a functional relation between the input flow and the information carrying characteristics of the signal. There is usually a signal-conditioning block that converts this signal into a symbol that may be conveniently handled by the following block, which performs any required functions of information transformation and communication.

This system passes the information to the effector block, to further processing, or to the human operator. The measuring instrument system operates under the control of a control block. An important part of the system is the operator or human–machine interface. Through this interface, the operator effects supervisory control of the measurement process. The interface embodies also any displays.

Measuring system analysis and design uses description by mathematical or like models – *see* **Article 71, Modeling Methodology, Volume 2**; and **Article 104, Models of the Measurement Process, Volume 2**.

Models involve abstraction, that is, the omission of irrelevant detail. This is required to reduce complexity, ensure tractability, and give access to analytical tools. In the case of instruments, we may distinguish a number of levels of abstraction in increasing levels of abstraction:

1. Embodiment models in terms of the physical variables and the shape, dimensions, and material properties of the system components and their physical interconnection.
2. Models of flow of power and power transformation; models of signals and their transformation.
3. Models of flow of symbols and of symbol transformation.
4. Models of information and knowledge flow, that is, representation and transformation of information and knowledge by the system.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

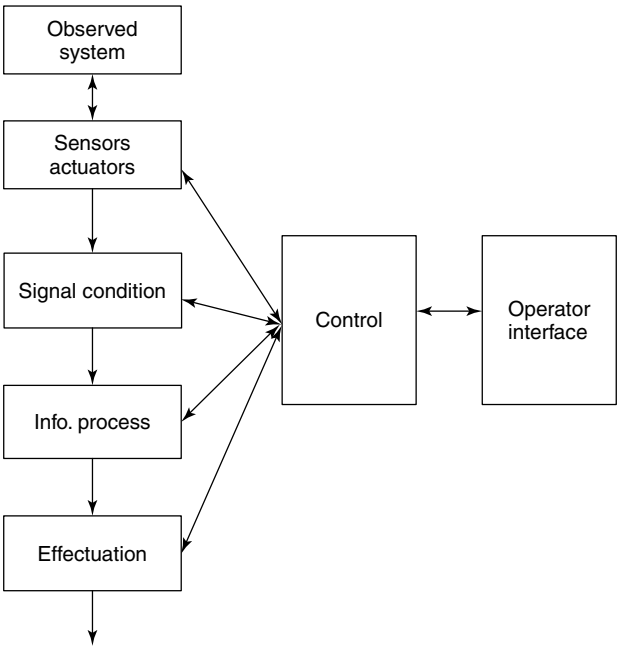

Figure 1. Measuring system.

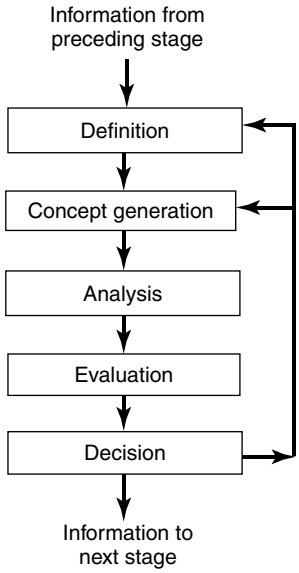

Figure 2. The design process.

We may also distinguish between functional models that represent only the transformation of input into output and embodiment models that represent some details of the physical realization of the system.

In modern measuring systems, the information processing block, the control block, and to some extent the effectuation and signal-conditioning blocks are designed and implemented by the standard methods and equipments of information technology.

In general, functional blocks for performing the required operations are available. Special problems arise in the sensor block and in the interaction between the measuring system and the observed system. They need to be designed at the embodiment level.

2 THE DESIGN PROCESS

The design of measuring systems follows the classical model of the design process.

Classically, design activity is represented as a process consisting of a sequence of stages, starting at the perception of need and terminating at the communication of the final firm knowledge necessary to implement or realize the artifact, or system. Each stage is itself an elementary design process, which starts with an initial concept and refines that concept. The stage is a sequence of steps, subprocesses, or operations.

Consider the elementary design process depicted in Figure 2.

The initial step of the process is that of definition of an initial design concept to be refined. The model and related knowledge is, in general, provided by the previous stage of design. Associated with this model is a set of evaluation criteria, or a value model, which express the degree to which the concept meets the requirement.

The next step in the process is the generation of a more refined candidate design concept. The generation of candidate design concepts is central to the design process. The candidate design concept is represented as a configuration, that is, in terms of attributes of its construction.

It is next analyzed to determine its performance attributes and evaluated using the value model previously established. A number of such design concepts are normally generated and stored.

The evaluation step passes information to a decision step in which the candidate design concept judged to be the most satisfactory is accepted for implementation, or as the initial concept on which the next stage of design will be based.

If none of the candidate design concepts is acceptable, it may be necessary to return to an earlier stage in the process, for example, to alter the value criteria, or to generate more candidate design concepts.

Viewed overall, design proceeds from a global view of the artifact or system to progressively more localized considerations, and from abstract and fluid descriptions to concrete and firm ones.

The design stages typically start with a definition of the overall system that arises from the original requirement. This establishes the main features of the system as a set of interconnected subsystems and also fixes the nature and

specifications of the subsystems. In turn, the subsystem design stage uses this information to establish the main features of the subsystem and the nature and the specifications of its simpler components.

This sequence of stages proceeds to the design of elementary components. If at any stage it appears that it is not possible to meet the specification generated by the preceding stage, it is necessary to return to an appropriate point of that latter design stage.

3 DESIGN CONCEPT GENERATION

The core of the design process is the generation of design concepts; its basis is decomposition and abstraction.

The components of a measuring system that handle knowledge and information are generally realized by the selection of available functional blocks and the use of essentially algorithmic methods of design. The design methodology of those parts of the system is not specific to instrumentation and is basically that of information technology.

In the case of sensors and the interaction between the sensors and the object under observation, it is commonly necessary to find an appropriate working principle and a physical embodiment of the principle.

There are a number of basic methods of determining such working principles and finding their embodiments. They are useful heuristics rather than algorithmic procedures.

3.1 Use of established equipment and design concepts

Established design concepts may be used in the design of a system. They may be retrieved from systematically organized knowledge bases and tools for searching them.

Formal knowledge bases of sensor principles may be organized on the basis of their mathematical models or in terms of their function.

Catalogs of commercially available sensors and directories of such catalogs are increasingly available on the Internet.

Searching through literature, also increasingly facilitated by the Internet, is an important method.

3.2 Design concepts deduced from the relevant physical effects

Instrument components that maintain a functional relation between physical variables may be deduced from the relevant physical effects.

One approach is the systematic listing of physical laws that involve a physical variable of interest, or that relate two physical variables that are to act as the input and output of a device. For example, if we require to generate concepts for sensing electric current, we may list the physical laws involving electric current, each of which may suggest a design concept. One law is that of force between current-carrying conductors, which suggests that we can sense current by sensing the force between two coils, as in a dynamometer instrument. The law of force on a current-carrying conductor in a magnetic field suggests the principle of the moving-coil ammeter. Ohm's law relating voltage and current suggests sensing current by sensing the voltage across a standard resistor. Joule's law of heat generated by a current in a resistor suggests the principle of the hot-wire ammeter. This list is illustrative but not exhaustive.

The second approach is the examination of a single law involving the variables in question that then suggests a design concept. Consider the generation of design concepts for instruments to measure viscosity. The relevant law is $F = -A\ (\mathrm{d}v/\mathrm{d}x)$, where F is the force acting on an area A normal to the velocity gradient $\mathrm{d}v/\mathrm{d}x$ of a fluid. This suggests two viscometer principles:

- generating a velocity gradient in a fluid and sensing the resultant shearing force;
- generating a shearing force and sensing the resultant velocity gradient.

From this we can proceed sequentially to elaborate variants of the principles. Taking two solid bodies with fluid between them, we may have the two bodies fixed with fluid moving, or one body fixed with the other body moving, or all may move. The mode of motion may be translation or rotation, and the motion may be steady, harmonic, or transient. We may then derive the idea of two coaxial cylinders with fluid between them. We may drive one cylinder (inner or outer) at constant angular velocity and measure the torque on either moving cylinder (rotor) or stationary cylinder (stator). Alternatively, we may drive the rotor at constant torque and measure the resultant velocity of stator or rotor. This systematic process then suggests oscillatory motion of the rotor. A complete range of variant design concepts is thus generated.

3.3 Analogies

A method of generating design concepts is the consideration of analogies. When considered in terms of an abstract description, a system may seem to be essentially similar to another and aspects of the second may suggest design solutions for the first.

Physical analogies such as those between electrical, mechanical, fluid flow, and thermal systems are often useful.

Another important source of analogies for instrumentation and information processing are living organisms, especially the animal system of receptors, nerves, brain, and effectors.

3.4 Divergent or lateral generation of concepts

Design concepts can be generated by creative thinking in which ideas diverge and move laterally. Design concepts are considered in abstract form, neglecting irrelevant details until the latest possible stage. Every attempt is made in the first instance not to consider an established practice, authority, or apparent obstacles so as not to allow promising concepts to be abandoned prematurely. Finally, for the same reason, idea generation and evaluation are separated.

3.5 Transforming concepts

Some existing design concept usually forms the first step in the process of generating a design. This may then act as a starting point for generating new concepts by transformation. Starting with a particular design, one may proceed to derive new concepts.

The basic steps are the functional description and decomposition. The instrument is considered as a system of components and each component is described in terms of the functions it performs. Variations are then derived by systematic analysis of the concept and its systematic variation to generate new options.

Foundational material on engineering design is available in Finkelstein and Finkelstein (1983, 1994) and Sydenham (1994, 2004).

1 MODELS RELEVANT TO MEASUREMENT SYSTEMS

Designers will invariably need to develop some form of model of the system or service being developed or operated (Neelamkavil, 1987; Holland, 1996). Models enable the system to be studied in the computer-based virtual domain. They allow the designer to study the behavior of a system before it is physically built. The place of measurement in the life cycle of a system is shown in Figure 1.

No one modeling tool suits all needs. There exist many factors of the system that will decide which particular tool has to be used. The first to consider is what basic kind of model is appropriate.

Three types of models are used. They will be based on one or more of the following:

- laws of physics – formal description
- process involved
- hardware artifacts – called *icons*.

1.1 Physics-based formal models

In these, a real-world activity, existing or not yet existing, is represented by the formal laws of physics that are expressed in terms of mathematical equations. The ideally desirable level of representation of the complete enough real world open system requires extensive mathematical development that is not always available to the degree of completeness needed. Corners are often cut by making unproven assumptions that can be overlooked later to the peril of the user.

Much of engineering practice has been modeled by this physical means, but it has been long recognized that not all systems aspects can be handled by use of 'hard' formal descriptions. Adding in empirical data is sometimes needed. Examples of this are found in the flight dynamics of aircraft, temperature distribution on an electronic circuit board, wing lift, and other fluid-flow designs.

1.2 Process-based models

Here, the modeled domain is represented by a set of heuristic and formal rules embedded into an algorithm or flow diagram. This 'softer' thinking approach can sometimes be superior to the hard-science model in terms of applicability and can often yield a model where the nature of the problem totally defeats formal description.

Examples of these types of models are the queuing of traffic in a road system, a logistics supply system in

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

ISBN: 0-470-02143-8.

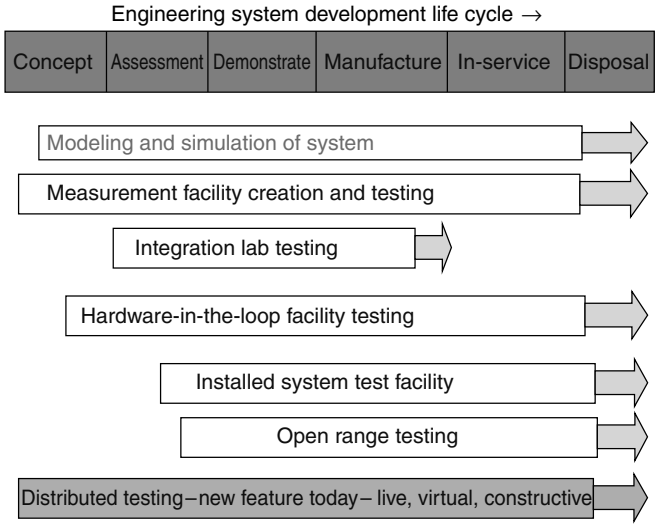

Figure 1. Place of measurements in the systems development life cycle.

operation such as loading a cargo ship in best time, flows in a manufacturing facility, and an Expert System control room support system.

This type can also accommodate the softer human issues – but not that well – using the class of problems called *Systems Dynamics* (SD).

1.3 Iconic models

An icon is an object representing something. It can be an image or a 3-D object. It is used to represent the physically existing model of something.

Examples abound: a scale model of an automobile used in a wind tunnel; a full-size aircraft cabin mock-up; and a scaled-down 3-D model of a large rainwater catchment area.

Being largely hand-crafted, these

- are costly to make;
- take a long time to build;
- are easily destroyed or damaged in testing;
- cannot be altered with ease;
- need special crafts skills to build;
- can only represent a small range of conditions;
- require costly testing instrumentation installations.

Once commonplace, they are rapidly becoming a thing of the past as the economic means for supporting design. Computer simulation is overtaking the need for these, for that alternative is often superior to an iconic model.

Furthermore, the computer model can also be placed in a virtual world environment to put the system under virtual test. In this domain, little is physically built.

For this reason, there is now a diminishing demand for physical model-testing facilities. Reduced demand pushes up costs, which can render them unaffordable. Some large wind tunnels, for example, have been closed down for lack of sufficient business. Physical test facilities are now used more for periodically testing a model under development and for application in design optimization.

Setting up a mathematical model to represent the simple first-level principle of the issue under investigation, as represented by known laws of physics, is rarely sufficient for engineering design use. Useful models usually must also allow for the numerous second-level effects caused by the imperfections of real materials, design inadequacies, and external influence effects. These greatly extend the model's sophistication. Models rapidly expand to be complex, needing ever-increasing effort to establish the particular equation-coefficient values that the model needs to run.

Over time, these have, however, been developed for some industries to the point where they can adequately represent the need – but at a cost that is not always evident, for much of the development has come from past projects and before that from university style research. Sophisticated models shown as selling demonstrator applications do not reveal how much effort has been expended in their development!

Some regimes have been particularly good for modeling realistic systems. One example is that of electronic circuitry where sophisticated models and tools can deliver an almost complete virtual development environment. Here it is often possible to design the systems in the model domain – few changes will be needed after it is made. Usually no prototype build is needed to tune the system.

Now, computational fluid dynamics (CFD) and mechanical and manufacturing design also have tool support for the design and development that needs minimal final physical testing.

Thermal modeling of instrument circuit boards and cases is also highly developed today.

With use of the tools, the new knowledge gained is fed back to continuously improve the model. The successful development of many quite remarkable tool packages may give the impression that all engineering design can, and should be, model based. That is a fine aspiration, but there are many areas where such support is coming slower for reasons of complexity not allowing adequacy of modeling or, perhaps, because the industry sector is too small to support the costs involved in developing the special tools it would like to use. This is the situation for much of the measuring systems design. For example, it is affordable, indeed essential, to develop models of a spacecraft instrument system but it is far less so to fully model a custom-designed single, weighing platform.

In the measuring system field, the problem in tool use is that the particular class of design need often cannot support the development of the sophisticated tools needed. Derivate use of tools built for other uses is usually necessary.

Modeling of the formal part of the information technology (IT) aspect of a measuring system is, however, well supported with virtual instrument modeling tools like LabView – *see* **Article 105, Modeling with LabVIEW™, Volume 2**.

Most design regimes – mathematical, electrical, mechanical, optical, chemical, thermal, and vibrational – have excellent tools available. However, the mixed regime use needed for many measuring system investigations is often complicated by the need to integrate the findings of several tools that are not directly compatible. It will be necessary to repeatedly transfer datasets between tools in instrument design. The time taken to become truly skilled in the use of a tool, and its cost, often limits its use to the higher-volume runs – that are not characteristic of measuring systems.

1.4 Aim for simplicity in model building

Models should be kept as simple as is just necessary to extract the information needed.

Models are NEVER a complete representation of a topic. They are built to exhibit chosen aspects of behavior and will be set to certain limits of dynamic performance.

Static, or steady state, models have their uses, but the most used are those that allow the dynamic behavior of the modeled system to be investigated – they are much more complicated.

If the external environment conditions are changed from those for which the model was designed, it is not likely to give accurate outcomes.

2 TYPES OF MODELING REPRESENTATION

Formal models of real-world systems can be formed by virtue of the fluxing entities of a design situation. The entity of interest will either flow as a

- distributed continuous flow (mechanical stresses in the skin of an aircraft; weather-flow patterns; pollutants entering a water channel; thermals in an electronic circuit board) or
- channeled flows, wherein the 'substance' flows in distinct channels and/or with varying discrete arrival times (manufacturing materials flow; public transport movements; digital control system; alarm instrumentation system).

Complex situations will often be formed as hybrid combinations of the above.

Flows of both types in a formal model can be formally represented by different descriptions of behavior:

- Deterministic
  - Future behavior is formally predicted from knowledge of the model on a single-point basis.

For example, given the laws of heat flow, the temperature rise of a thermometer allows upcoming values to be calculated at that point in the system space.

- Stochastic
  - Future behavior can also be predicted, but only for the behavior of a group of values having a known statistical relationship.

For example, the height of the individual vehicle driver who will next use a truck driver's seat cannot be predicted, but the range of heights for the set of likely drivers can be predicted.

- Chaotic
  - Behavior appears to be random but does not follow well-known stochastic laws; it appears to be haphazard, that is, chaotic. Mathematical expressions can handle some forms of chaos using different means from the above two behavior descriptions.

For example, work activity in a system engineering process often follows process model descriptions similar to that of a pile of sand grains that is sliding down from the top – that has been formalized as sand-pile chaos.

To make a model perform, they need a stimulator (driver, forcing function, excitation input) to make them represent a particular situation. The resulting system behavior depends both on the characteristics of the stimulator and the model.

Stimulators take several forms:

- Time driven
  These are the equations given as a function of time, such as heat transfer as an item is heated. A suitable time interval and discrimination is required to use the model. The time variable can be speeded up or slowed down in the formal mathematical models, which is not always possible in physical prototypes. This is useful for prediction of future behavior and for understanding events that are seemingly stationary or are arising very fast.
- Event driven
  These lead to a process-orientated model, such as operators conducting an assembly operation in which their task has one kind of statistical variability and the arrival of the parts they need has another.

3 MODELING INSIDE BLOCKS

Models of a system, or part of it, can be in a black or white box form.

3.1 Black box models

Here, the internal working of the model is not necessarily operating in the same way as the internals of the modeled system do. The output/input relationship is, however, a faithful representation of the characteristics of the block's ports as it would be in the real thing.

An example of this is the use of a simple low-pass filter model to represent the torque-speed characteristics of an engine in an overall automobile performance model. Here, the output/input does represent the torque behavior of the engine as a whole, but with this model, it is not possible to investigate such things as thermal behavior and fuel flow of the engine.

3.2 White box models

In this form, the internal workings are transparent and are modeled as a replica of the internal functions. Each subsystem, down to an appropriate level, is formed of white boxes that simulate true internal operation. These can be much harder to build than the black box form and are often not needed. For instance, to model an automobile engine as a fully white box model would be the most complex task, for the overall model would have to cover numerous energy regimes in a fully integrated manner.

Care is needed to appreciate which type of box is being used in a model. When constructing a model, it is necessary to look well ahead to ascertain whether white box modeling will be needed at a later stage of development. Starting with a black box model realized by, say, system identification methods cannot be delved into to give reticulated behavior of internal behavior.

Several methods exist for building the formal mathematical description of models. These are then converted into a suitable form for digital computation. The methods are

- equation – differential equations (DEs)
- finite element – (FE)
- discrete – nodal.

Engineering system or component models using DEs are based on there being available an in-depth understanding of the dynamic behavior, on the basis of the laws of physics that can be expressed in DEs.

Such models in engineering often have to use 'fiddle' factors to facilitate the modeling when the sufficient understanding is not available due to lack of time to develop more knowledge or where no explanation can be realized. For example, in fluid-flow modeling, various 'relationship' numbers are used, such as Reynolds Numbers.

It is highly useful that the formal descriptive equations for electrical circuits also are the same as that for the mechanical and the acoustic regimes. This gives rise to what is known as the method of the analogies. Basically, the DE set for each describes the same simple harmonic motion (SHM) behavior.

Real systems often involve a mix of energy regimes. For example, an audio loud speaker has a mechanical cone suspended by an elastic mount being driven in and out of the magnet assembly by an electromagnetic moving coil actuator. The air column acting on the speaker cone dampens motion. Thus, provided all movements are operating in the linear mode, the system exhibits SHM. Similarly, an automobile suspension system is formed with a coil spring and thus has energy storage in the spring and in the mass of the suspended structure, and there is damping of the energy effects with the shock absorber. This is also a SHM system. Thus, linear SHM systems can all be modeled with the same set of equations, provided the appropriate coefficients are used. It also allows one regime to be modeled with a set up in another. Equivalent electrical Resistor–Inductor–Capacitor (RLC) models are usually used as they suit the regime of operation of the electronic computer.

Given certain system assumptions (or some trickery), it is possible to write formal equations that relate the behavior of most energy regimes into one set of coherent integrated differential equations. This is the basis of many modeling tools. Details of SHM system behavior are covered in **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**; **Article 60, Zero-order System Dynamics, Volume 1**; **Article 61, First-order System Dynamics, Volume 1**; and **Article 62, Second-order System Dynamics, Volume 1**.

4 PROCESS FOR CREATING COMPUTER-BASED MODELS

There is a clear-cut process for developing a formal, and to some extent other forms, model. The following key steps need to be undertaken with care and quality consideration (refer to Figure 2).

1. Study the situation and all known requirements in order to ascertain the particular features that decide the characteristics of the type of model needed, as are described above.

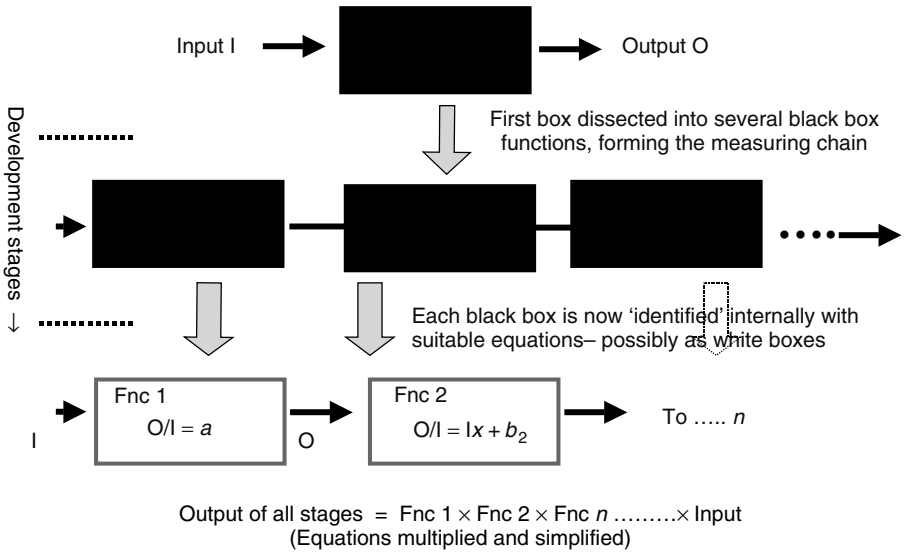

Figure 2. Simplified development of an identified model of a measuring instrument.

2. Decide the limits of the situation for modeling the subject as an adequately closed system – *see* **Article 64, Executing A Measuring System Design, Volume 2** and **Article 68, Setting the System Boundaries, Volume 2**.
3. Set up the architecture of the system in terms of the fluxes of energy or mass, process steps, or discrete activities.
   Consideration about which modeling tool to use commences at this stage. The final choice of model and tool may well take place as the result of many trial starts in which the features of a chosen tool become clearer to the user and are seen to be not suitable after all.
4. Assign blocks and their connectivity to system functions that can be described in terms of black or white boxes.
5. Assign a suitable equation for the output/input relationship of each box.
6. Assign suitable values to the coefficients to characterize the equations of the boxes for the task in question.
7. Integrating the whole equation set into one total equation may be useful here. This may be done automatically for the user in a modeling tool.
8. Set in the boundary conditions to limit the operation to that of interest.
9. Set up the appropriate stimulating functions, their coefficients, and initial conditions.
10. Run calibrating tests to exercise the model, using stimulations that have well-known and proven outcomes.

The model is ready to use in an investigative manner once all of these issues have been decided.

Many general-purpose formal mathematical tools support the above process – examples are MatLab™, LabView™, Ithink™, and so on.

Specialized tools are often available for particular applications.

5 SETTING UP THE ARCHITECTURE

Generally, measuring system architecture is developed mainly by the intuition driven by one's past experience of how things were done before and from the knowledge of new technologies and marketed 'block' products.

It is important to also decide where in the hierarchy of models does the one being developed sit (Davies, 1996). The integration of models in a hierarchical architecture needs addressing early in development as this can determine key characteristics needed.

Although measuring systems are usually thought of as small subsystems sitting inside a much larger whole system, some are very large indeed. For example, the model of a measuring and simulation system for testing aircraft warfare engagement can demand the use of numerous sensors and major computing. Figure 3 shows one such system.

A defined and methodical way to generate the architecture of a measuring system model is to apply the energy matrix method – *see* **Article 112, Systematic Description of Sensors, Volume 2** and **Article 110, Signal/Energy Matrix Modeling, Volume 2**. This is based on the fact that most measuring systems are formed as a chain of energy conversion stages that progressively convert the measurand

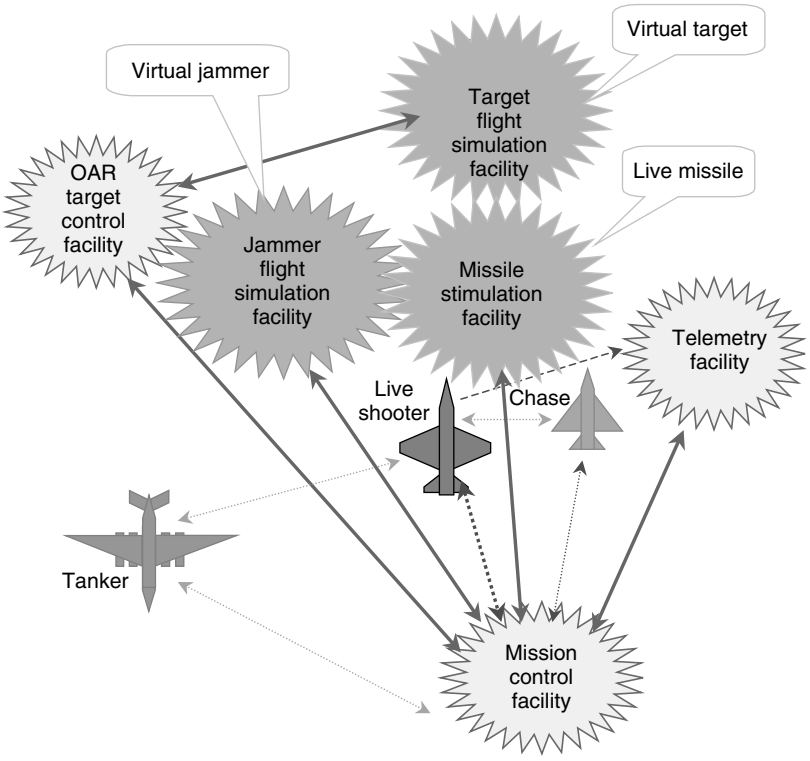

Figure 3. Example of a major measurement and simulation system.

of interest into the usually needed electrical entity required for the following communication and processing system.

Each conversion in the serial chain can usually be treated as a black box. White box models of each will be used where appropriate, but for much of measuring system modeling in support of design, black box representation suffices.

For each box, a suitable dynamic (or static in the simpler cases) describing equation can be assigned to obtain, by overall consolidation, the whole measuring system dynamic performance model.

6 IDENTIFYING EQUATIONS

Where the box behavior is to be selected by design – as is often the case in measuring system design – it is wise to keep them linear in operation because that allows easier and more accurate modeling. If nonlinearity exists, the SHM models cannot be used, except in piecewise modeling operations. Modern modeling tools can handle nonlinear components, but that is not 'keeping it simple'.

For each box, examine the known performance and structural and physical characteristics of the thing it represents. From this study, it is usually clear which type of mathematical description will adequately represent the operation of the box. An exact equation match is not usually necessary and not feasible.

Assign to each box a suitable equation type. Table 1 shows the simplest SHM equations used for modeling measuring systems stages.

For example, consider the design situation wherein force is being converted by use of a load cell on which a strain gauge is mounted to monitor the change in strain of the calibrated mechanical ring. This system clearly possesses

Table 1. Equation forms to select for a linear model stage.

Equation type	Example equation	Measuring example	Comments
Zero-order linear SHM system	a	R-only circuit; amplifier, or stage, gain or attenuation	Fixed value in any situation
First-order linear SHM system	$bx + a$	R–C or R–L circuit: temperature change on heating or cooling	Rise, or decline, without any oscillation, in exponential manner
Second-order linear SHM system	$cx^2 + bx + a$	Weighing scale spring balance; R–L–C circuit	Some level of oscillatory motion, depending on degree of damping

mass, springiness, and a low level of damping so that it can to be modeled with the second-order SHM equation. At the early stage of development, the higher second-order level is selected, ruling it into a lower order when the coefficients of the real situation show that simplification is sufficient.

In some cases, it is immediately clear that a constant (e.g. an amplifier working only in its constant gain frequency range), or first-order (e.g. a temperature sensor immersed in a fluid) description will suffice.

If the describing equation is already known, then use it after reduction to the simplest form that suffices. An example of this availability is the dynamic describing equation often quoted on data sheets for operational amplifiers and instrument motors.

In many modeling tools, a library of linear and nonlinear functions and statistical distributions is provided for selection in mathematical, tabular, or graphical form. The need to appreciate the mathematics has been lessened by these tool features, but one still needs to appreciate what is being used from a foundational viewpoint lest the wrong ones be selected. A safeguard is that good testing of the eventual model will reveal faulty versions – but at that stage, rework can be tedious and expensive.

7 ASSIGNMENT OF MODEL COEFFICIENTS

When all blocks have equation forms assigned, it is time to characterize the model. This process identifies the value of several coefficients of the equations. For example, a spring-mass-damper system of the weighing platform unit will possess gain, damping factor, and resonant frequency, each of which will need to be identified in numerical terms.

When these are assigned, the system should be evaluated by inspection to verify if this higher-order description is still needed. The degree of damping, or the resonant frequency, could well be so high that the system can be modeled with a first-order model, or even zero-order model, thus simplifying the model.

When all blocks have appropriate equation types and coefficients assigned, the serial chain of equations is multiplied together to arrive at the overall model of the specific measuring system being modeled.

Again, inspection of relative coefficients may well show that some stages are insignificant compared to the others and that they can be approximated with a lower-order model.

With modern electronic components and systems, the following communication and processing will often be of zero order (i.e. no phase shift) and, thus, not deteriorate the overall dynamic performance. This always needs to be verified as such, for latency and cable-filtering effects may be significant.

It is best to reduce the forms in the above sequence. Seeking reduction after all equations have been integrated may make it less clear as to which blocks are less significant.

As an example, in the design of the serial set of blocks for an electromechanical seismic recorder system (an inherently low-pass system), the electronic amplifier response will usually be well below its cutoff frequency, meaning that it can be modeled as a constant (zero-order system). In contrast, in the case of an acceleration sensor (which is a high pass system), the amplifier response may be critical and it must be modeled as a second-order system,

7.1 Initial conditions for models

All models need to have their initial conditions set correctly when they are started up. This usually means setting conditions to zero, but it is not always so. System components that need setting are storage elements, positions, voltage levels, fluid levels, and the like.

It is not that well appreciated that some kinds of systems will, given the same initial condition, start up differently giving different solution paths. For example, there exists a class of vibration situations where Eigen values are involved that give differing trajectories.

8 EXERCISING THE MODEL

It is possible for a person with good knowledge of the model and situation to set up tests that seemingly work to show that a model is sound – when it is not! A well-developed test must exercise the system well – not just at obvious points.

The person accepting a model must be familiar with the range of modeling needed. For example, an electronic warfare (EW) instrumentation detection system may well be able to respond as needed for an aircraft flying through a zone containing just one EW threat. This is, however, not a realistic situation, for most real cases will have many more than one hazard present.

Testing should commence from a simple situation for which there is a well-established output. For instance, a new signal spectrum analyzer model can be fed a sine wave. The output should then be a single spike, as shown in Figure 4. A square wave should give a series of reducing spikes.

As confidence grows, the input is expanded to be more complex.

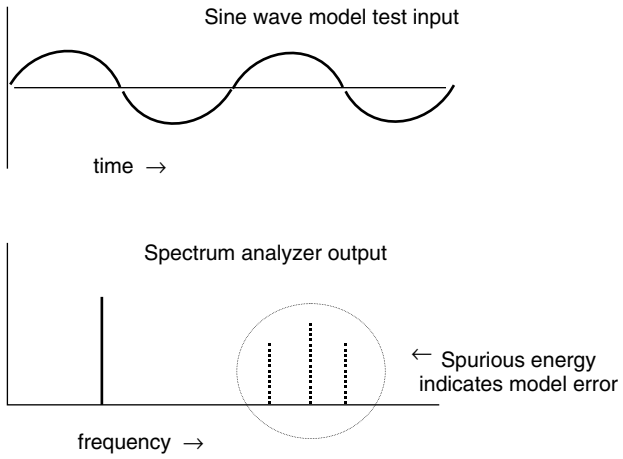

Figure 4. Use of predictable tests to verify models.

9 LIMITATIONS OF MODELS

Models are not perfect representations. The following list of commonly met model performance parameters can be applied to ascertain limitations:

- Shared data consistency – how well does it facilitate data sharing with other models?
- Real-time interaction – does it work well enough in real time or is it really working in 'near real time' that is not 'near enough'?
- Scalability – can the model parameters be scaled up or down and with what loss of precision?
- Extensibility – can its boundaries of operation be extended as the modeling exercise grows?
- Bandwidth – how fast can it model behavior? Lack of adequate response can attenuate the results without any obvious indication that it is now in error.
- Reliability – obviously, one seeks a tool that does not need constant repair and resetting.
- Latency – this refers to the lag time for data to arrive. This is not the same as lack of dynamic response, for lag produces a different kind of error in a response.
- Heterogeneity – does it work uniformly over its working range or do strange and unexpected things happen in certain situations?

10 MODEL VALIDATION

Verification, Validation, and Accreditation or VV&A are the cornerstone activities for ensuring that any model is a faithful representation and can be used with the confidence that whatever is built from it, or whatever uses it, will have a sound basis. Each term is covered in turn in the order in which they are applied in practice. The terms tend, quite incorrectly, to be used synonymously; each of them is quite different in purpose.

10.1 Verification

In general, verification is the process applied first to determine that a model implementation accurately represents, to a sufficient level, the developer's conceptual description and specification. In short, is it what was intended?

Verification is done largely by study of the model needs, as can be found from documentation.

10.2 Validation

Validation is the process of determining the manner and degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model, and also the level of confidence that can be placed on the assessment.

This is performed largely by testing and evaluating the model against the earlier verified requirements.

10.3 Accreditation

Accreditation is the official certification given that a model is acceptable for use for a specific purpose. Obtaining a clear understanding of the 'specific purpose' is a problem at times – models are used in other contexts all too easily.

This is performed after reviewing the verification and validation results. If all is adequate, accreditation is given once a clear statement of its purpose and scope of use is recorded to ensure it is not pressed into incorrect use. This should be carried out by an independent authority who has not been too deeply involved in the model's development.

These three sequential steps seem to be clear-cut, but they can rarely be done on a totally crisp and formalized basis in large systems. Conversely, in smaller systems, they are all too often ignored to save time and money!

VV&A can easily be done against the inappropriate level of documentation and with too narrow and selective a viewpoint.

There is no such thing as absolute truth – not even a real test will necessarily duplicate all of the important real parameters – they are just not known until the actual uses take place. Models must always be used with care, and regular real-world testing must be used to ensure they are adequate.

More detail on modeling in design and its role in prototyping is available in Sydenham (2004). Several texts are devoted to modeling, but they do not address measuring systems in particular – Severance (2002), Zeigler, Kim and Praehofer (2000), Fjeldly, Ytterdal and Shur (1997).

1 USE OF MATHEMATICAL ANALYSIS IN OPTIMIZATION

Optimization is applied in many disciplines, such as engineering, science, control systems, cybernetics, information theory, computer systems and networks, economics and other social sciences, and so on.

In many engineering, science, and technology applications, optimization is used to maximize or minimize the value of a function chosen as the performance index or cost function, J.

The performance is optimized for numerous reasons such as improving the quality, increasing production, maximizing profits, decreasing waste, obtaining greater efficiency, maximizing safety, saving time and energy, and so on. However, in many problems, boundary conditions exist because of limited power, storage capacity, capability of machinery, various temperature constraints, limits in speed, force, acceleration, and so on.

The cost function (see Figure 1) can be continuous and/or discrete. Appropriate selection of the performance index for a given system is important since it determines the nature and complexity of the problem. The system may be linear or nonlinear, stationary or time-varying, continuous or discrete, static or dynamic, constrained or unconstrained. Therefore, appropriate formulation of performance index involves a compromise between a meaningful evaluation of the system performance, availability of feasible mathematical descriptions, and application of meaningful algorithms for their solutions.

It is important to understand that an optimal system under a selected performance index may not be optimal for another performance index.

Figure 1 illustrates a typical optimization problem. In this figure, the sign of the first derivative $\mathrm{d}J/\mathrm{d}U$ of the cost function changes as the function passes through the maximum point. This method commonly uses an initial estimated point (1) where the first derivative is considered (guessed) to be zero. This point (2) is then used, in the direction of steepest ascent (3) or descent as the case may be, for the next point until the absolute maxima or minima is found without getting trapped in local extreme points.

An optimization problem involves two basic stages; first stage is the appropriate mathematical description of the system and the second stage is the solution of the problem using suitable techniques and algorithms. For solving an optimization problem, the following steps may be necessary:

1. A mathematical description has to be formulated.
2. The desired form of the objective function has to be specified.
3. The variables have to be specified.
4. The constraints have to be determined.
5. A suitable optimization method needs to be selected and implemented.

© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

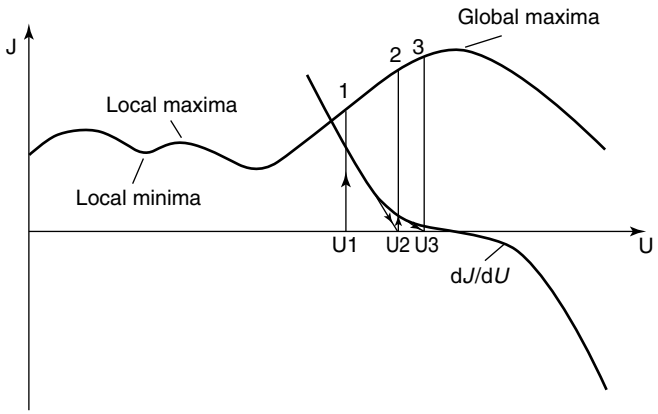

Figure 1. A typical cost function with local and global extremes.

6. Once the problem is solved, solutions must be related to the physical system.

Physical systems are defined (modeled) mathematically usually by identifying the related parameters and using the known properties. The application of optimization allows the selection of those parameters that give the best properties for a chosen preference function.

Once described mathematically, the optimization problem may be solved using computers backed up by powerful software tools, such as linear and nonlinear programming methods, stochastic methods, tabu search algorithms, genetic algorithms, artificial intelligence methods, and so forth.

For the solution of an optimization problem, depending on the nature of the problem, many different methods may be used. For example:

1. If the performance index and constraints can be formulated as linear algebraic functions of the variables, then selection of an appropriate linear programming method, such as simplex programming, is sufficient.
2. If the equations describing the system are nonlinear, then the solution may involve nonlinear techniques or linearization of the problem in some subregions.
3. If the problem involves determination of the largest value of a function with two or more variables, then the steepest ascent (or descent) method, sometimes termed as *hill climbing*, or gradient method may be a good choice, see Figure 2. In this figure, the steps taken to find the optimum point are shown by $S_{T_0}, S_{T_1}, \ldots, S_{T_5}$.
4. If the problems are complex (termed *NP hard problems*), traditional optimization methods based on local information are not adequate to solve them; global optimization methods need to be applied. Some of these methods are Lagrange duality in partly convex programming, robust minimizers, adaptive optimization, decomposition techniques, iterative topographical methods, and so on.

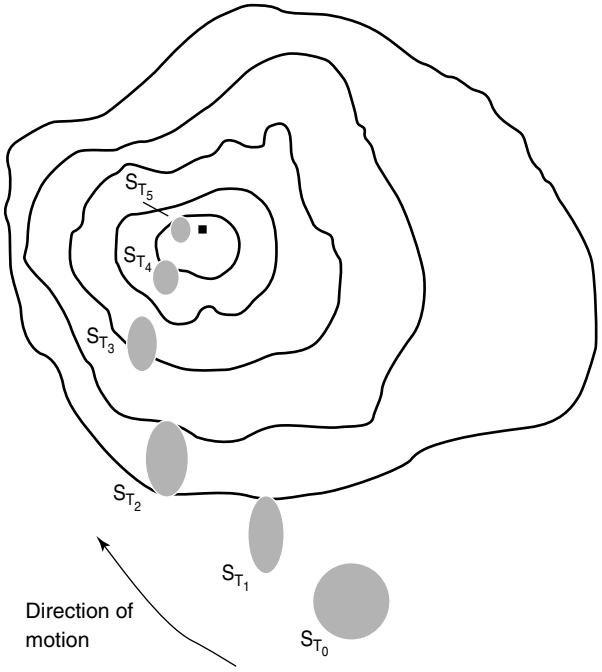

Figure 2. Illustration of hill-climbing with gradient method.

2 SETTING UP THE GENERALIZED MATHEMATICAL DESCRIPTION

Optimization has two main objectives. The first is to identify a set of conditions for a function, f, where min or $\max\{f(x, \theta)|x \in D(\theta)\}$ for constraints, D, will exist as a solution. The second is characterization of the set of optimal points and the application of algorithms.

The mathematical problem involves the determination of a set of values of variables x_i such that the cost function $\varphi|x_i|$ is as small (or as large) as possible. x_i represents the set of all possible variables for $i = 1, 2, \ldots, n$.

However, each variable may be subject to equality or inequality (or both), linear or nonlinear constraints in the form of

$$f_j(|x_i|) = 0, \quad j = 1, 2, \ldots, p \tag{1}$$

or

$$g_k(|x_i|) \geq 0, \quad k = 1, 2, \ldots, q \tag{2}$$

2.1 Linear systems

Many practical problems lead to linear systems of equations, which can involve hundreds of variables thus requiring the solutions of numerous simultaneous linear equations.

The simplest case is the optimization of a single variable, $\varphi(x)$. In simple cases in which there are not many variables,

linear programming can be employed yielding to solutions in n-dimensional space.

If a linear programming problem has a unique optimal solution, then it is an extreme point; if not unique, there is an optimal solution at an extreme point, thus the solution obtained is within a finite set of extreme points.

2.2 Nonlinear systems

Many problems lead to nonlinear (transcendental) systems of equations, which can only be solved by computational methods.

A problem is nonlinear if the objective function $f(x)$ in which x is a vector or any of the constraint functions is nonlinear. Nonlinear functions are classified according to whether their defining functions have the appropriate convexity.

Solutions of nonlinear functions may often be dependent on the differentiability of the constituent functions. If all constituent functions are differentiable, there is an analogous result on the necessary conditions of optimality that can be closely related to the Kuhn–Tucker conditions.

3 EXERCISING THE MATHEMATICAL DESCRIPTION

Standard computational methods for solving nonlinear optimization problems may be divided into three main groups:

1. Zero-order methods (coordinate comparison, simplex methods, and stochastic methods);
2. First-order methods (gradient and quasi-gradient, methods of associated directions, variable-metric methods);
3. Second-order method (Newton method).

Nonlinear optimization aims at mathematical formulation of problems and implementation of algorithms. In the implementation stages, many different algorithms exist, such as numerical optimization, random walk (Figure 3), convex analysis, calculus variations, stochastic methods, game theory, statistical and probability techniques, and more recently, genetic algorithms, and neural networks.

Stochastic methods consist of the calculation of the values of the cost function at a large number of selected points. The selection is made such that each point has an equal probability of being selected. The best points are determined by comparing the function values at a large number of points. Although requiring intensive computational time, stochastic methods are useful for finding the global optimal points, that is, unlike the conventional methods, their likelihood of getting trapped in local minimums is small.

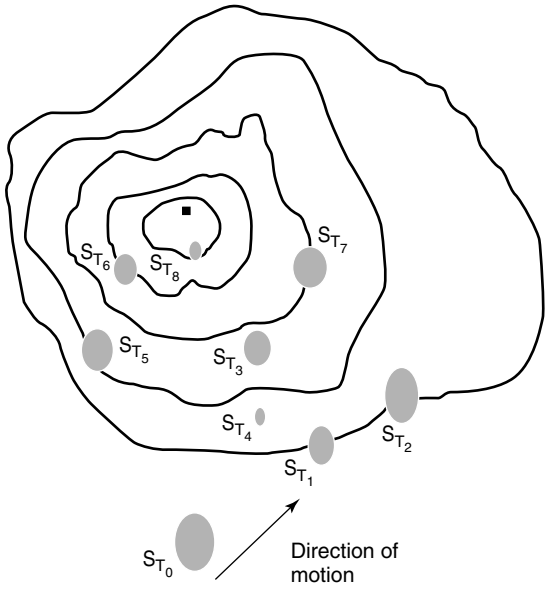

Figure 3. Illustration of random walk method.

Therefore, they find the nearest minimum point as quickly as possible and search for all potential solutions in an optimum manner.

Recently developed, genetic algorithms are used for optimizing the parameters of an unknown system whose mathematical description is either too complicated or unknown. The genetic algorithms are usually applied to neural networks in two levels. The first level determines the suitable weights in the neurons and in the second level, the number of hidden layers as well as the number of neurons is determined.

4 COMPARISON OF MATHEMATICAL DESCRIPTION AND MODELING

The nature of the mathematical description and computational method indicate if the type of problem is to be linear or nonlinear. For example, a linear program is defined as the optimization of a linear cost function whose variables satisfy a system of linear equalities or inequalities.

The term mathematical programming usually refers to linear programs. Mathematical programming has a long history and has been influenced by operations research, game theory, mathematical economics, control theory, dynamic programming, calculus variations, and combinational theory.

The standard form of a linear program is expressed as an instruction to maximize or minimize a linear expression in n nonnegative variables.

Any system of linear inequalities can be reduced by simple substitutions. Associated with each linear programming

problem is a duality as a second linear programming problem. In this association, the original problem is referred to as the primal.

However, the general study of nonlinear programs usually involves such items as integer programs, stochastic programs, and network flow theory.

One broad class of nonlinear programming problems is that concerning minimizing the cost function subject to no constraints; another is the linearly constrained nonlinear programs that include subclass quadratic programs concerning minimization of quadratic function subject to linear constraints.

There are many different ways of solving nonlinear programs depending on whether they display convexity properties and/or differentiability.

Some optimization problems are difficult to solve by conventional numeric optimization methods, even if they converge to an acceptable optimum point in a reasonable time. To solve these problems, other methods have been developed. For example, despite the large size of information to be handled, the stochastic methods reach the global optimum point easily.

In the hill-climbing algorithm, it is possible that an extreme is reached without finding the global minimum. Here, the starting solution is generated at random. Once a local solution is obtained, it is used as the center of a new neighborhood in which the optimization is repeated to determine the other extremes.

Even this way, this method might revert to the local minimum that has already been passed in a previous step, called the *problem of looping*. The program may need to be repeated several times with different randomly generated initial values.

The tabu search algorithm is based on a hill-climbing method that tries to avoid the problem of looping. The hill-climbing algorithm has a short-time memory in which it remembers the optimal solution transformations to generate new centers for iterations. These optimal solution transformations are prohibited (hence the name tabu) when the new neighborhood is created for a given current solution. A hill-climbing algorithm modified in this way systematically searches the entire area in which the global minimum of a function is to be found.

The genetic algorithm is used to optimize systems with unknown parameters. It is useful when other algorithms fail in such problems as where computational time is an exponential or factorial function of a number of variables. In the applications, it is sufficient to know the price of each individual in the population. Therefore, the pricing selection for each individual bears special importance as it is directly related to the outcome of the optimized problem. By application of artificial neural networks in two stages, genetic algorithms are used to determine population, pricing, and optimum points. There are improved versions of genetic algorithms such as scatter search, path relinking, star-paths, and so on.

1 RELEVANCE OF ELECTRICAL AND ELECTRONIC TECHNIQUE

Although electricity was the most recent technological discipline to develop, it was very rapidly found to be the most appropriate for many tasks required in a measuring system. Certain classes of instrument can be constructed without recourse to electrical principles, examples being the microscope, the micrometer, the direct recording water level gauge, and many more. However, if an application needs extensive information processing, signal transmission over long distances, uniformity of manufacture at low cost, ability to be extended, and use systematic design procedures, then electrical technique will usually (but not always) provide a better design solution than other alternatives.

In the context of the thousands of years of measuring systems development, this situation has only arisen in the last half century, wherein solid-state integratable electronic circuitry has provided unprecedented ability to produce low cost, very powerful processing and data handling ability.

Here is presented an introduction to the capability and methodology of electrical and electronic techniques. It must be made clear that although electrical and electronic technique is so extensively used and is very attractive it is not always the optimum means of solving a measurement systems design need. Indeed, there are many applications where the use of electrical methods are either not applicable or they are not preferred, even if usable, for a variety of reasons.

Despite the fact that electrical methods appear to be able to supply every measurement system data handling needs, it must be remembered that the natural world is usually the system that must be interfaced to man's inventions; that world does not possess many signal sources having the same form of physical manifestation as occurs in man-made electrical systems. Thus it is that the other energy regimes will always be important in measurement system design to assist formation of the input and output transudation interfaces. By itself, an electronic system has no practical use – it must be interfaced to an application with some kind of transformation device – the sensor.

Electrical technique includes both the traditional electrical and the more recent electronic disciplines. Initially, the two aspects could be reasonably well divided for purposes of exposition and administration. Prior to 1910, electronics was virtually unknown and electricity was, therefore, clearly defined.

Electrical methods were partially displaced by electronic methods (that grew out of the application of thermionic devices) since electronics provided the circuit theory considered necessary, and initially much of the practice. As time progressed, electronic methods were devised that could also handle most power needs, previously only possible through the use of electrical devices. Today the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

distinction between electrical and electronic methodology is very blurred, although many institutional mechanisms and groupings continue that might imply otherwise.

Until very recent times, electronic technique was generally only suitable for stages following the sensor. In the 1970s decade, however, silicon integratable devices were first developed to yield a new generation of electronically based sensors that are now in prolific use. As time progresses, electronic capability is steadily being extended; the sensor principles are still as current as when first applied.

It is certainly true that in any new application requiring a measuring instrument the designer must now consider the appropriateness of electrical methods for the specific task in question.

2 HISTORICAL DEVELOPMENT OF ELECTRICAL REGIME

The origins of electricity and electronics can be traced to ancient Greece. The distinction between the two is usually based on the premise that both are concerned with electron flow, the former being at a macrolevel, the latter at the discrete electron level; this is somewhat artificial in modern terms of application. Their contribution was, however, minimal compared with advances that began in the seventeenth century A.D. Furthermore, their knowledge was rarely put to use and there was certainly no ordered use of principles of design.

Interest in, and application of, electricity started in earnest with work on electrostatic devices of the form of charge generators and detectors, this being in the century preceding 1800 A.D. Knowledge of charge, its quantity and storage, its transfer from place to place by the use of insulated wires, and its physical effects gave eighteenth century experimenters a tool for further experimentation. Out of their work, gradually, there grew useful applications. Electrical telegraphy first began in the late eighteenth century in a static electricity form. Static electricity led to knowledge about the quantity and potential of electricity and to the understanding that there exist two forms of electric charge: positive and negative. What did not develop so well at first was an appreciation of charge flowing as a current in wires.

Experiments with static electricity, coupled with the improvement in vacuum technique, gradually provided knowledge of discharge effects in gases. These provided a place for the understanding of the behavior of electrons, a maturity that took some 200 years to reach the point where the electron was finally proven to exist as a discrete entity in J. J. Thomson's experiments of 1899.

Although there was much activity in seeking knowledge about the nature of electricity in the eighteenth century, significant progress came only after the invention of the simple primary cell by Volta in 1800. Prior to that time experimenters had only very high-voltage sources possessing high output impedance. It was not exactly the preferred apparatus to use in an investigation of the practical applications of electrical knowledge!

In 1800, the electric primary cell became generally available and, being simple to make, was rapidly adopted by experimenters. Its low output impedance, reasonably long duration of operation, low voltage, and ease of manufacture was admirably suited to the needs of the gentleman scientists of those times. Progress was steadily made in gaining understanding of the fundamental nature of practically useful electrical circuits and devices and in their everyday use.

During the nineteenth century, the laws of circuits, both DC and AC, were formulated through careful experimental and theoretical work. As new laws were published, they were taken up to form technological devices. For example, the relationship between electricity and magnetism was established first as the motor effect in the 1820s. This enabled electrical indicators and electromagnetic actuators to be made. Better indicators of electrical quantities (meters) enabled more laws to be discovered and weaker effects to be applied.

The laws of electromagnetic radiation were also enunciated in the middle of the nineteenth century. By 1888, Hertz had experimentally proven that the theory was correct and that practical apparatus could be constructed that enabled it to be put to use. Marconi, in the last decade of that century, assembled the first practical radio system using simple, purely electrical, components and understanding.

By 1900, many of the basic circuitry laws and physical principles, which are today used to devise instruments, were known, if only as scientific entities. The Victorian era produced much of the electrical systems groundwork needed in twentieth century instrumentation.

A chance encounter occurred in the latter part of the nineteenth century, this being discovery of the Edison effect. It proved, experimentally, that a thermionic device could rectify alternating current. Edison did not, however, make use of this at the time. By 1900, designers of telegraph, telephone, and radio communications needed three important improvements in technological capability. Telecommunication needs provided strong commercial reasons to seek them. These needs were: how to amplify a weak electrical signal, how to rectify radio frequency, alternating currents, and how to generate radio frequency currents. Each of these needs was being catered to at the time by very unsatisfactory methods.

The first decade of the twentieth century saw these three basic needs being met by the invention of one

device, the thermionic valve. It first emerged as the purposefully built diode in which the Edison effect was utilized. The diode was capable of rectification and signal generation. Soon after, the triode valve was devised; it could perform all functions of amplification, rectification, and generation. By the 1920s, the thermionic device had evolved into many forms satisfying many needs, not only in telecommunications but also in the emerging, derivative, instrumentation areas.

Electrical and electronic techniques began their partnership from the onset of the electronic discipline in the 1910s. Tuned circuits, special purpose devices built with valves as their basis, developed; the bistable flip–flop and the DC amplifier being examples that initially fulfilled some special need.

The First World War proved that electronic devices were practical. Training in radio, given to military servicemen, helped the general public to subsequently take an interest in electronics for wireless applications.

Gradually electronic technique spread into industrial usage. By the 1930s, industrial electronics was clearly established. It first began to have an impact through the use of the electric eye, a photocell coupled to a suitable electronic amplifier.

Thermionic components, along with purely electrical devices such as the magnetic and amplidyne amplifiers, were able to cope with most of the heavy current industrial needs that arose; but, in general, electronic method was, by modern standards, slow to be accepted. Basically valve-based electronic circuitry was then too expensive, too unreliable, and too sophisticated for the times to find the widespread use that we have come to accept as the norm of the electronics of today.

It is the field of computing that helped generate incentive to find better technological ways of carrying out the functions developed for valve-operated apparatus. Digital computing, especially, provided impetus for activity, for, by the 1940s, it was clear that very powerful computers could be built that far exceeded those economically possible with valves. A superior replacement for the amplifying valve was needed. Valves used too much power, they ran at too high a temperature, they were too large, they cost too much, and they were not reliable enough to be used in huge numbers.

In the 1940 decade, the transistor was devised at the Bell Laboratories. It did not emerge quite as suddenly as it might seem but came about from gradual evolution of earlier work on the solid-state diode of the 1900 era and after. Valves, in fact, being able to satisfy many of the designers' early needs and expectations, tended to slow down development of solid-state devices.

From the time of the invention of the practical transistor, there has been great increase in the pace of electronic development. Integration made devices smaller, cheaper, and far less power consuming. They enabled the basic level of systems to be gradually, at a quickening pace, extended in sophistication. As an example, in the 1960s a digital counter would normally have been assembled from discrete components using individually picked transistors. Today, the whole multidecade counter, with its display, would normally be purchased as a single basic commercial chip unit that is vastly smaller, far more reliable, and much less costly.

The discipline of electrical and electronic engineering has, for use in the design of instrumentation systems, passed from a stage where originally only relatively small-extent systems could be handled by the average person to one in which very complex and powerful systems are assembled with few technological constraints being placed upon the designer. It is now very much a procedure of being able to more fully express a designer's innovative powers and ability with extensive systems built from basic, very powerful, marketed units, doing this to the limit of his or her imaginative ability.

Space only allows a very short history to be given here. A detailed account is to be found in Sydenham (1979a), where reference to other historical studies is given in the general history of instrumentation presented there.

3 SYSTEMATIC NATURE OF ELECTRICAL AND ELECTRONIC REGIME ENGINEERING

Electrical engineering, as has been described above, developed with a well-ordered basis of theoretical understanding. Indeed, much of what resulted would not have emerged so rapidly without the theory being known. Unlike mechanical engineering, where a large part of its output was able to emerge through the technological path of experimental experience and intuition, most electrical topics can only be understood and applied if the user has a good theoretical grounding in the principles involved. The physical nature of the subject material has allowed its constituent knowledge to be ordered systematically.

Electronic technique rests upon well-understood, theoretically enunciated principles. When used at the level that most users assemble systems (from commercially marketed modules), it also requires a considerable degree of inventive skill. It can, however, be efficiently applied using reasonably straightforward and simplified theoretical aids, such as designing procedures and rule of thumb relationships. The nature of the range that electronic parameter values cover implies that the components, and their assembly, do not usually require very tight tolerances of design.

People with very little training in the basics of electronics can build worthwhile systems. Naturally, specially trained persons can handle the topic with greater ease and better performance.

This fact should not be interpreted as meaning that electronics does not somewhere require in-depth scientific understanding and application of sophisticated methodology. That has become today more the role of the component and subsystem designer, those people have provided a buffer for the end user and general systems designer.

Marketing forces have assisted simplification of electronic and electrical instrument design. The quest for sales, in large numbers, has enticed manufacturers to provide a truly useful and extensive application service. They have sought ways by which sophisticated devices can be used effectively by semitrained persons.

This account is aimed at the semitrained person. It is not intended for the specialist in some aspect of electronic or electrical engineering. It begins by presenting information about the most basic components used to form electronic systems. Whereas many of these may not be used as discrete devices very much in these times, it is, nevertheless, important to have an understanding of the concepts and hardware entities that go into a marketed system module. These basics presented then allows discussion to rise to a higher level in the systems hierarchy wherein description can be given of the marketed building blocks that are commonly used to assemble the specific system needed in a given application. It is then feasible to rise yet further to the final design level in order to discuss how extensive systems are generated.

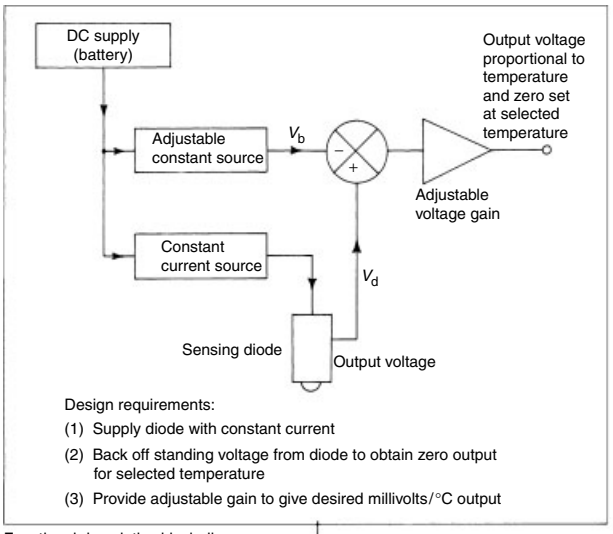
Other conceptual aspects of system design that need consideration are sources of noise in these systems and the power supplies that supply energy for the building blocks.

As an example of the systematic nature of electronic systems consider the diode-based electronic thermometer shown in Figure 1. It illustrates how a system is progressively broken down into subsystem blocks, each of which in turn can be further broken down, the process continuing until adequately basic levels of description are reached. In many systems, there is no need to progress to the individual component level, as the necessary modules can often be assembled from inexpensive high-performance units that only need wiring into the system in the appropriate manner.

The above procedure allows any system to be portrayed on paper at the level needed to adequately specify its functional architecture. Often the reverse occurs and the user may be initially confronted with the final subsystem details, not the primary stage block diagram. At first this may well overwhelm the beholder but the use of the systematic realization procedure to form the constituent, higher-level blocks will reveal how the system operates as each circuit group is identified as a known and familiar building block.

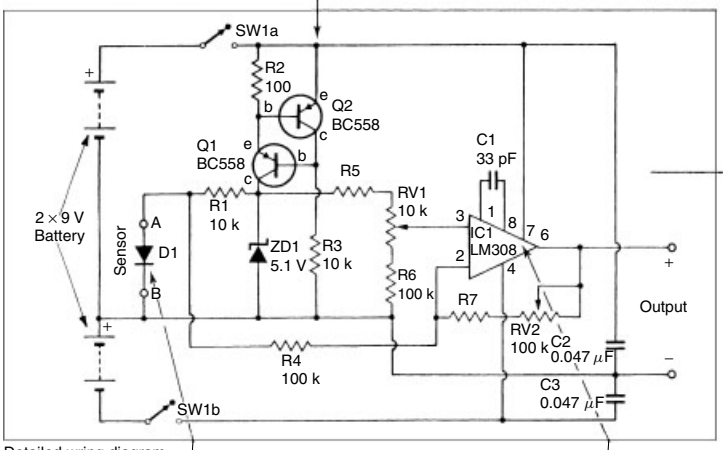
4 LITERATURE OF ELECTRICAL AND ELECTRONIC REGIME ENGINEERING

It is of value to provide an overview of the extensive printed literature before continuing. There exist numerous texts on electronic and electrical engineering. They range, in marketing approach, from trivial expositions to esoteric academic theoretical works. Each has its own usefulness. Although popular texts are often denigrated by experts, they have, over the years, risen in quality, now providing excellent introductions for persons who wish to use and understand electrical and electronic technique at the level of practical use yet not become formally trained in this way. Academic works may often be found to be too advanced for middle-levels users. The reader is cautioned to study a text carefully to establish if it adequately matches the need.



The following selection of published works is presented to assist selection. It must, however, be stressed that many others are available. Electrical engineering principles are presented in Baitch (1972), Bureau of Navy (1970), and Smith (1976) as introductory courses. Similar material is also available in the many handbooks of electrical engineering, but where it is not usually presented in a didactic manner.

Electrical engineering overlaps electronic technique in the area of circuit networks. Linear networks are the easiest to design and theorize (see Leach, 1976; Van Valkenburg, 1974). Nonlinear systems are covered in Fox (1957), Van der Ziel (1977), and Willson (1975). Older texts are still useful for they lay down enduring principles.



Systems of circuitry originally were developed by analyzing given arrangements, but a more positive design approach was developed through which the system can be synthesized to provide a prestated performance: Fox (1952) is but one text following this approach.

One particular class of network is the so-called filter. Modern design procedures for these use previously developed mathematical expressions to arrive at the desired performance using feedback placed around an active amplifier element. Several texts exist on these forms of filter (refer to Burr-Brown, 1966; Hilburn and Johnson, 1973; Huelsman, 1977; Spence, 1970).

Computers have made simple circuitry design almost trivial and more complex systems possible. Director (1974) and Szentirmai (1974) describe computer-aided design of circuits. This aspect has matured greatly and tool suites are available to support efficient design – once the user is familiar with the tool and can afford to purchase the tool system.

As in electrical engineering, but probably more so, there exist many works covering general electronic principles and method. A selection spanning the ranges of depth and of age (early texts contain useful conceptual information and theoretical derivations) is Brophy (1977), Carson (1961), Churchman (1971), Delaney (1969), Langford-Smith (1955), Lowe (1972, 1977), Millman and Halkias (1976), Mitchell (1951), Pender and McIlwain (1950), Ruiter and Murphy (1962), Squires (1967), Starr (1959), Sydenham (1979b), and Waters (1978). Several of the electronic equipment and component suppliers offer packaged courses, which often include aural recorded tapes, experimental apparatus. An example is Heathkit (1978).

Electronic circuits (these involve electrical circuits plus specialized components) are the subject of Jones (1978), Millman and Halkias (1967), Sands and Mackewroth (1975), and Senturia and Wedlock (1975). Lowe (1974) deals with drawing practice for electrical and electronic engineering: caution is, however, needed in using works on this aspect due to the existence of several different standards of practice.

Electronics, as did electrical engineering earlier, spawned numerous new words in its technical vocabulary. Dictionaries are often needed to understand terms used in written and spoken descriptions. Such definitions are given in Handel (1971), IEEE (1972), and Radio Shack (1975). There is a surprisingly close, but not identical, agreement on terminology across the world in this discipline but very few people appear to make general use of the standard terminologies that do exist, so minor localized differences often occur.

It is difficult to separate electronic instrumentation from the total field of electrical and electronic engineering. For this reason, many of the above mentioned general texts may well provide the information sought. There are, additional to these, many books available that indicate from their title that they relate to electronic instrumentation and testing, the main theme of this article. As with all works, they must be consulted to establish their usefulness in a given situation. The following list refers to those specifically on instrumentation and testing: Banner (1958), Booth (1961), Diefenderfer (1979), Edwards (1971), Gregory (1973), Herrick (1972) IEE (1979), Kidwell (1969), Kinnard (1956), Lion (1975), Maeison (1974), Malvino (1967), Mansfield (1973), Norton (1969), Oliver (1971), Partridge (1958), Piller (1970), Prensky (1963), Regtien (1978), Soisson (1961), Studer (1963), Sydenham (1980), Terman and Pettit (1952), Thomas (1967), Turner (1959, 1963), Waller (1972a, 1972b), Wedlock (1969), Frenzel (1997), Gibilisco (1997), Grob (1996), Horowitz and Hill (1989), Mano (2001).

Texts continuously appear that describe new devices as they arrive in the market. To the titles given here must be added, in any search for information, the enormous amount of application notes and internal publications provided by the component suppliers and marketing agencies. Electronic engineering is one of the areas of technology where tradition has given rise to sales backed by extensive published assistance about product use. Some of these publications are included in the following list on devices and components: Cleary (1969) and Thornton *et al*. (1966) on transistors; Lancaster (1976) on the transistor–transistor-logic assemblies, called *TTL*; and Lancaster (1977) on the text advance on TTL, but not its replacement, the alternative CMOS circuitry. Integrated circuits are covered in many books (see Millman, 1972; Rosenthal, 1975; Turner, 1977). Other components are dealt with in Sheingold (1972, 1974). Turner (1978) is on field-effect transistors (FETs).

Thermionic valves are still used in a general way in some countries and will be found in older equipment; their operation is explained in the numerous electronic subject works compiled before 1960.

Often poorly considered when designing electronic aspects of a measurement systems is the need to supply adequately conditioned power. Texts on power supplies and on handling power include Csáki *et al*. (1975), Dewan and Straughen (1975), H-P (1973), Kepco (1966), Marston (1974), and Motorola (1961, 1966, 1967).

As will be explained in more detail below, one regime of electrical and electronic systems is those systems using continuously varying signals that can take any level of voltage or current within defined limits. These are called *analog signals* and the components for use with such signals have become largely known as *linear devices*. The operational amplifier is a salient linear circuit unit. A selection of works on the linear regime includes Burr-Brown (1964), Clayton (1971), Connelly (1975), Faulkenberry (1977), Graeme and Tobey (1971), Gupta and Singh (1975), Melen and Garland (1978), NS Corporation (1976), and Signetics (1977).

The other kind of signal regime uses a signal form that can only exist at two, or sometimes three levels, the former being the more usual. This is known as a *digital signal*. As will be explained below, several basic units exist for building digital systems. They are variously described as units or as combinations in Blakeslee (1975), Bouwens (1974), Breeze (1972), Helms, Kaiser and Rabiner (1976), Kostopoulos (1975), Middleton (1977), Millman and Taub

(1965), Namgoster (1977), Peled and Liu (1976), Rabiner and Roder (1973), and Wakerly (1976). General works on electronic method, mentioned earlier, also discuss the two regimes of signal use.

Manufacturing aspects of electronic systems using computer aids are covered in Cassell (1972). The works Dummer and Griffin (1962), Simpson (1976), and Waller (1972c) deal with testing and reliability of components and materials. Servicing electronic systems has become an important aspect due to the large size extent of equipment used and the responsible position held by it in the general integrity of a plant. Information about this topic is given in Garland and Stainer (1970), Sloot (1972), and Waner (1979).

Finally, in this introduction to the literature of electrical and electronic systems used for measurement, mention is needed of the many books and booklets available from the commercial press and the marketing companies on the use of electronic instrumentation in specific fields. These often repeat some of the basic information in their introductions before moving onto the details of their specific topics. Two examples are Van Santen (1967) on weighing and Piller (1970) on electromedical instrumentation.

5 SIGNALS IN THE ELECTRICAL REGIME

Measurement is the process of obtaining meaningful information about a topic. In the sense of relationship with the real physical world, this is achieved by interpreting received modulations of energy or of mass- transfer. The entity that conveys the information is known as a signal. Electrical and electronic systems make use of electrical energy for information transfer, so their signals occur in some form of variation in the amplitude or phase relation of either voltage, current, or impedance. These three entities are related according to Ohm's law in linearly operating circuits and through other relationships in nonlinear systems. For example, the system may use a constant voltage-source impedance, variations in the, say, sensor causing current modulations to occur at the receiver. Alternatively, the current may be held constant, the impedance variations giving rise to voltage fluctuations. By suitable conversion, through the use of an impedance varying stage, a constant-voltage supply system can be used to supply varying voltage signals.

If the current flows only in one direction, it is called *a direct current (DC) system*. If the current alternates backward and forward in the connecting link, it is known as an *alternating current (AC) system*. Where the system has DC bias added to the AC signal (Figure 2) the current

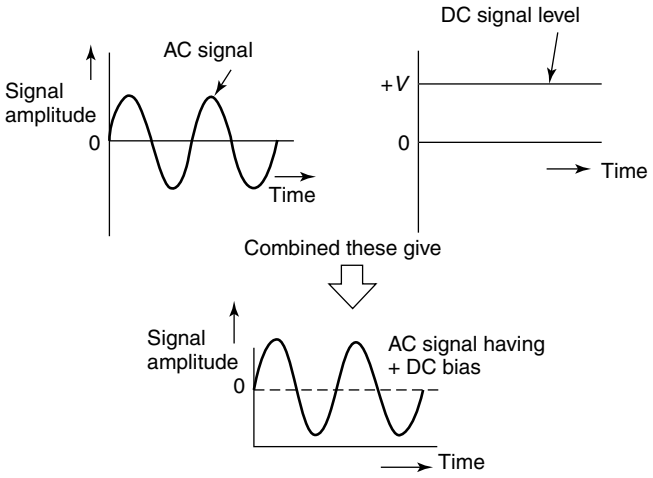

Figure 2. Amplitude-time graph of an electric AC signal having DC bias.

may, in fact, always move only in one direction. This is, however, still regarded as an AC system (possessing a DC level) because the AC signal can be recovered, as can the DC level. A DC level cannot carry information, unless it is modulated with an AC signal, but it is essential in many forms of electronic arrangement.

Signals varying in time (the same concept applies to those varying in space) can be broken down into their Fourier frequency components. Sine wave signals are, therefore, the most basic signal form. Many of the concepts and explanations arising in electrical and electronic engineering rest upon the assumption that the AC signal in question is sinusoidal. If it is not, then considerable error can occur in the inappropriate use of presented information.

Where no qualification is given as to the waveshape or to the averaging criteria used, it is usually safe to assume that the signal is indeed sinusoidal and that the root mean square (rms) value is that which is given.

As amplitudes of the signals and the frequencies that are used in instrumentation range over numerous decades, the practice of compressing the scale from a linear expression is used extensively. The most usual form is the decibel method, which provides compression of magnitude on a logarithm basis.

The range of frequencies involved in signals and systems explanation and operation begins at the cycle period of thousands of years (as arises say, in considerations of the movements of the orbiting planets), passing through the most commonly encountered region of around 10 Hz to 20 kHz (due to widespread interest in audio systems), rising to much higher frequencies for communications and then into the lesser known and used areas above X-ray frequencies. Cosmic rays occur in the 10^{25} Hz region. The most dominant energy frequency spectra used are those

of the electromagnetic spectrum and the audio spectrum. Spatial frequency systems, as arise in optical systems, closely follow many of the fundamentals expressed within the material contained in electrical and electronic method.

This account will now begin at the most fundamental system level at which most users of electronic and electrical systems will need to go, that is, at the components level. Systems will then be considered at progressively higher levels of extent and sophistication.

1 MATERIALS USED IN ELECTRICAL AND ELECTRONIC REGIME

The features of materials and their use that places them in the electrical and electronic regime are their electrical characteristics. Suitable components and assemblies, however, must be made of some form of substance, and design will always rest on possession of knowledge about other properties of both electrical and nonelectrical materials. For example, a transistor is formed of silicon, shaped and arranged with various electrical properties, arranged in various positions to which conducting leads are attached to make electrical connection. The whole is then mounted in a suitable container. Thermal and mechanical requirements of the transistor are as important as electrical characteristics.

Materials are formed of combinations of the basic elements. Atoms form the smallest level of discreteness that generally concerns the electronic and electrical component designer. Atoms comprise electrons, of relatively small mass, that are in orbit around a central, much larger mass, nucleus formed of protons and, perhaps, neutrons. The electron carries, by convention, the negative electrical charge, the nucleus possessing positive charge that retains one or more electrons attached to it.

Normally, charges balance to neutrality, and they usually attempt to establish this position in a material system. Removal of an electron leaves an atom positively charged; this is the positive ion. Addition of an electron forms a surplus of negative charge; this is the negative ion. Atoms are combined to form larger molecules, and these can form myriads of compounds or mixtures that make up all solids, liquids, and gases.

When material is formed of charge-stable arrangements of similar, or different, elements, it becomes unclear as to which atom is attached to which atom of the matrix. This (simplified explanation) results in a matrix formed of immovable atom nuclei between which there exist electrons moving around in what is known as the *sea of electrons*.

This primitive depiction of the make up of materials is far from the complete, real situation but does provide for a superficial understanding of the classes of materials that find different use in electrical and electronic technique.

2 CONDUCTORS AND INSULATORS

A material in which the sea of electrons is very mobile, in which any particular electron can easily be swept away and another attracted into the space resulting, is known as a *conducting material*. Typical electrical conducting materials are the metals including silver, copper, aluminum, gold, and tin. It only requires a small energy level to cause a flow of electrons, the current, in these materials, hence the name conductor. As well as solids can, certain liquids and gases can be good conductors under certain conditions.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Some materials require very high energy potential to obtain electron flow. These are the insulators or resistors. Rubber, wood, glass, most plastics, and ceramics are typical insulating materials. Liquid and gaseous insulators also exist.

Conductors and insulators are at the two ends of the range of resistivities of materials. In reality, there are different materials available with specific resistivities covering the range from one extreme to the other.

Electrical engineering in the main is (or was so in the past) concerned with insulators and conductors and their application. The former are used in suitable arrangements to contain charge (Figure 1) and its flow so that electric current flows in space where it is required. In a wire transmission system, for example, conducting wires are insulated to ensure that the electrical energy arrives at the desired destination with as little loss as possible. In an electrical generator, insulators force current to flow in conducting wires that are revolving in suitably placed magnetic fields.

Materials that form insulators and conductors generally obey the linear Ohm's law given by

$$V = RI \tag{1}$$

where V is voltage potential applied to exert forces upon the electrons, I is the electric current that flows, and R is the resistance to flow, a constant of proportionality for the material.

The electrical resistance between two points on a piece of material is decided by its specific resistance, the cross-sectional area of the material, and the distance between end connections.

3 SEMICONDUCTORS

These form a class of material in which current flow is not necessarily proportional to impressed electrical potential. They have resistivity values just above those of metals. The physics of semiconductors can be most complex. Fortunately, electronic systems development is more likely to need only understanding of what semiconductors can do than of why and how they actually provide their characteristics. For this reason, it is not necessary to provide an in-depth study here. As time passes, the electronic systems designer moves further away from such fundamental considerations, the only people concerned being device

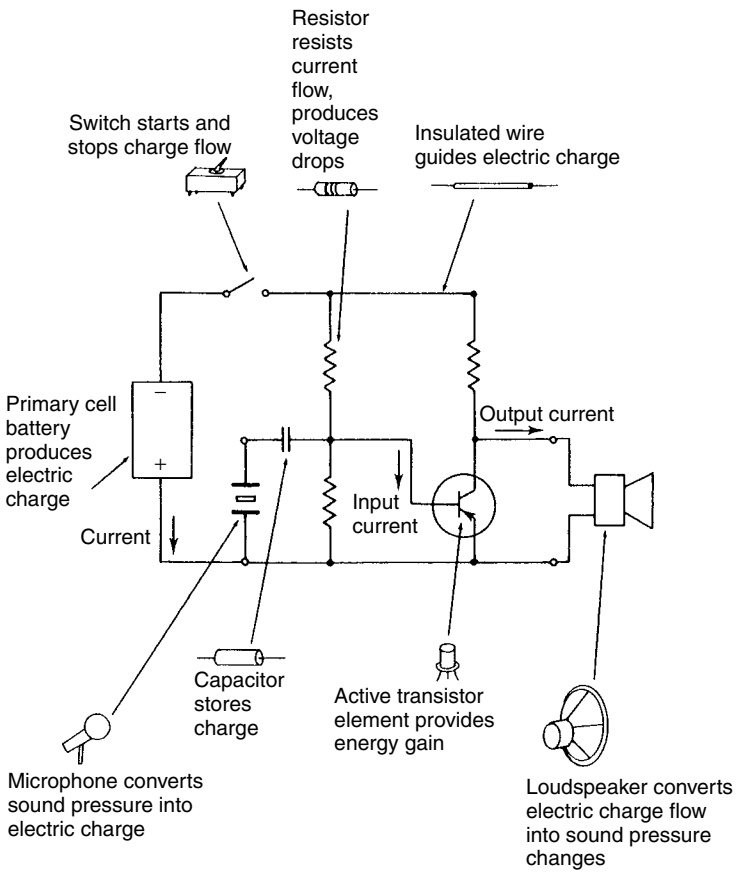

Figure 1. In a simple circuit (a sound amplifier is shown), selected materials provide electrical charge, controlling current flow into the speaker where it is converted back into acoustic energy at greater than input level.

developers and research workers seeking new devices and principles.

Semiconducting materials can usually be distinguished from conductors by their property that thermal energy will cause electron movement, which is not the case for conductors. This is usually (again simplistically) discussed in terms of the energy gap existing in the semiconducting material. If additional energy causes electrons to vacate their positions, causing current flow, the material is denoted as *n-type*. The spaces left are termed *holes*. A second form of current flow can occur in which adjacent valency electrons move to fill the holes. The materials in which this happens are termed *p-type*. As electrons move, they leave holes, thus giving the appearance that the holes migrate.

Suitable additions of impurity into extremely pure semiconducting materials (germanium was first used but silicon is now more generally the basic material in semiconducting devices and with gallium-arsenide for high-temperature uses) can enhance the n-type and p-type behavior.

When a conductor is interfaced physically with a semiconductor, or two of the latter materials are so connected, a flow of electrons occurs across the boundary, reaching some form of equilibrium situation. These connection regions are called *junctions*.

4 PASSIVE ELEMENTS

Subsystem components used to build energy conversion systems can be divided into passive and active kinds, these two being combined into a system to provide the required response.

Passive components are those devices that operate upon signals to provide conversion between voltages and current without being able to increase the output energy level beyond that of the input signal. The output signal energy is always less, because of losses, than the input signal energy. A combination of resistors, for example, can be used to attenuate a signal's energy but not to increase it. It is, however, possible to transform the energy product of voltage and current so that one is made larger than the original form at the expense of the other that is then made smaller. Examples of such transformations are the voltage step-up, or step-down, transformer, and the resonant circuit.

The mainly used passive components are the resistor, the capacitor, and the inductor. The resistor acts to dissipate energy and to resist energy flow by wasting what it does not allow to flow through it. The capacitor and the inductor, on the other hand, can store energy; they do possess losses but these are normally small compared with the storage energy capability. It is the energy storage property that enables signal frequency processing to be obtained. Purely resistive systems exhibit zero-order dynamic behavior; capacitive and inductive systems can be used to realize higher-order dynamic systems as their number is increased in suitable arrangements. The behavior of systems of passive components forms much of the material of introductory electrical engineering.

Calculation of circuit behavior for resistive systems is relatively simple compared to those circuits having storage elements. The simpler resistive circuit theory can, however, often be applied to storage element systems, provided the storage element is considered as a frequency-varying impedance.

The capacitive reactance (its apparent resistance) of a capacitor is given by

$$X_{\mathrm{C}} = \frac{1}{2\pi fC} = \frac{1}{\omega C} \tag{2}$$

and the inductive reactance of an inductor by

$$X_{\mathrm{L}} = 2\pi fL = \omega L \tag{3}$$

where f is the frequency of interest, in cycles per second (Hz), ω the angular frequency in radians per second (rad s^{-1}), C the capacitance in farad (F), and L the inductance in henry (H).

The time-transient behavior of either a capacitor or an inductor combined with a resistor is a first-order response, that is, the rise or fall of signal level to a step input follows an exponential change given by the time constant τ of the combination in question; ($\tau = RC$ or R/L). Resistance acts to alter the time constant and it gives rise to losses in RC and LC combinations. Such losses are not necessarily of importance. Much of electronic engineering makes deliberate use of practical arrangements in which loss occurs, this being quite unlike power electrical engineering where reduction of losses is generally a prime design target. In recent times, engineering of low energy level electronic information signal systems has also concentrated on less lossy arrangements as a means to increase the density of components and to reduce the size and cost of the necessary power supply.

Networks comprising only resistances can be converted into equivalent networks or be reduced to a single equivalent resistance value between two terminals. Inductors and capacitors can only be reduced to equivalent resistive values at a given frequency of operation and when one kind does not interact with others. Generally, this means only series or parallel combinations of a like kind (of inductor or capacitor) are reducible. When the two forms interact to form a second-order or higher-order system, reduction is more complex as it must take into account the vectorial, amplitude, and phase nature of the two components.

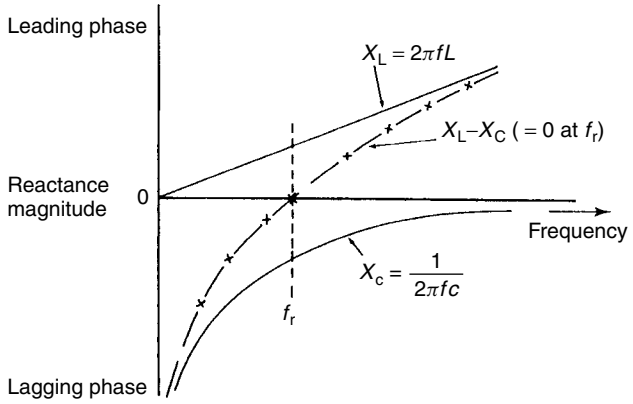

Figure 2. Behavior of inductive and capacitive reactance with frequency f_r is the resonant frequency.

When the two different forms of storage elements are combined, second- or higher-order systems are formed. Losses arising from resistive elements can still be significant but they are, there, usually of secondary importance in basic theoretical considerations.

Figure 2 shows how inductive and capacitive reactance vary with frequency. At a certain frequency, called the *resonant frequency*, where the two reactances X_L, X_C are equal in magnitude, their vector addition results in a combined impedance of zero. This is because they each possess an opposite phase angle. In terms of the complex algebra description, the imaginary components cancel, leaving only the zero, real component to resist current flow.

Resonance, therefore, occurs at

$$\omega L = \omega C \qquad f_r = \frac{1}{2\pi\sqrt{(LC)}} \tag{4}$$

where ω is the angular frequency, f_r the resonant frequency, L the inductance in henry, and C the capacitance in farad.

In practice, no resonant system is free of loss; the real, resistive part has a finite value. This acts to limit the current in the resonant circuit at resonance: the less the resistive component, the higher the series resonance current.

Resonance using an inductor and a capacitor can be established as a series or as a parallel connection of the two, and each of these can be used in a series or a shunt connection in a system. The availability of four options can lead to confusion about how a resonant stage influences the system. It is, therefore, necessary to verify which connection is used. In electronic method, where power loss is often permissible, shunting is commonly used to selectively remove signal frequencies that are not needed. This apparently wasteful but useful practice in electronic systems could not be tolerated in power electrical and electronic engineering.

As the windings of an electrical transformer form an inductor, it is possible to resonate each winding with a capacitor. This forms the tuned transformer, each or one side only being used to increase the sharpness of the frequency selection process provided by resonance. Selectivity is quantified in terms of the Q-factor. The higher the Q-factor, the sharper the resonance; its magnitude depends very much upon the resistance losses in the resonant system. Such losses can be made up by the use of active amplifying elements.

While the resistor, the capacitor, and the inductor are very common in electrical and electronic systems, there do exist other passive elements. Some of these are the transformer, rectifier, temperature sensitive resistor (thermistor), light-generating device, the panel indicator, and other transducers. These, however, can each be reduced, in theory, to combinations – called *the equivalent circuit* – of resistance, inductance, and capacitance.

They are consequently generally regarded in theoretical circuit considerations in an equivalent form. A thorough understanding, therefore, of the characteristics of resistors, capacitors, and inductors, and their combination forms a most basic and important part of electrical and electronic method.

5 ACTIVE DEVICES

Networks formed only of passive devices can be devised that will provide much of the signal processing needed in electronic systems. However, their inability to maintain the signal energy level at, at least, that driving the system stage is a serious disadvantage for the signal progressively degrades down to the noise energy level and becomes lost. Furthermore, the signal input energy may be insufficient to drive the required output transducer. As an example, a signal can be mathematically integrated reasonably well with a simple RC, low-pass filter stage. To obtain accurate integration, however, it must also provide high attenuation. Some method must usually be added to the output to restore the signal level – this is called an *amplifier*. (Early circuit designs did just this but it is often more powerful to use the amplifier in an alternative less-obvious arrangement to obtain an improved overall performance.)

If the network has the ability to make up the circuit losses or increase the energy at the output to more than occurs at the input, the arrangement is known as an *active system*.

Any arrangement that has active properties is capable of providing amplification. Amplifiers are able to provide larger energy signals at their output than occur at their input. At first sight, it appears that the network provides the extra energy needed, but in reality the amplifier acts as

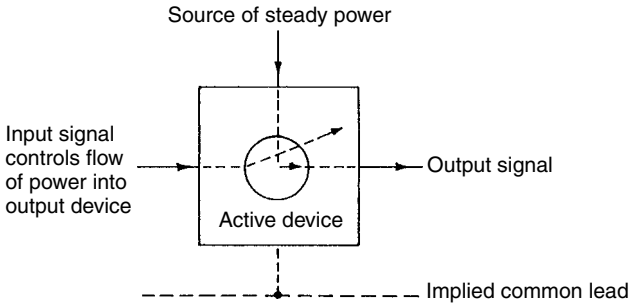

Figure 3. Generalization of a three-terminal amplifier element.

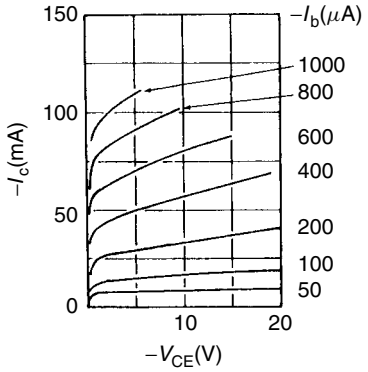

Figure 4. Characteristic curves for a typical, small-signal p–n–p transistor. I_c is the collector current, I_b is the base current, and V_{cc} is the collector to emitter voltage.

a control that allows flow of energy from a supply into the output in accordance with some relationship with the input signal. The output signal is often not electrically connected to the input signal. Figure 3 shows the generalization of an amplifier.

In electronic systems, amplification, also called *gain*, is used in many ways for many purposes. Each of the uses has a different terminology. For example, a preamplifier conditions a low-level signal ready for connection to a following stage. A stage inserted to obtain a more optimum stage match is called a *buffer amplifier*; as the name implies, it buffers one stage from the other so that they do not interact. At the output end of the cascaded system, there is often a need for a power amplifier; this raises the signal power providing the specific matching needed to suit, say, the actuator coupled to the output.

Another is the instrumentation amplifier. These are vaguely defined units that may carry out any, or all, of these functions: the term generally implies that they are able to preserve signal purity and thus retain the meaning of measurement signals passing through the system chain. The operational amplifier is an instrumentation amplifier designed to use feedback in an analog computational mode: they are popularly called *op-amps*.

Each of the above active amplifiers needs to be designed to suit the application in question. Although there are a certain number of basic designs in existence, the specification of an amplifier can only be achieved properly and satisfactorily when the task and the amplifier are well understood.

It is the availability and use of active devices for processing information that largely distinguishes electronics from electrics. Prior to the thermionic valve era, that began around 1910, it was very difficult indeed to obtain gain in a system. The thermionic valve overcame that prime need, allowing numerous active networks to be devised and implemented. It enabled electronic technique to develop. Following the valve came the solid-state semiconductor transistor element. This performs the same role as did valves, operating it in quite similar ways, although not at the electron level of understanding. Electrical method also has some active elements available. The magnetic amplifier, the rotating electromechanical amplidyne amplifier, and the Ward–Leonard motor-generator arrangement are methods for obtaining gain. They are, however, not practical at very small power levels, the devices being too large compared to even valves for them to have been adopted in signal processing in the widespread manner that transistors have over the past years.

The most basic amplifier, in the general sense, is a three-terminal device having characteristics between the three terminals that can be expressed along the lines shown in Figure 4 for a representative electrical component. Transistors, valves, and any other amplifier can be described in this way. Gain occurs when signal input energy can be used to reproduce the same signal at a larger power level at the output. Several other forms of characteristic describing curve can be drawn.

The transistor is the most-used active electronic element today. It is capable, in different forms, of handling very small (picowatt) signals through to very large (kilowatt) signals. It is not practical to use exactly the same actual transistor assembly for all cases; the designer chooses that unit which is most suitable for the purpose in question. Since the development of the transistor, there have appeared many other active semiconductor devices that can provide gain. Each has its special virtues; devices include the silicon controlled rectifier (SCR), the field-effect transistor (FET), the thyristor, and many more. Sophisticated junctions have been devised using a variety of manufacturing methods, these including multiple junction devices. For most practical purposes, it is only necessary to learn about the actual physics of operation within the device on rare occasions. Generally, use of makers' published characteristic curves and numerical values suffices.

As it stands, the transistor, as were valves, is not capable of amplifying AC signals centered at a zero DC voltage

level. This is because the basic transistor p-n-p, or n-p-n, junctions can only pass current in one direction. Only one polarity of the alternating current signal waveform fed into the base connection will be amplified, the other being severely attenuated. It is, therefore, necessary to add extra passive components to the transistor to obtain practical operation. The design of transistor amplifiers used to be very important to electronic system builders but the introduction of low-cost, high-quality integrated-circuit amplifier modules enabled highly specialized amplifier designers to apply considerable effort to the design and to use many more active elements in the design than would have been used in former times. Thus, it is common practice now to assemble systems using commercially available units chosen to suit the need. The user needs to know little about internal amplifier design; only the external characteristics.

The active element can be used to produce gain for use with continuous linear signal analog systems, or it can be used to provide gain through a switching action for use in digital systems. In early times (1840s onward), the electromechanical relay was able to provide gain; it was a prime component in enabling telegraphy to be developed so successfully.

The design of amplifiers is covered in many texts. Of those already listed, refer to Brophy (1977), Carson (1961), Clayton (1971), Cleary (1969), Csáki *et al*., (1975), Delaney (1969), Faulkenberry (1977), Graeme and Tobey (1971), Heathkit (1978), Lowe (1977), Malvino (1967), Millman and Halkias (1976), Senturia and Wedlock (1975), Sydenham (1979), and Thornton *et al*. (1966).

6 SUPPLEMENTARY DEVICES

To the range of passive and active devices mentioned so far must be added a very wide range of supplementary components and devices. These are combined with the previously described active and passive elements to form electronic instrument (and other) systems. It is not practical, or necessary, to cover all of these as a description of a few will give the understanding needed here.

The variety available is most easily seen by reference to electronic component suppliers' catalogs. Electronics always has had a popular following. It began with radio in the 1920s, being added to by audio equipment and television interests. Popular interest then moved somewhat toward all manner of instrumentation for the domestic person's entertainment and use. A typical suppliers' catalog has around a hundred pages of listings.

Systems are generally built assembling the commonly available parts but design needs, where a very large market is assured, will allow new products to be considered. An example are new modules that are appearing as the result of electronic technique being used to a greater extent in mass-produced motor vehicles.

Thermionic devices, although no longer used much for basic amplification, still find some places where they have not yet been replaced by superior solid-state equivalents. Examples are the cathode-ray tube used in television monitors and in the cathode-ray oscilloscope and the older forms of video camera. Thermionic devices are also used to obtain spectral emission in gas analysis equipment. The electron microscope also requires electron emission from a cathode.

Such supplementary devices are not normally built by the less specialized user but are obtained ready to use. If they fail, they are replaced rather than being repaired.

Another example of a supplementary device is the number and letter alphanumeric display device. Such devices again are purchased ready to wire into the circuit. Originally, these were manufactured by the user and were a significant part of the cost of a system. Today, they are often integrated into the complete, ready-to-use, subsystem module complete with any decoding and power drivers required.

Electronic systems need mechanical frames to support the various circuit boards, switches, variable controls, and connections to other stages. These are called *chassis* in older terminology and more recently *frames*. Most network systems are today formed in their final version on printed-circuit boards. These are boards in which all wiring connections between the commercially made components are made by selective etching of a copper coating to form conducting tracks. Holes are then drilled in the copper tracks, so formed, to take the leads of the components, which are then soldered into the copper by hand, or solder-flow methods. Wire-wrapped connections are also used, especially where greater reliability is called for. Printed wiring boards, called *p.w.b. boards*, are also used with wiring on both sides, selected holes being plated through to connect both sides where needed. The actual layout of components on a board more often is to suit manufacturing convenience and does not then follow the schematic block diagram layout.

Printed wiring boards are often connected into the complete system using plug and socket connectors. This makes for easy repair and faultfinding. It also modularizes the system design.

A smaller circuit assembly can be made by printing suitable materials onto a usually ceramic substrate – called *printed circuitry*. These plus, vacuum-deposited conducting metal connecting tracks, make up the passive part of hybrid circuits. To these are added unencapsulated semiconductor active elements formed by the monolithic process. A complete hybrid circuit may then be totally encapsulated to provide environmental protection.

Still smaller assemblies are made by the monolithic methods using masks to lay down progressively conductors, junctions, and components onto the usually silicon chip base. A very large capital investment is needed to create integrated circuits (ICs). The number of circuit elements possible on a single IC now ranges from the original 15 or so to greater than one million.

A myriad of major and minor supplementary components are also used (see Figure 5). Some have already been mentioned: the switch, plug and socket, printed wiring board. It is the ready, and relatively inexpensive, availability of electronic components that allows people with relatively little training to form quite sophisticated electronic instrumentation systems. In many instances, the module required can be purchased in kit form ready for insertion of the components onto a ready etched and plated, printed wiring board. Very little skill is needed to assemble these. The need for skill and understanding arises if they do not function properly!

1 LINEAR UNITS

Electronic systems are built using a relatively small number of various kinds of building block units. They are divided into two main groups: those using analog signals and those using digital operations. Here the former is considered.

After many decades of research and development, a satisfactory general purpose amplifier came into being in the 1950s for use in the first electronic computers: they used analog techniques. The demand for these was rather specialized and their cost and availability were, therefore, rather restricted. However, the introduction of integrated circuit semiconductor technology in which the active and passive components of systems that have many tens to hundreds of elements in their construction and are made by mass replication methods using photomechanical methods, led to the availability of a very cheap and stable DC amplifier. These were taken up en masse because of the versatility that they offered, when appropriate feedback connections are applied.

2 AMPLIFIER TERMS

The satisfactory operational amplifier, the op-amp, must have open-loop gain (without feedback connections) of at least around 10 000, and draw a relatively insignificant input current. It must also be reasonably stable with temperature and time, for any drift of its DC levels internally will provide a related output drift. Furthermore, it should be able to handle both polarities of input signal. Simple integration allowed designers to package a design (Figure 1) with around 20 active junctions, plus some 12 passive resistors, and a few capacitors. Inductors are generally avoided in integrated circuits due to their relatively large size in the integrated form at low frequencies of operation. The cost of the IC op-amp is so low as to now be almost insignificant when compared with assembly costs to place it into use.

Naturally, a general purpose op-amp may not be suitable for more exacting uses and more expensive designs are marketed for such cases. The selection of the op-amp must be made to suit the application. Guidance is generally given in texts on op-amp use and in makers' application notes.

To understand why the op-amp is so versatile, consider the general case of an amplifier with a single feedback path and multiple inputs, as shown in Figure 2. To simplify this explanation, only resistors are considered but in practice the same derivation can be made for complex impedances in place of the resistors.

It can be shown that the transfer characteristic between the inputs $V_1, \ldots, V_n$ and the output V_o, if the amplifier

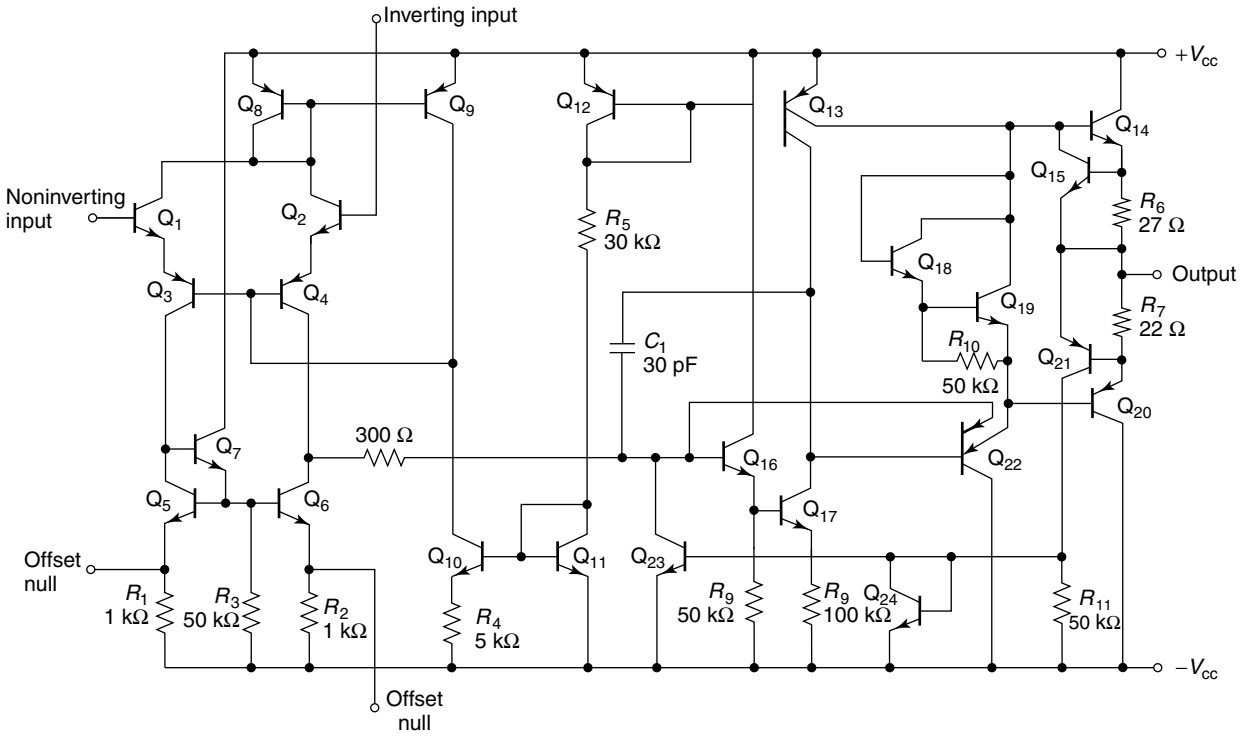

Figure 1. Schematic layout of circuitry of an integrated circuit amplifier.

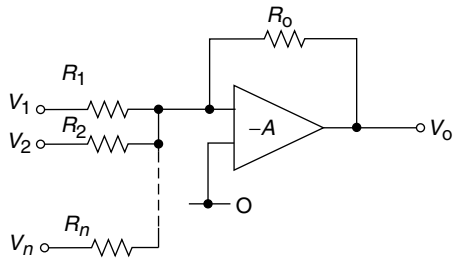

Figure 2. Generalized op-amp feedback connections.

draws negligible current, is given by

$$V_o = -\left(\frac{R_o}{R_1}V_1 + \frac{R_o}{R_2}V_2 + \cdots + \frac{R_o}{R_n}V_n\right) \times \left[1 + \frac{1}{A}\left(1 + \frac{R_o}{R_1} + \frac{R_o}{R_2} + \cdots + \frac{R_o}{R_n}\right)\right]^{-1} \quad (1)$$

This simplifies greatly if the gain A of the amplifier, in the open-loop state, is very much larger than unity, say at least 10 000. Then the above becomes simply

$$V_o = -R_o \sum_{i=1}^{n} \frac{V_i}{R_i} \quad (2)$$

This expression is, therefore, independent of the actual amplifier gain and shows that the gain of the feedback-connected op-amp is decided only by the ratio of the input and feedback resistors. These can be made very stable and accurate in value. As the gain of the op-amp is not a critical parameter, it can be seen that variation of the open-loop gain of the amplifier does not alter the feedback connection gain, this leads to increased stability by the use of feedback. The gain of the op-amp is made very large to allow for closed loop operation.

The gain stability and selectivity features are but one virtue of op-amp feedback usage. It can also be seen from the above expression that input voltages are summed according to a multiplier factor for each input channel. Furthermore, a single input signal appears at the output with the opposite polarity. This is called an *inverting arrangement*. Modern op-amps provide both inverting and noninverting inputs. Their output can swing around a zero voltage level by a typical ±10 V. They are rarely used in open-loop due to the existence then of extremely high gain (100 000 is typical), which has associated with it instability that rises in magnitude as the gain of the feedback system arrangements moves toward the open-loop gain value.

By suitable application of feedback connections, the op-amp can be used to mathematically integrate, differentiate, multiply, divide, summate, subtract, convert from voltage to current source, provide buffer amplifiers of many kinds, act as an analog signal filter, and more. The number of possible uses for linear circuit operation is enormous and

Figure 3. grows continuously. Figure 3 shows some commonly used examples that illustrate this versatility of use.

Op-amps are usually selected and designed according to application notes provided by their makers and to designs published in the, now many, texts on their use. Application notes are generally obtained on request from the op-amp marketing agencies. Suitable texts concentrating on their use are Burr-Brown (1964, 1966), Clayton (1971), Connelly (1975), Faulkenberry (1977), Graeme and Tobey (1971), Huelsman (1977), Melen and Garland (1978), and NS Corporation (1976). Most general electronic texts that originated after around 1965 include articles on op-amp use. Several manufacturing companies specialize in high performance op-amp production; they also provide relevant users guides and design assistance.

The actual manufacture of integrated circuits is discussed in most introductory texts about general electronics. It is continuously changing in refinement and a bewildering

range of terms have been coined to describe the conceptual basis of the new technology. As it is not particularly important to the majority of electronic systems generation, for measurement applications it will not be discussed here. The user should not be daunted by a lack of ability to understand just how an integrated circuit of any kind operates internally. Schematic diagrams are usually published for ICs but these are of passing interest to the user, becoming important only when the information provided elsewhere on the data sheet and application note fails to satisfy the need. On the very rare occasion, it will be found that internal connections may give rise to unexpected operation when the IC is used in a system.

Op-amps and other amplifiers (buffers, servo, instrumentation, interface, and converter) form only part of the range of linear devices. Others are voltage and current regulators, analog-to-digital (A/D) and digital-to-analog (D/A) converter units plus sample-and-hold units all that are used in Data Acquisition Systems (DAS). Other linear modules include specialized radio, wireless, and audio integrated circuits; video amplifiers for television use arrays of transistors and diodes, timers, numerous different purpose units made for use in industry and automobiles (special experimental runs are sold for original equipment manufactures OEM to develop large volume products), display drives, phase-lock loops, and voltage level comparators. Some of these transcend the linear and digital boundary enabling conversion from one signal domain to the other, a very common practice.

3 DIGITAL UNITS

Information can also be processed using digital signals through application of logical principles. The foundation of these principles was laid by philosophers of the late nineteenth century, who had little inkling that one day their work would be applied to actual electrical hardware. Boolean algebra handles, in a mathematical sense, the interaction of logical situations.

These are typified by the use of simply two-state conditions, the most general and basic being connective statements, such as AND and OR. For example, a switch must be turned on if input A AND input B are energized, but not for either one of them. It could also be that the switch is on if A OR B is on.

This kind of thinking and problem solving was first developed to help philosophers conduct arguments on strictly objective logical lines. Their methodology was applicable to electrical switching networks and the first digital (computing) systems were formed using electromagnetic relays. These gave way to faster-acting thermionic valves and then to solid-state semiconductor devices, such as the transistor and the diode as the basic switching element.

The digital family of devices comprises relatively few basic units, but as can be expected they are made in many forms. In the 1970s, a considerable degree of standardization came about and two prime logic systems came to the fore. These are the ones using transistor–transistor logic (TTL) and those based upon complementary metal oxide semiconductor (CMOS) logic families of device. TTL systems are always used with high and low logic levels of nominally 5 and 0.5 V, respectively, CMOS, however, can be used at varying levels of supply. The range of digital devices also is often referred to as the *logic range*. Since then, all manner of logic types have been developed. Fortunately, to build digital systems one does not need such detailed internal knowledge. Basic digital building units are now described.

4 GATES

Systems that perform logical AND, OR and the complementary negated functions NAND, NOR plus some special cases, such as EXCLUSIVE OR, are called *gates*. As an example, two electrical switches in series will provide transmission of a signal if both are closed, that is, if switch A AND switch B are closed. This is denoted as A.B. Placed in parallel, A or B will give transmission; denoted as A+B. The negated NOT form results when the opposite switch state case is considered, the sense of the switches being reversed; denoted $\overline{A \cdot B}$, $\overline{A + B}$, $\overline{A}$, $\overline{B}$.

Modern practice no longer carries out gating functions with mechanical contact switches (some will be still encountered in special applications), the active semiconducting junctions being used as equivalent switches instead.

In use, logic ICs are provided with adequate buffering and suitable interfacing such that the user only has to first decide the logic gating needed and then connect the units accordingly. For large sets of gates – hundreds to thousands – more advanced gate-array methods are used. The internal design of logic units is, again, of little importance to the user. The number of gate functions available in a particular IC is decided by the number of pins available for connection to external circuitry, two being needed to supply power to the IC. For example, a 14-pin IC can provide 12 gate connections, which can be supplied by the maker as either four, two-input/one-output gates; three, three-input/one-output gates; or six, one-input/one-output signal inverters (these negate the logic polarity, but do not invert the signal polarity in the same way as does a linear signal inverter). Logic ICs usually contain only one kind of function on the IC chip; basic functions may be combined

together to form a higher-level function. The exception occurs when a much greater scale of integration (large-scale integrated circuits (LSI) to very large-scale integrated circuits (VLSI)) is used.

A basic theorem about logic gates shows that all digital logic systems can, in fact, be formed from just NAND gates. In practice, however, such methods are not cost-effective and makers subsequently offer a range of different ICs for appropriate selection. To make full use of its available logic elements, the gates on one physical IC unit are connected to different points of the circuit. Many of the functional units that are needed can be formed from gates alone, but again it is generally more practical to use purpose-designed units.

Two active elements can be so interconnected that there exist two inputs and two outputs with a large degree of positive feedback between them. The interstage passive element coupling used between the two elements decides the resulting function. This family was originally described as the multivibrator set. The three forms are the astable, bistable, and monostable. These provide three other basic digital system building blocks.

5 ASTABLE DEVICE

If the interstage coupling between two amplifying units (transistor) is capacitively, or AC, coupled to provide a large amount of positive feedback from one active element to the other, the system will oscillate from one side in the low state, with the other at the high state, changing the states cyclically to form a square-wave output source. The parameters of the interstage circuit largely control the frequency of the switching. These units are also called *clocks* (because they are used to pace in a digital computational system) or square-wave generators.

6 BISTABLE DEVICE

If the two stages are DC connected to provide the positive feedback to the other, the system will rest with one side high and the other side low. A change of the state occurs if one input is fed with sufficient energy to toggle the system to the other state. Such a unit can divide pulses by two as each output state only repeats a state after two input transitions. In early bistable designs, true short-duration pulses of energy were used; today, it is the transition energy of a signal going from a high to a low state (or vice versa) that operates these units. These are more commonly called *flip-flops, binaries, two-states,* and *memories*. They can be used to store a binary state for a chosen output that remains at a given state until toggled, or the power is disconnected. Several forms of flip-flop IC are available, some include gating into its inputs.

7 MONOSTABLE DEVICE

If one intercoupling is made capacitive and the other a DC link (combination of the astable and the bistable connections), the system will toggle over for an input transition returning to the first state after a time period set by the circuit's passive components. This is able to provide a small time delay to digital signals or to restore the squareness of incoming signals as a repeater for digital signal restoration. These are called *one-shots,* or *monostables*.

In each of the above multivibrator units, there are two outputs, one being the negated or complementary output of the other. Either output can be used depending on the logic sense needed. This often allows an inverter to be omitted to create the required logic gate system.

8 INVERTER DEVICE

Already mentioned is another basic digital unit, the inverter. This is used to invert the logic sense of a signal. The need for this often arises in digital system design.

Inverters also can act to buffer one stage from those connected to it. Digital systems often require many connections to an output. The ability of a unit to drive a given number of other inputs is expressed by its fan-out. In TTL systems, the number refers to standard TTL inputs; other uses have to be decided on their merits.

9 SCHMIDT TRIGGER AND COMPARATOR

When a varying level analog signal needs to be quantized into the two standard digital levels, the Schmidt trigger can be used. This unit provides a rapid square-edge output transition from a high to a low, or vice versa, state at a given level of input of analog signal. The trigger level for a rising signal may be higher than for a falling signal, the difference is called *backlash*. Backlash is often deliberately enhanced to give the trigger system a window in which it will not keep retriggering until the signal level has changed its analog level by more than a given amount.

A similar element is the comparator. In this, two voltage levels are compared. If one exceeds the other, the output toggles. By fixing one as a reference voltage, a comparator toggles at that level, as does a Schmidt trigger.

10 OVERALL FEATURES OF DIGITAL SYSTEMS

The above listed units form the basic building blocks of all digital systems. Figure 4 illustrates this point. Digital systems design rests on understanding their characteristics at the conceptual level. Where costs justify it systems formed of several of these units are manufactured as large-scale integrated (LSI) or even larger very large scale (VLSI) integrated circuits. With time, increasing numbers of basic functions are being made available as more sophisticated and powerful, higher level systems units. They are the subject of **Article 76, Electronic Systems Design, Volume 2**. For many projects, it is economical to design and make what are called *application specific integrated circuits* (ASICs).

Digital systems convey their information primarily as the timings of the level transitions; not by their signal levels. The actual voltage, or current, levels of the square waveforms are not of the same significance as they are in analog systems. For this reason, rise and fall times are kept as short as possible. Modern systems will make the transition in fractions of microseconds, that is, in nanoseconds. Circuit connections and component layout can degrade the switching edge. For this reason, high-speed circuits must be carefully laid out and interconnected inside their integration layout. Long interconnecting leads are especially bad unless designed appropriately. The fast rise times of the signals also lead to generation of stray signals. These can influence other parts of the circuit by electromagnetic induction. Furthermore, the energy transients within a stage can cause influencing transients on the power supply line. This would affect other units in the system. For this reason, it is usual practice to add decoupling filters to each small group of ICs to prevent signal unwanted transients disturbing the operation of others on the same mount.

The testing procedures for digital systems are quite different from those of analog circuits. First, information is only available about logic levels at various positions in the circuit. Display, using a logic analyzer, of numerous states is used to fault-find a digital system. Another feature is that the system can be stepped, or clocked on, one step at a time at any speed that is convenient. Analog systems must act in real time to provide proper operation of many of the circuit functions. Timing between stages is important in some digital designs and time delay may need to be considered in what is called a *race condition*.

The design of digital switching systems can be made very sophisticated using well-established logical mathematical and graphical procedures. Design is largely aimed at reducing the presence of redundant logic gates that generally occur in the first realized logic network design. In many applications, however, it is often less expensive overall to leave redundancies in the system; their location and elimination can be very time consuming and requires an in-depth understanding of switching theory.

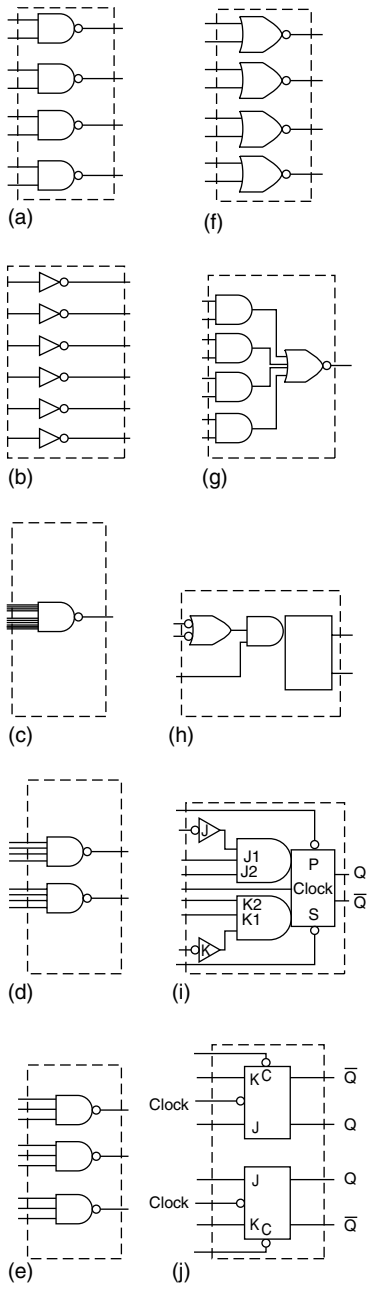

Figure 4. Schematic diagrams of some typical integrated digital circuits: (a) quadruple two-input positive NAND gates; (b) hex inverters; (c) eight-input positive NAND gate; (d) dual four-input positive NAND gates; (e) triple three-input positive NAND gates; (f) quadruple two-input positive NOR gates; (g) four-wide two-input AND–OR invert gates; (h) monostable multivibrator; (i) edge-triggered j–k flip-flops; (j) dual j–k master-slave flip-flops.

Digital systems units are covered in Blakeslee (1975), Bouwens (1974), Brophy (1977), Diefenderfer (1979), Heathkit (1978), Kostopoulos (1975), Lancaster (1976, 1977), Middleton (1977), Millman and Taub (1965), Millman (1972), Namgoster (1977), Sydenham (1979), Wakerly (1976), Frenzel (1997), Gibilisco (1997), Grob (1996), Horowitz and Hill (1989), Khalil (2001) and Mano (2001).

More detailed works exist on the various aspects, such as switching theory, Boolean algebra, and manufacture of digital systems.

1 APPROACH TO ELECTRONIC SYSTEM DESIGN

Originally, electronic instrumentation systems were devised using the basic active and passive elements, plus supplementary devices, to realize whatever basic functional units were needed. Almost all early electronic design was carried out using *discrete* components. Design then, therefore, first needed to form the functional building blocks, which were then interconnected to obtain the overall required performance.

As an example, to build a fast reversible digital counter in the 1960s, it was necessary to first develop a fast flip-flop using more active elements than were commonly used at the time for slower speed counters. A logical arrangement had then to be devised that would count as fast as possible, providing the output digital code needed for the display. It was also necessary to develop the display for the numerical output as a distinct project facet.

Today, the same detail of task no longer exists for the designer of measurement systems: complete counters like that mentioned above are now offered for sale with integral display. The most basic way to assemble the system now is to make use of standard integrated circuits driving an integrated digital display. The same unit is also available as a single LSI (Large Scale Integration) unit costing the equivalent of less than an hour of a technician's time.

Systems design is based on first having a sound conceptual understanding of the task, this being committed to paper in the form of block diagrams that lay down the signal flows and show the characteristics needed. These are then refined, until the first apparently workable system is ready to assemble. A prototype is then put together using temporary assembly, with soldered or plugged joints. A number of proprietary assembly methods are available; many avoid the need to solder. When the prototype is thought to be satisfactory (from actual tests) the circuit is made in the printed wiring, printed circuit, or hybrid integrated form. Large organizations will make use of advanced design support tool suites that can be used to create a design in the computer, which will be almost perfect when actually manufactured. While such tools do exist, they take time to install and learn. For this reason, many electronic systems created for measuring systems are built from components, the design being tested as it is developed.

It is generally the case that the first system design will not be entirely suitable. This occurs because design of any technological system relies on the designer making the correct assumptions about a system that he or she is not yet familiar enough to make. The actual act of assembly and testing the prototype considerably improves understanding

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

of the need. The degree of success in arriving at a suitable initial design relates to the complexity of the problem and the designer's experience. Where possible, proprietary modules are usually used to reduce the need for design knowledge. This eliminates many design decisions. If the modules are well tried and proven, then the whole is more likely to be reliable. Digital systems tend to be easier to develop than analog ones.

Interaction between stages is probably the greatest source of prototype development difficulty. Stages may excessively load the preceding one or transient signals can influence other parts of the system. Race conditions, in logic systems, can also occur if some part of the system acts faster than others where timing is an important parameter. Many of these problems cannot be dealt with by rigorous mathematical methods, unless a model-based tool is being used. The designer's ingenuity is called upon to ensure that as many of these likely problems as possible are circumvented, or allowed for in some way.

When a suitable prototype assembly has been developed, it must then be tested for operation in a real situation. Temperature, vibration, mechanical strain, humidity, and many more influence quantities may prevent proper operation. Because layout can be important, it will first be necessary, in some cases, to construct an assembly that is very close to the actual construction method to be used. The prototype should never be destroyed or changed as the next version is being made. It will often be found that the second, supposedly superior, system exhibits faults that were not seen before. A check of the first prototype may well show that the faults were also there in that model, thereby showing that the design is at fault, not the change in layout.

The design of integrated circuits is usually more rigorously achieved but even there, where it is possible to devote more effort to a specific problem, similar methods are often utilized to produce a layout for integration. Prototyping of this level only occurs in specialized groups.

A very common error is to regard a single, apparently satisfactory, assembly as being necessarily typical of a batch production run. Too often, production begins on the strength of inadequate testing and tolerance-spread checking. It is wise to expand from 1 to 10, to say, 100 systems, when very large numbers of an identical unit are needed. Specialized functions such as reliability and thermal behavior are often overlooked in low volume designs, with subsequent need for redesign.

This short article can only introduce electronic systems. In practice, the electronic part of a measurement system is usually but a portion of the whole, each module being considered in turn, and then the whole, on other grounds such as reliability, production needs, and sales and service requirements.

2 COUNTERS

Many modules are now available from which a system can be assembled. It is usually not necessary to build systems using the basic linear and digital integrated circuits with, perhaps, a few discrete components. This section considers a few of these larger subsystems; the number constantly grows as designs and demand appear, enabling integration to be used at a commercially viable level. A good set of maker's catalogs and Web links need to be developed to support chip availability information.

A cascaded chain of flip-flops will divide a time sequential string of digital logic levels according to the math of binary division. By suitable arrangement, the chain can be used to count up, or down, or be reversible according to an external direction control signal. If the signal passes from stage to stage in sequential order, the pulse *ripples through* taking a considerable time (up to microseconds) to pass through many stages. This form of counter is called *asynchronous* for state changes happening in any stage of the chain are not necessarily made all at the same time.

By suitable interconnection of the stages, the ripple-through time can be greatly reduced by causing an input pulse transition to set each of the stages simultaneously. These are called *synchronous* counters. They are more complex to interconnect, but, as they are rarely built from discrete components, this is not a problem for systems designers; it has been done in the manufactured IC. Counters can easily count at rates of 100 MHz and higher rates in the low GHz region, the reversible kinds reversing in as little as nanoseconds.

Binary counters count in a *binary* sequence. To change the contained binary code numerical value into the often more useful *decade* form, they must be decoded by a suitable conversion logic network.

It is sometimes more convenient not to count in pure binary, but to use what is called a *binary coded decimal* (BCD) system instead. In this system, four flip-flops are used to form a counting chain that passes through only 10 and not the binary's 16 states. Feedback between the counting stages is used to achieve this. The actual coding used within the four-element system decides the form of decoding network needed to drive the chosen decade number display. The individual BCD units are then cascaded using simple connections to obtain the number of decades display needed. Many of these design variables need not be known by the use of ready-made LSI counter/display modules. In many instances, their price is so low as to make any thought of new development quite unrealistic. They are very well tried and proven.

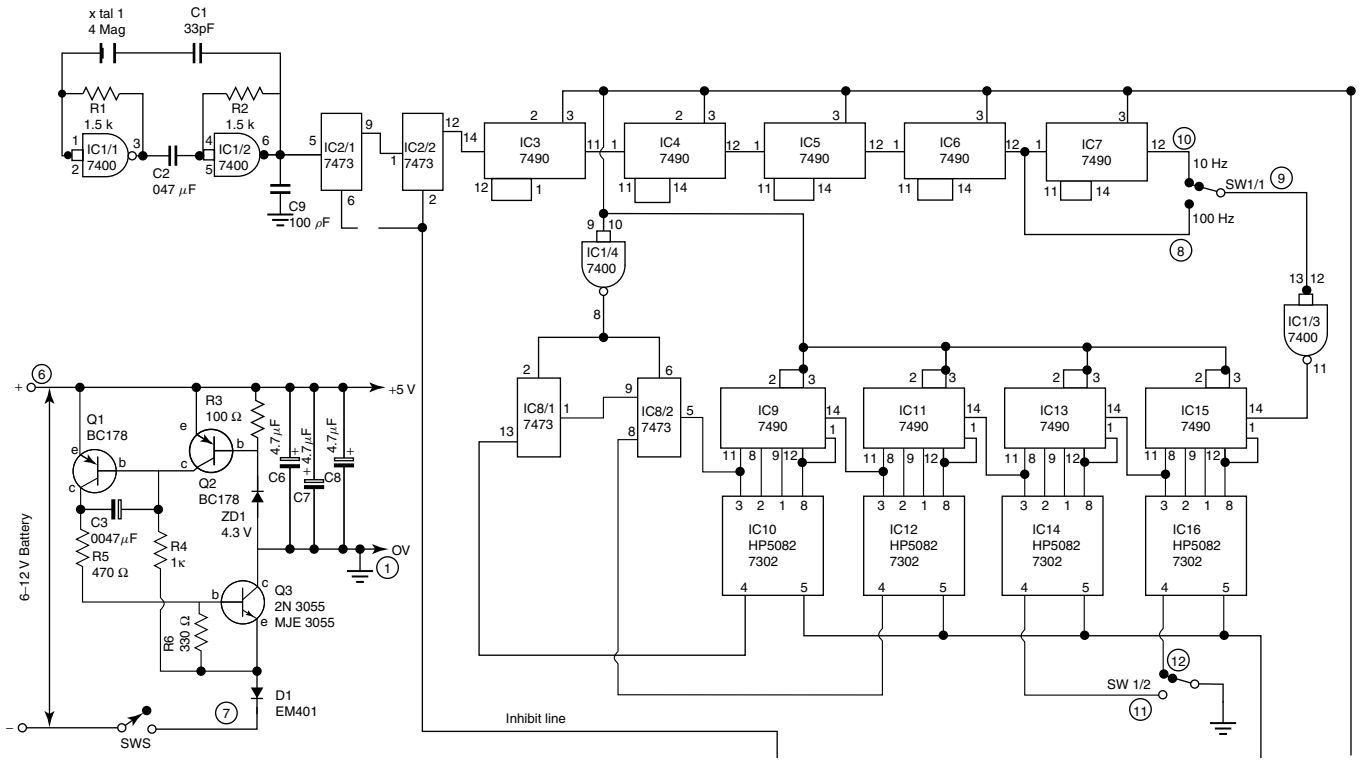

Figure 1. Schematic block diagram showing, as an example, how basic IC modules are used to form a general-purpose digital stopwatch.

3 FREQUENCY COUNTERS AND TIMERS

Addition of a *clock source* (a square-wave generator of known frequency) and a suitable turn on, and off, gate system forms a method for measuring the frequency of a signal. The gate is, in one version, operated from the clock allowing the counter to accumulate one count per cycle of the signal being measured, for a known period of time. This determines the frequency of the signal; the count is displayed as frequency. If a count from the clock is measured for the time during which the gate is held open by the cycle time of the signal, then a period will be measured. Figure 1 shows the IC modules used to build such a unit.

Similar principles are used to count objects as part of, say, a batch control system.

Timing is also possible using linear modules in which an output is held, say, high for a preset duration. In linear methods, mathematical integration is used to produce a time interval. Linear methods are not capable of the high timing precision afforded by properly designed digital counter/timers.

4 REGISTERS

A register is a form of cascaded flip-flops. A digital binary number is passed into the digit stages from one end (*serial input*) or to each simultaneously (*parallel input*); each flip-flop then records a respective digit of the number. Action of the clock-pulse input causes the number to remain intact, yet be stepped sideways in either direction. This is used as part of the hardware of several mathematical operations using digital binary numbers.

5 DIGITAL-TO-ANALOG CONVERTERS

A digital number is often needed in an analog equivalent form, for example, as might arise when an electronic digital calculation has been made and the resultant must operate an analog signal device. Several methods of conversion exist for this direction of conversion and for the reverse, where analog signals are converted into digital forms. These functions are rarely made any more from discrete components; the cost of ready-to-use modules being low enough to encourage selection for direct use in the larger system. Although designers do not need to develop these converters, it is very important that their internal operation is understood as the performance can vary greatly with application.

6 MULTIMETERS

As an example of an electronic instrument system, consider the apparently simple high quality multimeter. This instrument has undergone extensive change in internal design philosophy in recent years and exemplifies the general trend in electronic systems operations.

A multimeter has the purpose of allowing the user to measure voltages, currents, or resistances of a system and its components. Originally, these were always made from an electromagnetic meter indicating movement to which appropriate multipliers (series resistors – for voltage ranges), shunts (shunt resistors – for current ranges), and operational battery, and series resistor (for resistance) were switched into circuit as needed by the operator. A multimeter of better quality would normally have overload protection to safeguard the meter from accidental damage by inappropriate connection.

The entire unit used analog methods and could also incorporate a linear amplifier in the circuit to raise the terminal resistance to 1 MΩ or more in order to remove loading effects in use.

The alternative design, now almost always used, contains ICs and some discrete components. It operates internally almost entirely using digital, rather than analog, signals.

The user must still select which variable is to be measured, but need not select the range; systems are *autoranging*. The input signal is first converted into a digital equivalent using an analog-to-digital converter stage. The signal is then used with counters and digital display to show the value in digital format.

Another example is the use of digital methods to produce a very accurate *sample-and-hold* module, over a long period of time. In these, the analog storage capacitor that stores the voltage level in the linear analog system has *internal leakage* that degrades the voltage level with time. If the capacitor is used to sample the level and the value so obtained is immediately converted to a digital equivalent form, it can be stored for an indefinite time period. Recovery uses a digital-to-analog converter.

The relative cheapness, increased reliability, and often enhanced accuracy of digital alternatives easily outweighs the fact that internally their design is far more complex, and uses many more elements, than does the analog alternative.

7 MICROPROCESSOR

The concept of a totally general-purpose basic electronic digital building block was taken a step further with the introduction of the *microprocessor*. This is an LSI circuit, Figure 2, that contains the architectural features of a basic digital computer system. It can be set up internally, through the use of external *software* programming, to perform an incredibly wide range of circuit functions. It operates internally as a digital computing, but the interfaces used to connect it to the chosen application allow it to be connected to analog devices when needed. Its low cost enables it to be used as a most basic single component that is set by the user to perform specific tasks. It is set by software programming rather than by hard wiring.

In reality, a considerable amount of peripheral equipment may be needed and the cost of this can far exceed the cost of the microprocessor itself (less than a few man-minutes of time). Even so, the general-purpose nature of the module makes it a first choice, when seeking to design a complex control system. Rather than make connections with wires the user writes a program. Once set, the microprocessor-based system can be reset reasonably easily.

Use of microprocessors needs little understanding of the concepts, basic modules, and building blocks of electronics. Microprocessors have brought about a marked change in the design philosophy of electronic systems of the future. Some predict that the cost of the microprocessor will fall so low that it will find use in numerous low-cost applications. There is a running shoe with one in it. A modern automobile has dozens in its control and instrumentation.

With microprocessors, little electronic knowledge is needed to create the system: programming skills have been largely exchanged for network and system design expertise.

Despite this, peripherals still need to be designed and connected and in many situations, microprocessors and other marketed general-purpose computational designs are not able to match the performance possible from special-purpose designs.

The programmable logic controller (PLC) can be placed in the same class as microprocessors. These are systems in which the circuit wiring to provide the actual system task needed (basically switching networks) is again done by a form of direct programming into the computer-based system. Changes to the system operation are easily carried out without the need to enter the electronic level of operation, or to be an expert at programming a computer.

The operational power that can be provided by one, or more, microprocessors has, as did valves in their more primitive way, allowed the designer still greater freedom of action in implementing conceptual schemes.

It is now normal to build electronic systems that are self-checking, that can diagnose themselves, and that can make reconnections to overcome failures – these have been coined the *smart* systems. A useful level of artificial intelligence has already been achieved in electronic systems. The low cost, small space, and power needs

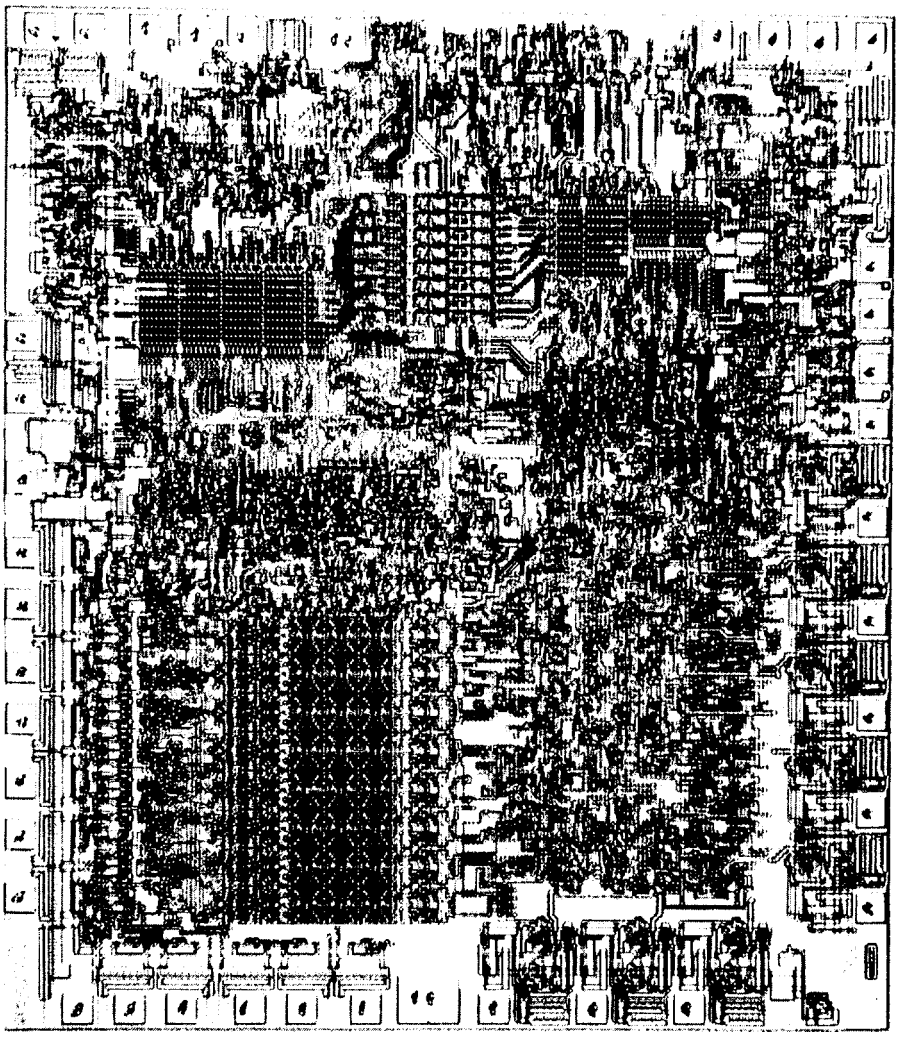

Figure 2. Internal arrangement of a typical microprocessor IC.

of the microprocessor enable very extensive strategies to be implemented on reasonable budgets of finance and time.

An original suggestion was that as the microprocessor was standard methodology, texts written on the microprocessor would be general purpose. To some degree this is true, but usually there is the need to access information on the one being used in a design. Too many variations have emerged from this very powerful technology.

8 INTERCONNECTING STAGES AND SIGNAL TRANSMISSION

Whereas the modern electronic system designer has less to consider now about the internal design of building blocks and modules than in the past, it is still as important as ever that they be interconnected properly. If the connecting links are considered as additional stages, then they are likely to receive the attention that they must be afforded. Even when modules are wired in close proximity, they must be connected appropriately.

It is necessary to consider the connections carefully, for the link itself may act as a frequency filter, alter the amplitude of signals, pick up unwanted signals, introduce phase shifts, or be mechanically unreliable.

Within closely assembled circuitry, simple printed and insulated wiring will generally suffice unless high frequencies are involved above around 1 MHz. If the distance between units exceeds a few meters, then it becomes necessary to select a more suitable form of signal transfer method. The *open-wire*, as seen on old telephone poles, is usable to around 10 MHz, but beyond that the higher frequency signals need other transmission methods. The open wires are very lossy and not particularly secure from damage.

An alternative is the *coaxial cable*. This is formed from conductors suitably placed with a separating dielectric. They are made in circular, flat, and strip sections each having its special application. They can convey signals to around 5000 MHz. Multicore insulated cables could be considered to be of this type, but they are not usually designed for high-frequency use, having excessive losses.

Above the usable range of signal frequency suited to coaxial cables, it is necessary to make use of *waveguides* and open-space *electromagnetic* radio links. Laser-based *optical fiber* links are also capable of conveying these high bandwidths and are used prolifically, see Wolf (1979) for details. They play a major role today as they are not prone to the same stray signal, pickup, effects as are electronic transmission systems.

Whichever kind of electrical communication line is used, certain basic generalizations can be made. First, a short line will possess small values of self, shunting, capacitance, and resistive losses. As the line length is increased, the capacitive effect becomes more dominant, the line then acts as a low-pass filter: this gives attenuation and phase shift to the signal being sent over the link.

The coaxial cable exhibits an interesting feature for reasonably high frequencies of use. There the impedance that can be seen by looking into the end of an adequately lossless line of any length can be regarded as being of fixed pure resistance. This is called the *characteristic impedance*, Z_0, of the line. Common values made are 600, 100, and 75 Ω. Thus, the actual length of the line matters little.

When high frequencies need to be sent over transmission links, a serious effect occurs if the terminating impedance is not purely resistive and equal to the characteristic impedance of the line used to make the connection. If mismatched, *reflections* of signal energy occur, and time-varying signals are generated in the links that feed on and back, at each end of the link. At lower frequencies, the mismatched line acts to alter the signal magnitude and phase; reflections produce distortion and loss of power transfer. It is, therefore, always important to properly match high frequency–signal terminations. This subject is covered in Johnson (1950) and in Sinnema (1979).

9 GROUNDING AND SHIELDING

Another aspect of stage coupling is the need to preserve the signal-to-noise ratio (SNR). Ideally, a coupling should not degrade the system, but in practice there will always be some reduction.

Analog signals are more prone to this, for their information is conveyed as an amplitude. Coding and the use of digital signals are often better alternatives to use.

Several connection techniques can be used to reduce stray pickup in wiring. The principles apply to both long and to even very short leads in low-level detection systems.

A first possibility is to transfer the information over the link at some frequency away from that of the expected noise. It is then theoretically possible to filter out the signal at the receiver. This method can be satisfactory, but all filters allow some level of signal through, and the price paid for sharp highly discriminating filters may not be acceptable; for instance, they tend to *ring* to rapid transient changes of signal level.

A better approach is to reduce the noise level at its source. If that is not possible, then the wiring can be arranged such that two parts of it pick up similar noise signals, which are out of phase by 180° at the detection stage. They then cancel to leave only the unbalanced contribution. This principle is known as *common-mode rejection*. A twisted cable pair does this, as each wire has an equal signal induced in it by common radiation coming from the noise signal source; the two being induced in opposite directions in the detector input circuit. To obtain the best from common-mode rejection, connectors, and the input stage of the active circuitry must also be differentially arranged in this manner. Common-mode rejection should not be used to remove noise that can be reduced at source, for the common-mode noise signals can require amplifiers with unduly large dynamic ranges to avoid serious distortion occurring.

Shielding is also a method used to reduce signal levels induced into connecting leads. Leads form antennae in which electromagnetic fields will induce voltages. Thus, the shorter the leads, the lower their impedance. The better they are shielded, the smaller will be the induced currents. Shields, and their necessary earthing connection, should not by themselves form a significant resistance closed electrical circuit, for the *earth loop* then produced will produce circulating currents that also induce unwanted signals elsewhere.

Radio frequency energy – electromagnetic interference – can also be bothersome. Often the problems are overcome by preventing it escaping from the generating source by careful scientific design of the enclosures. Alternatively, the detecting apparatus is screened.

Several specific texts are available that provide detail on long line–transmission systems, for example, Johnson (1950). Low noise systems, and how to couple them, are the subject of Morrison (1977), Motchenbacher (1973), and Ott (1976).

1 SOURCES OF FUNDAMENTAL PHYSICAL LIMITS ON DETECTION

As in all of the energy regimes, electric energy systems also possess certain physical processes that prevent sensitivity from being increased to infinity. No matter how well contrived and constructed the apparatus is, the designer must face the fact that these fundamental effects cannot be eliminated. They provide an ultimate limit to detection for a given methodology. Three fundamental noise sources, and other controllable noise sources, are shown pictorially in Figure 1.

2 JOHNSON NOISE

Within the resistive components of any electric component, thermal energy causes the electrons to vibrate with increasing activity as the thermal energy increases. It is related to mechanical Brownian motion within matter. Thermal noise, also called *Johnson noise* after its prime investigator, has been quantified as

$$\overline{v}^2 = 4kTRB \tag{1}$$

where $\overline{v}^2$ is the mean-square voltage generated, k is the Boltzmann constant, T is the absolute temperature of the resistance, R is the resistance in question (in ohms), and B is the frequency bandwidth of the signal in the resistor.

This can also be expressed in terms of noise current and noise power. Unlike the Brownian motion noise of mechanical systems, which rarely is observed, this noise is relatively easily detected by electronic systems and is always a serious factor to consider when designing low-level (below microvolt) detection stages. Clearly, from the equation, reduction of bandwidth, temperature of the resistor, and magnitude of the resistor reduces the Johnson-noise level.

The frequency spectrum of this noise, in its purest form, is uniform, there being as much energy in a given bandwidth at any place in the frequency spectrum. If this condition applies, the noise is said to be white. Gray and pink noises are of this general form but they possess different frequency spectra. Gray, for instance, reduces in amplitude in a linear manner as the frequency rises. Such noise types are close approximations to different noise situations that arise in practice and, thus, can be used as test noise sources.

3 SHOT NOISE

Wherever electric current flows, the corpuscular nature of the electrons gives rise to discrete signal energy packets called *short noise*. If there are enough of them, their sum averages to a steady current and the effect is not generally

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

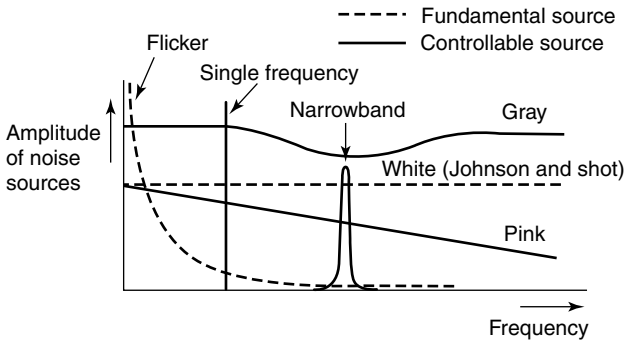

Figure 1. Frequency spectra of fundamental and other electronic noise sources. (Amplitudes of each type not shown to any strict scale.)

observable. If, however, each electron becomes an event in the detection system, as it does when very low-level signals are concerned, then this discrete randomness makes its presence detectable. This was first investigated for electron discharge in the former thermionic valves by using the assumption that the space charge was not filling the space available. The theoretical expression derived to explain the effect quantitatively was thus an estimate; in most applications, space-charge conditions alter the magnitude of the effect. The usual basic expression quoted is

$$\bar{i}^2 = 2eIB \tag{2}$$

where $\bar{i}^2$ is the mean-square current generated, e is the electron charge, I is the average current passing, and B is the frequency bandwidth of the signal passing.

However, valves, transistors, and other active electronic devices, each differ a little from this generalization. Suffice to say that this effect is also detectable by quite simple electronic apparatus and, therefore, must also be allowed for in the detection of stage design. Reduction in signal bandwidth and the through-current level reduces the level of this type of noise. Choice of detection device also has an important bearing on the magnitude. This form of noise is also spectrally white if it follows the given equation.

In both these cases, the formulations express the levels of noise signals generated within a component. The level that is received by the following stage depends upon the matching conditions between the two stages.

4 FLICKER NOISE

A third important fundamental noise source of electronic systems is called *flicker noise*. Since it varies approximately as the inverse of the frequency, it is often referred to as 1/f or *hyperbolic noise*.

Despite considerable research, it is still not possible to entirely quantify this noise form on the generalized basis. The physical reason for this in valves and in transistors is not proven. As a rule of thumb, an electronic system's flicker noise begins to become significant compared with the other fundamental limits at around 400 Hz, increasing below that frequency to be at infinity at absolute zero frequency. This is one reason for using carrier systems to provide good signal-to-noise ratios in detection equipment: the signal to be detected is generally modulated at well above 400 Hz, where this noise effect is lower than the other noise types.

Flicker noise has a direct counterpart in mechanical and thermal systems, for the greater the integration time that is used in an attempt to remove long-term, slowly changing, drift effects, the lesser the rate of improvement obtained.

The above-mentioned noise sources are the three dominant sources that cannot be reduced beyond certain limits. The use of bandwidth-reduction techniques reduces their level but at the usual expense of increase in response time. Cooling is often employed to reduce the operational temperature, including use of cryogenic stages. Electronic noise sources are well described in the literature (see Bennet, 1960; Connor, 1976; Delaney, 1969; Usher, 1974; Van der Ziel, 1954; Whalen, 1971; Wainstein and Zubakov 1962).

5 SOURCES OF NOISE RESULTING FROM IMPERFECT DESIGN

Assuming that fundamental limits do not restrict the design, then the system must also be assembled, connected, and shielded such that additional noise pickup is kept as small as is required. The common unit used to describe the degradation that always occurs from connection and stage performance is the noise figure (NF). It is given by

$$\mathrm{NF} = 10 \log \frac{\mathrm{SNR}_{\mathrm{in}}}{\mathrm{SNR}_{\mathrm{out}}} \,\mathrm{dB} \tag{3}$$

A perfect stage would add 0 dB, that is, nothing, but in practice, around 1.5 to 3 dB is the lowest addition obtainable. Shielding, layout, wiring, device selection, connection modes, matching, and other factors must be considered as possible means to reduce the NF of a stage. The order that stages with differing NF are connected in cascade is also an important factor. As a guiding rule, the stage with lowest NF should be used closest to the detection stage. Often, an initial stage is inserted that provides little useful gain but has a low NF that

assists the overall NF to be minimized. As practical measurement systems usually involve more than one energy regime, the noise sources of each regime must be considered.

Further information on noise in electronic signal systems is provided in the Section **Noise and Interference** and **Signal Recovery in the Presence of Noise**.

1 DEFINITION OF AN EMBEDDED SYSTEM

The term *embedded system* implies one computer or computers embedded within a system or product, which form an important part of that system, generally undertaking the system control. Related functions, for example, data processing, can also readily be undertaken. The embedded computer may be hidden from view, and the user may not even be aware of its existence.

Many definitions for embedded systems exist. The consulting company Dedicated Systems Experts (http://www.realtime-info.be) offer the following definition: An embedded system is a computer system that is enclosed in another system and makes an essential part of it.

Wilmshurst (2001) uses the following alternative definition, which explicitly evokes the control nature of most embedded systems: An embedded system is a system whose principal function is not computational, but which is controlled by a computer embedded within it.

Noting the characteristics of the embedded system, discussed below, Wilmshurst also uses the following more descriptive definition: An embedded system is a microcontroller-based, software-driven, reliable, real-time control system, autonomous, or human or network interactive, operating on diverse physical variables and in diverse environments, and sold into a competitive and cost-conscious market.

2 CHARACTERISTICS OF EMBEDDED SYSTEMS

The scale, complexity, and cost of embedded systems vary enormously. A typical system has some or all of the elements shown in Figure 1.

At the heart of the system lies an embedded microcomputer. Most commonly this is a microcontroller, although larger-scale computers (e.g. embedded personal computers) are also widely applied – *see* **Article 158, Microcontroller Systems, Volume 3**.

The embedded computer is itself made up of its hardware and software. Feeding into the embedded computer are input variables, taken from sensors and passing through input signal conditioning and a data conversion stage.

The computer may be networked with other systems, and it may have a user interface, although neither of these is essential to the concept.

The system is likely to generate output signals that are used to control system variables, for example, by driving actuators through a power electronic interface.

Figure 1 indicates the breadth of expertise that is required in the design and commissioning of an embedded system, including sensors, data acquisition, microcomputer hardware and software design, data communications and networking, human interface, control, and actuators and their drives.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

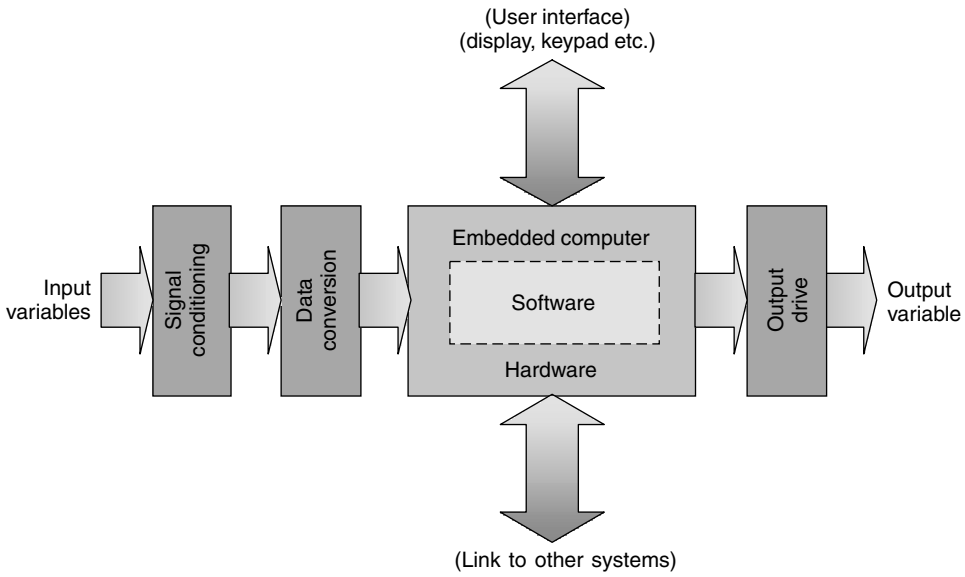

Figure 1. The essence of the embedded system.

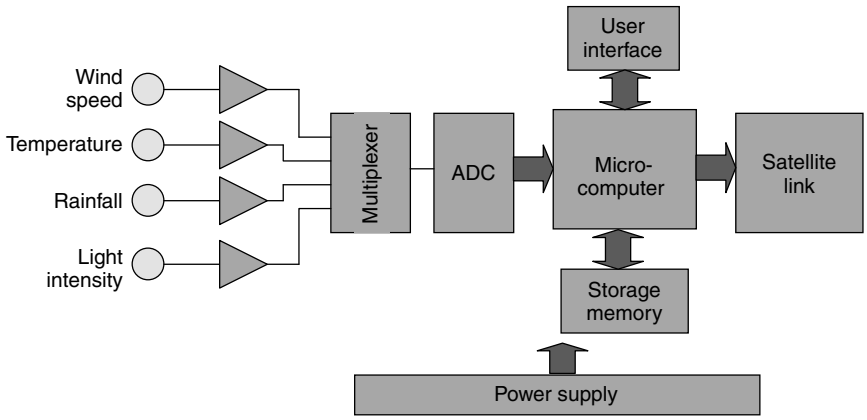

Figure 2. An example of an embedded system, a remote four-channel automatic weather station.

An example of an embedded system, a remote four-channel Automatic Weather Station is shown in Figure 2. Here four inputs are sampled periodically (not necessarily with the same period), and the resultant data processed and stored. It is also transferred via a telemetry link to a satellite. As it is designed for operation in the field, power supply is a critical feature of the system.

Further important characteristics of the embedded system are as follows.

2.1 Timeliness

Most embedded systems operate in an environment that is strongly time dependent. They must respond in an appropriate timescale to external events, or must generate time dependent outputs. This is generally known as operating in real time.

2.2 Efficiency of hardware/software utilization

Embedded systems are often sold in markets that are extremely cost sensitive. Alternatively, or as well, many such systems requirements are very space and/or power conscious. For these reasons, the embedded system is normally designed with restrictive hardware and software constraints.

The result of this, for example, is that the CPU may be only 8 or 16 bit, with limited computing power, and a restricted memory size may impose limits on program length or data storage capability.

2.3 Reliability

Many embedded systems now operate in situations having high demand on reliability. This includes, for example, many medical and motor vehicle applications. Appropriate techniques for hardware and software reliability are therefore applied.

2.4 Constraints of the operating environment

The operating environment of many embedded systems places further demands on its design. Many are battery powered, and so must be designed from a low power viewpoint.

Some operate in environments of hostile temperature, humidity, or vibration, for example, a motor vehicle engine management system.

These characteristics, taken in summary, form the final definition given in Section 1.

3 DESIGN OF EMBEDDED SYSTEMS

Pahl and Beitz (1995) have identified a design methodology for engineering products, which starts with

- *Clarification of Need*, and then moves through
- *Conceptual Design*, to
- *Embodiment Design*, and finally to
- *Detail Design.*

An adaptation of this process to the embedded system environment (Wilmshurst, 2001) is shown in Figure 3. This is a form of system life cycle – *see* **Article 63, Outline of Systems Thinking, Volume 2** and other articles of the subsection on 'Engineering a measuring system'.

This model provides a sequence of design phases. The principal characteristics of the system are identified in clarification of task, or requirements generation, that is then defined in the specification – *see also* **Article 69, Requirements Allocation, Volume 2**. From this, the principle hardware and software functions emerge. These then continue as two interlinked design strands. These strands should proceed in parallel, a process known as *codesign*.

Important aspects of the design process, whether or not this model is followed, are outlined below. Note however that software program design issues are mainly covered in Section 4 below – *see also* **Article 159, Designing and Building Software for Measuring Systems, Volume 3** and

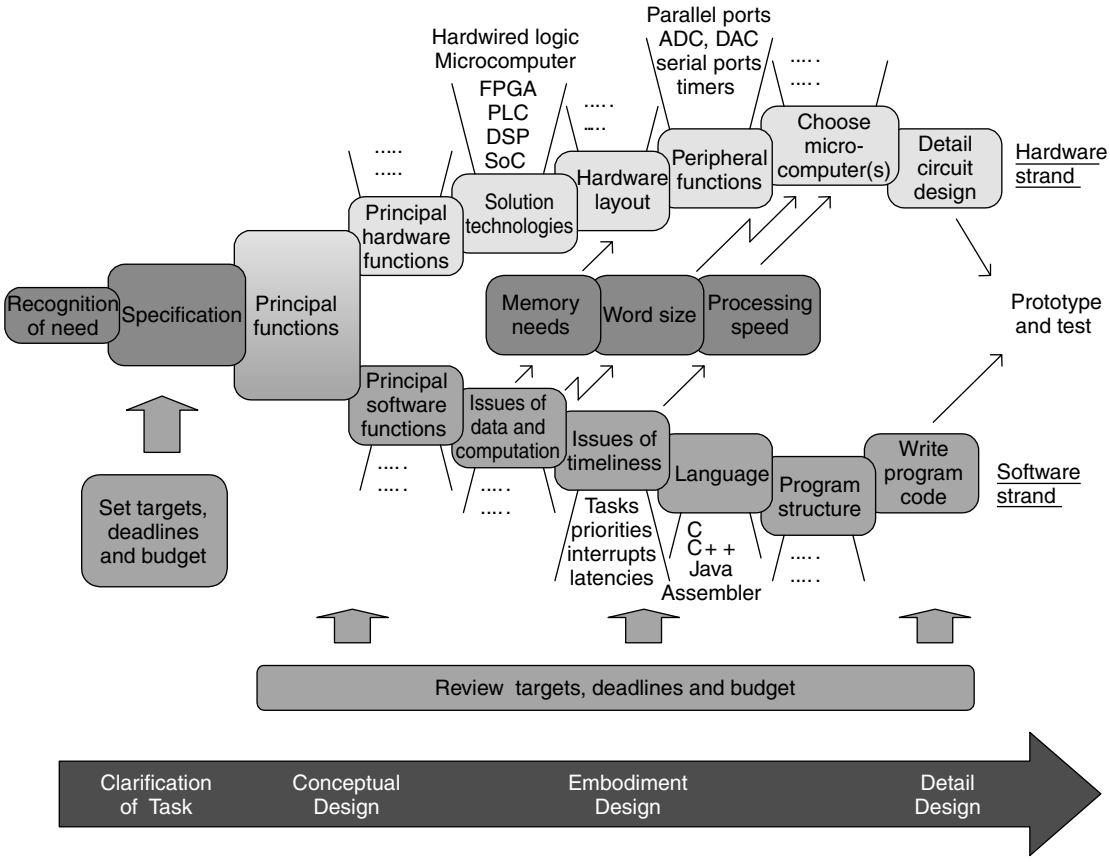

Figure 3. A design model for embedded systems. (Reproduced by permission of Institution of Electrical Engineers, with modifications.)

other articles of the subsection on 'Software aspects of measuring systems design'.

3.1 Solution technology

It is essential for the designer to be aware of the current technologies available for system implementation. The conventional approach, of designing a microprocessor or microcontroller into a hardware system, is to a large extent being replaced by the opportunities of ASIC (Application Specific Integrated Circuit), Field Programmable Gate Array (FPGA), and System on Chip (SoC) technologies. Thus, a microprocessor is not necessarily purchased as a piece of silicon, but as a piece of Intellectual Property, (IP) which can be downloaded onto an FPGA, along with other devices.

The SoC strategy takes this further, with CPU, memory, data buses, and an array of other system elements available, in user-configurable form, on the chip. Xilinx® (http://www.xilinx.com/) and Altera® (http://www.altera.com/) are important suppliers in this field.

Other distinctions, such as that between the conventional microprocessor and the DSP (digital signal processing) device (*see* **Article 146, Principles of DSP Hardware Design, Volume 3**), are also becoming blurred, with microprocessors and microcontrollers moving to take on DSP capability, and DSP devices taking their place in embedded systems.

As a complete alternative, Programmable Logic Controllers (PLCs) nowadays carry out sophisticated measurement, control, and network capability, and can themselves form the basis of embedded control.

3.2 Hardware layout

This process identifies the principal blocks of the hardware system, and their interconnection. It will include such fundamental decisions as whether there are one or more microcomputer elements, how data is transferred internally, what input/output techniques are used (and hence what peripherals are required), and so on.

3.3 Choice of microcomputer(s)

Having evaluated both the hardware and software demands that will be placed on the microcomputer(s), a device selection can be made. Alternatives include the

- ASIC/FPGA/SoC options, mentioned above;
- externally supplied microcomputer subsystem; and
- microcontroller designed into a custom piece of hardware.

Selection will be initially on device performance and cost. Other aspects, however, must be considered. These include cost of development tools (which can be significant and take time to learn), and the level and quality of support available for the chosen device.

There are a huge range of microcontroller suppliers, including Atmel® (http://www.atmel.com), Hitachi® (http://www.hitachi.com/products/electronic/semiconductorcomponent/index.html), Microchip® (http://www.microchip.com/), Motorola (http://e-www.motorola.com/webapp/sps/site/homepage.jsp?nodeId = 03M0ym4t3ZG), and Philips Semiconductors® (http://www.philips.semiconductors.com/products/standard/microcontrollers/).

4 PROGRAMMING THE EMBEDDED SYSTEM

The usual requirement in an embedded system is for a program with compact and reliable code, which executes efficiently, and which can interact in a direct way with the hardware resources.

Programming normally takes place using an Integrated Development Environment (IDE). This runs on the host computer, and develops programs for the target system (the embedded system under development).

4.1 Programming language

The requirements mentioned above make High Level Languages applied elsewhere less attractive.

One possibility is to use the native assembler of the processor. This leads to the most efficient code possible, and allows excellent interaction with the hardware. However, programming in Assembler is error prone, and time consuming.

An excellent compromise is the language C. This leads to compact and well-structured code, which can interact with the hardware, and which can be developed reasonably rapidly. Techniques adapting C to the embedded environment, including in high reliability applications, are widely documented (e.g. van Sickle (2001), Hatton (1994), MISRA (1998). C compilers are available for all microcontrollers, some with special extensions or restrictions, based on the controller architecture.

As larger-scale program memory (particularly with the wide-scale adoption of Flash memory) is now becoming available, C++ and Java are becoming increasingly used. Language subsets, removing the more memory-hungry

aspects of the languages, and targeted at the embedded world, include Embedded C++ (EC++) and Embedded Java.

4.2 Multitasking in real time

Most embedded systems are multitasking, and must meet real-time programming demands, that is, they have a number of distinct functions, which must be performed more or less in parallel, and which must meet certain deadlines. These may be of different relative importance, and may or may not be synchronous with each other.

A particular technique for dealing with this situation is to apply a Real Time Operating System (RTOS).

An RTOS determines which task is given CPU time, and for how long. This is called *scheduling*. It also controls task synchronization, use of system resources that may be needed by more than one task, and passing of data and messages between the tasks.

Various scheduling strategies exist. In Cyclic Scheduling, each task runs until completion, before the CPU turns to the next task. A Round Robin scheduler simply gives CPU access to each task for a fixed period in turn, irrespective of its priority. This is an example of preemptive scheduling, as task execution is interrupted before completion. A prioritized preemptive scheduler gives priority to tasks that have been designated as high priority; low priority tasks are not executed unless there are no high priority tasks waiting. Further details are given in many sources, for example, Simon (1999).

5 TESTING OF PROTOTYPE EMBEDDED SYSTEMS

Embedded systems can be a particularly challenging type of product to test. Signals and logic states may be deeply embedded within the system, and impossible to monitor. Worse still, the system is under the control of a fast-moving program, which may instigate fault conditions under circumstances that are then very difficult to replicate. A range of tools, of varying levels of sophistication, exists to address these challenges.

It is highly advantageous to avoid a situation in which untested software is run in untested hardware. This can be avoided by the use of software and hardware simulation. A software simulator is a computer package, usually part of the IDE, which attempts to replicate the action of a particular microcomputer under test, and which can run a trial program. It is low cost, and sometimes provided free of cost by microcontroller suppliers (e.g. Microchip's MPLAB™). Importantly, it holds values of all internal processor registers and memory locations, which can be examined by the user. It can run the program continuously or single-step.

MPLAB allows breakpoints to be set, which cause the program execution to halt at a specified instruction. Its Trace function maintains a record of register values up to the time of program halt. Although it does not operate in real time, instruction or machine cycles can usually be counted, from which program execution time can be deduced. It is possible to simulate the external environment in only a limited way. Despite these shortcomings, once a program has run on a simulator, there can be a fair degree of confidence that it will operate in the target hardware.

It is attractive to retain the facility of the software simulator when the program is downloaded to the target hardware. This can be achieved by using an In Circuit Emulator (ICE). This is a device that usually exists in the form of a pod, which is inserted in the target hardware in place of the microcontroller or processor. It remains connected to the host computer by an umbilical cable.

The ICE is designed to act precisely as the processor it replaces. However, it allows its internal registers to be interrogated by the host computer, and generally it has the breakpoint, trace, and other facilities of the software simulator. The ICE is not without its drawbacks. It is a costly tool, and committed to only one processor, or family of processors. There can be subtle restrictions on its use, for example, it may have clock frequency or power supply range constraints, or it may introduce awkward timing errors in high-speed systems. For these reasons, and because digital electronic devices are becoming ever more complex and compact, the ICE is slowly being replaced by other test methods.

Certain manufacturers now integrate diagnostic tools onto their chips. A good example is the Background Debug Mode (BDM) facility of many Motorola™ devices that allows values of internal registers to be read by the host computer via a dedicated serial link. As the diagnostic facility is built into the device, it is by definition noninvasive, and can have very valuable results.

Conventional electronic test tools, notably the oscilloscope and logic analyzer, remain useful, especially in simpler designs. Certain products, for example, from Agilent, combine the functionality of both instruments into one.

1 CIRCUIT TEST PRINCIPLES

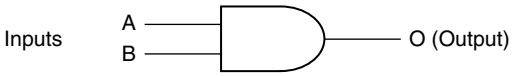
The term unit under test (UUT) is often used in the context of electronics testing to refer to the item or system being tested. The term fault is used for any defect or malfunction.

1.1 Analog circuitry systems

Testing analog circuit functions and parameters involves a range of measurement technologies and instruments. Some of the most important and frequently applied tests are:

- current, voltage potential, and resistance
- gain, impedance, waveforms, and other aspects of AC circuits
- signal characteristics, such as frequency, gain, power, distortion, jitter, and so on, for audio frequency (10 Hz–10 KHz), radio frequency (RF) (10 KHz–1000 MHz), and microwave (1000 KHz–100 GHz) and high-speed digital circuits.

1.2 Digital circuitry systems



The basic approach to testing digital circuits is to check that the output logic is correct for each possible input state. As a simple example of combinational logic, consider a 2-input AND gate (Figure 1). The possible input conditions and the correct outputs for each of these is shown in the truth table. In principle, it is simple to test such a device for all possible input conditions and faults. The fault conditions in this basic approach are inputs or outputs stuck at 1 SA1 and stuck at 0 SA0.

In this case, four test conditions, or test vectors, are sufficient to test all operating conditions. For any logic network, the number of vectors necessary to show correct operation is 2^n, where n is the total number of possible input conditions. For a simple digital circuit, this presents no problem, but as device complexity increases, the time taken to perform such a test can become too long to be performed practically and economically in mass production.

In devices such as memories and processors, or complex circuits that include such functions, the outputs depend upon the inputs as well as on data flow and memory locations of stored data. This is sequential logic. Alternative test methods have been developed for these devices, such as pattern sensitivity tests for memories.

There are other practical limitations of the basic SA fault model approach to testing. There are other kinds of fault condition that can occur, such as a stuck at input condition, in which an output follows an input logic state. Fault occurrence can also be dependent upon other factors, such as timing, speed, interference, temperature, or voltage supply, as described in O'Connor (2001).

2 MANUAL TEST EQUIPMENT

Manual test equipment is used primarily during development since, at that stage, it is not important to minimize test time and greater flexibility is possible.

The main types of manual test equipment are:

- basic instruments, such as AVO meters (amps, volts, ohms) or digital multimeters (DMMs), power meters, and transistor testers;
- oscilloscopes, spectrum analyzers, and waveform generators to measure, compare, and analyze voltage and current levels and waveforms and to provide inputs so that circuit responses to input waveforms can be analyzed;
- logic analyzers, which are similar to oscilloscopes but specialized for displaying digital pulse streams;
- special instruments, such as radio frequency testers, distortion meters, high voltage testers, optical signal testers, and so on.

Figure 2 shows some typical modern manual test instruments.

2.1 Computer-based testing

Computer-based testing uses software that enables personal computers (PCs) to emulate test equipment. The PC is connected to the circuit to be tested via a data acquisition adaptor card. The PC screen becomes the instrument display, and the tests are controlled from the keyboard and mouse (Figure 3). Software such as LabVIEW™ – *see* **Article 105, Modeling with LabVIEW™, Volume 2** and LabWindows™ (National Instruments Corp. (URL: http://www.ni.com) (Johnson, 1997)) ease the task of test design. Computer-based testing can reduce the costs of test equipment since one PC can perform a range of test functions and test results can be easily stored, analyzed, and transmitted. The microprocessors in PCs also enable tests to be performed faster.

3 AUTOMATIC TEST EQUIPMENT (ATE)

Electronic equipment is tested as part of the manufacturing process to ensure that faults are identified and diagnosed

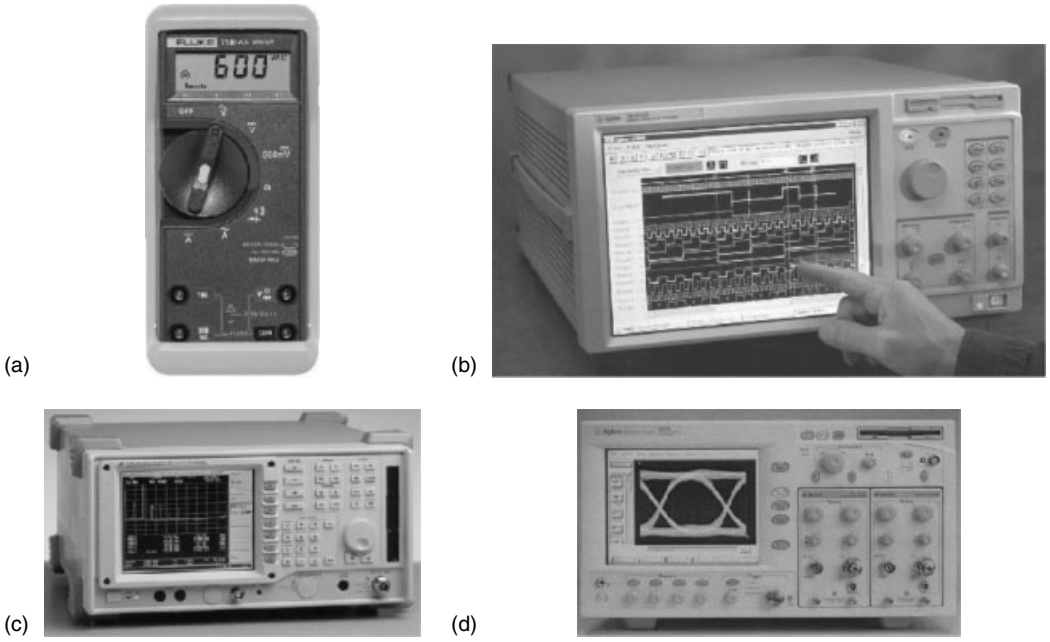

Figure 2. Manual test instruments: (a) DMM (copyright © Fluke); (b) logic analyzer (copyright © Agilent); (c) RF tester (copyright © IFR); (d) optical signal tester (copyright © Agilent).

Figure 3. PC-based oscilloscope with conventional instrument. (Copyright © National Instruments.)

and that shipped units are fault-free. In order to perform the tests economically, especially at high production rates and for complex circuits, most manufacturing testing is performed using automatic test equipment (ATE). The main types of ATE for electronic assembly testing are given below.

3.1 Vision systems

These refer generically to inspection systems that acquire an image and then analyze it. These include automatic optical (AOI) and X-ray inspection (AXI). They do not actually test circuits, but they have become part of many production test sequences because of the great difficulty of human inspection of the large numbers of components, solder connections, and conductor tracks on modern circuits.

3.2 In-circuit testers (ICT), manufacturing defects analyzers (MDA)

ICT (In-circuit testers) tests the functions of components within circuits on loaded circuit boards. It does not test the circuit function. The ICT machine accesses the components, one at a time, via a test fixture (sometimes referred to as a *bed of nails* fixture), which consists of a large number of spring-loaded contact pins spaced to make contact with the appropriate test points for each component. MDAs (manufacturing defect analyzers) are similar but lower-cost machines with capabilities to detect only manufacturing-induced faults such as opens, shorts, and missing components: justification for their use instead of ICT is the fact that, in most modern electronics assembly, such faults are

Figure 4. In-circuit tester (ICT). (Copyright © Agilent.)

relatively more common than faulty components. Figure 4 shows an ICT system.

3.3 Flying probe testers

Flying probe testers (also called *fixtureless testers*) access test points on the circuit, using probes that are rapidly moved between test points, driven by a programmed high-speed positioning system. The advantage over ICT is the fact that the probe programming is much less expensive and more adaptable to circuit changes than expensive multipin ICT fixtures are, which must be designed and built for each circuit to be tested. A consequent advantage is that they can be used for testing during development as well as in production.

3.4 Functional testers (FT)

Functional testers (FT) access the circuit, at the circuit board or assembly level, via the input and output connectors or via a smaller number of spring-loaded probes. Functional testers usually include facilities for diagnosing the location of causes of incorrect function. There is a wide range, from low-cost bench-top ATE for use in development labs, in relatively low complexity/low production rate manufacture, in-service tests, and in repair shops to very large high-speed high capability systems. The modern trend is for production ATE to be specialized and focused at defined technology areas, such as computing, signal processing, and so on.

Figure 5. Functional tester. (Copyright © Agilent.)

Some ATE for circuit testing during manufacture includes combined ICT and FT; the ICT functions are performed first, followed by FT. Figure 5 shows a typical modern test station.

Electronics ATE is a very fast-moving technology, driven by the advances in circuit performance, packaging and connection technology, design automation, and production economics; O'Connor (2001) and Brindley (1991) provide more information.

4 SPECIAL TEST EQUIPMENT

There is also a wide range of specialized ATE, such as for integrated circuits, power supplies, cable assemblies, communication systems, and so on.

4.1 Hot rigs

A 'hot rig' is a system that is used as a test facility for the subassemblies from which it is constructed. Any of the subsystems can be tested by being inserted into a cabinet that contains the other subsystems and then the system can be tested. 'Hot rigs' are often used for testing in the manufacture of systems, particularly when the quantities produced are relatively low so that test time is not critical. They are also used in repair depots for testing repaired items.

4.2 Electromagnetic compatibility (EMC) testing

Testing for electromagnetic compatibility EMC and electromagnetic interference EMI is described in **Article 17, EMC and EMI, Volume 1** and **Article 216, Test Facilities, Volume 3**.

5 COMPONENT TEST

Since electronic components are always tested by their manufacturers, and since modern manufacturing quality is very high, nowadays, it is very seldom appropriate or necessary for components to be tested by equipment or system manufacturers. We can consider electronic components to be in two categories from the test point of view: discrete components and integrated circuits or ICs.

5.1 Discretes

Components such as resistors, capacitors, connectors, coils, transistors, and other relatively simple types generally possess a relatively small number of performance parameters. Therefore, testing them is relatively easy, quick, and inexpensive, and they are fully tested by the component manufacturers. The manufacturing processes for these components are also relatively easy to control, resulting in high yields or low proportions of defectives. Therefore, testing by users is rarely cost-effective.

5.2 Integrated circuits

ATE for IC testing must be capable of testing all or most of the functions of the very complex circuits, at the maximum operating speeds. The problem of testing very large and fast ICs is one of the major challenges of modern electronics technology. New methods for testing very large and fast ICs are being developed in response to the challenges of complexity and cost. ATE for IC testing is very expensive, so testing by users is seldom cost-effective.

6 DESIGN FOR TEST

6.1 Tasks of an ATE

In order to test a circuit or system, the ATE must be able to perform the following functions:

- *Initialization*. The ATE must put the UUT into known initial conditions, for example, digital inputs and outputs at known logic states, parameters at known values, and so on.
- *Control*. Inputs must be generated to stimulate changes on the outputs.

- *Observation*. The ATE must be able to detect the changes in output states and values.
- *Diagnosis*. The ATE might be required to perform automatic or guided diagnostics to identify the origins or causes of faulty output states.
- *Partition*. It is often important that the ATE can test relatively small parts of complex systems separately to maximize test coverage, to enable effective fault diagnosis, and to minimize test time.

These capabilities are affected not only by the performance of the ATE but also significantly by the design of the UUT. Therefore, it is important that the system design takes account of the need for test. This is called *design for test* (DFT).

7 TEST SOFTWARE

Test software must be developed for any circuit that is to be tested on ATE. Automatic test program generation (ATPG) software is available to perform this task. The ATPG will create the test software from the circuit information on an electronic design automation (EDA) system and indicate the fault coverage. For some systems, particularly aerospace electronics (avionics) and military systems, the abbreviated test language for all systems (ATLAS) test language is used.

7.1 Scan design

For very large digital electronic circuits, internal circuits are often provided, which assist the ATE to perform the tests. The best-known approach is boundary scan. A boundary scan circuit receives test instructions from the ATE and then performs logical tests on the interconnections between the digital circuits that it controls. This capability is important for large IC packages containing many connections, particularly if they cannot otherwise be accessed for test by the ATE. The international standard for the boundary scan approach is IEEE1149.1. Most modern digital ICs include boundary scan capabilities. The boundary scan method is described in Parker (1999), and information is also available from JTAG Technologies (URL: http://www.jtag.com).

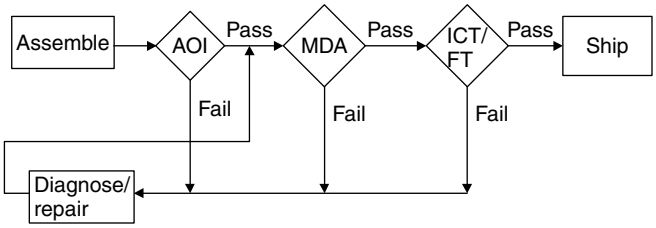

Figure 6. Typical electronic manufacturing test flow.

8 EXAMPLE OF MANUFACTURING TEST

For any manufacturing situation, the optimum test approach must be planned in relation to technologies, economics, and other factors. This topic is covered in Davis (1993) and O'Connor (2001). Figure 6 shows an example of a typical manufacturing test sequence.

1 PURPOSE OF MECHANICAL DESIGN IN INSTRUMENTS

Mechanics is the subject that deals with the study and application of the motion and equilibrium states of material bodies. The aim, in the mechanical aspect of instrument design, is to create a specific mechanical system that provides the necessary controlled movements in such a way that predetermined moving and fixed relationships are preserved under reasonable conditions of operation.

Reuleaux, in his *Kinematics of Machines* of 1875, was apparently the first person to see machine design as more than a complete design that was modified until it worked. He defined a machine as 'a combination of resistant bodies so arranged that by their means the mechanical forces of nature can be compelled to do work accompanied by certain determinant motions'. He further expanded that motion of parts is simply determined by the geometry of the system of parts (Burstall, 1970). Reuleaux's generalizing definition applies equally well to mechanical instruments that are a form of machine.

Departure from the ideal concept will occur for many reasons, for example, unavoidable elasticity of component members, clearances and wear in joints, and 'second-order' influences such as thermal expansion of the material. Design is the process whereby a satisfactory compromise is made between the range of envisioned parameters to come to a single adequately satisfactory arrangement. The designer strives to produce a design statement that will lead to an article being made, which performs the set task within the stated specifications of performance without the need to remake the article after it is first assembled.

Mechanical design has two main stages of progression. The first is where the kind of necessary mechanisms are realized as a system. The following stage then selects a method of creating the chosen individual mechanisms as hardware that will suit the total task. For example, the mechanism seen to be needed may be a means of rotating one shaft at a different speed to that of the other while maintaining a strict gearing ratio. This is the first step. Followed by the study of the various ways of achieving this – toothed belts, friction gearing, spur gears, and others – to see which suits the case in hand.

No matter which type of mechanism is involved, the fundamental issues behind the choices of the first step are concerned with controlling the freedom of movement of selected parts and points. This will be expanded later.

The design of a measuring instrument, that a machine uses for handling informational rather than energy quantities, generally requires specific attention to the fidelity of the input–output and other relationships over extended

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

periods of operational life. There is less interest in efficiency of energy transfer (although in mechanical design, losses due to friction can cause thermal changes to components that give rise to error). Instrument design is generally dominated by attention to deflections of the system and its components rather than to their strengths.

A general introduction to mechanical machine design can be obtained from the widespread works describing the design of machines that can transfer energy, examples being Shigley (1988), Erdman, Sandor and Kota (2001), Juvinall and Marshek (2002), Mott (1998), Faires (1955), Beggs (1955) and Lent (1970). These accounts will, however, only take the user a limited distance into instrument design, for they generally lack specific detail about fine mechanism requirements.

Work which discusses the general systems level of design of instruments are few and generally now seen to be old by virtue of their date of publication. They are, however, most useful accounts, encapsulating considerable experience and know-how. These include Glazebrook (1922) Vol. III, Rolt (1929) Vol. II, Whitehead (1934), Strong (1938) and Braddick (1954). This material is provided to help overcome the difficulties in procuring information on this topic, now that it has little research in place.

Factors important to design include the methodology for controlling the design itself, cost of producing the design, building the instrument and servicing it, the degree of serviceability, the ease of measurement in production, the needs for calibration after manufacture, and ergonomics requirements (now often called the *man–machine system* – MMS). These and others must all be properly thought out so that the users get correct results. Many of these vitally important factors are often neglected in the initial design, being added by adaptation or modification at a later stage when the design has progressed so far into production that major change cannot be entertained. For example, a firm making fever thermometers only realized that their product must fulfill certain calibration criteria when they were ready to launch the product on the market place!

At present, instrument design is largely a case of some intelligent application of science plus a very large component of experience through years of actual involvement with similar products.

Design procedures for each of the different physical regimes of an instrument have their own peculiarities. Mechanical design must allow for the fact that a wrong choice is not as easily corrected as in, say, the electronic medium. There is, for example, no simple mechanical counterpart of the variable resistor of electronics, which can be placed into the system to find an optimum value with great ease and with little cost or performance penalty. To obtain adequate performance from a mechanism, usually very close tolerances are required. Dimensional parameters in mechanical systems will often require parts per million precision compared with parts per hundred in most electronic techniques. If adequate performance is to be achieved, it means that the various parts of a mechanical system must be made precisely, or at least be capable of being assembled to close tolerances. Control of wear is important since it may degrade performance.

Electronic design, in contrast, can more easily compensate for changes to the value of components, since they have been initially burned in to eliminate the few that will fail early.

To its credit, mechanical design is more intuitive and readily understood; wrong factors in a mechanical system often show up very easily without the use of sensory aids because mechanical systems interface more directly with the human sensors than concepts of other disciplines. Mechanical resonant systems can also yield very high-Q oscillations for low component cost.

An important feature of mechanical systems, which may be either advantageous or deleterious, is the inertia of components. The necessary inherent mass of mechanical parts is often the limiting parameter to dynamic performance when high frequency operation is needed. It can, of course, be a useful factor providing time integration properties. In a multiregime instrument, the mechanical parts will often dictate the upper frequency limit of operation. Generally, unless specifically and carefully designed to be otherwise, mechanical systems will be low pass in performance.

2 SPECIFICATION OF MEASUREMENT SYSTEMS

There exists a maxim '$pecify $anely or $uffer'. It sums up the importance of spending enough time on raising adequate and realistic specifications on which to base the design. Mechanical design does not differ from any other design in that to get started one must have a set of specifying statements that will outline, in a quite rigorous and meaningful manner, what the instrument must do. These statements are called *specifications*. Too often, instruments just happen with the specifications growing as the design proceeds. A proper set of 'specs' at the beginning of the design will aid the designer in realizing what is ultimately required. They should be set to paper *before* in-depth design begins, for once the designer has become immersed in the design, it is a fact of life that he or she can become very resistant to change.

Specification should not be raised by the designer or user alone but as a group effort. There should be a joint agreement between three parties – the system end user, the

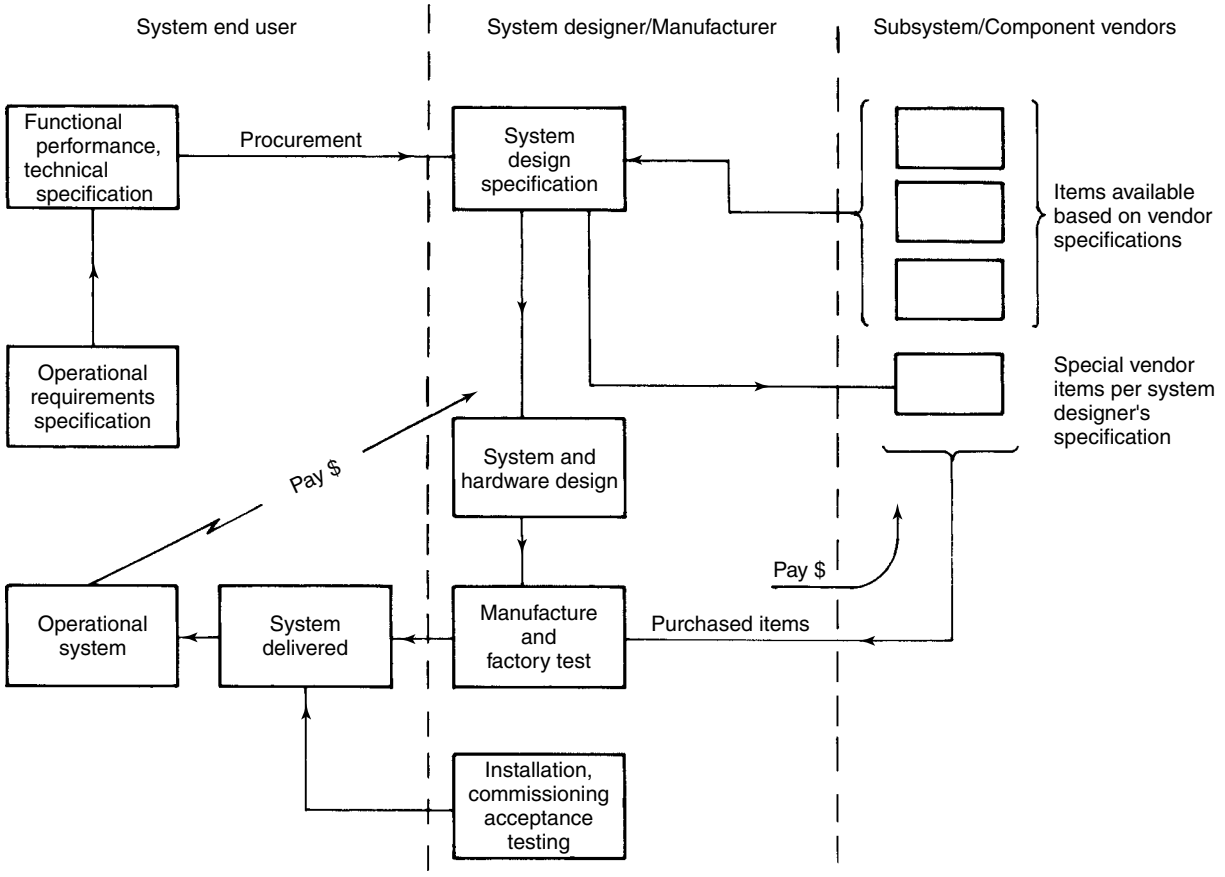

Figure 1. Vested interests in a typical system design process.

system designer and manufacturer (if they are of the same group), and the subsystems and component vendors who supply the parts that will be used, generally without modification. Figure 1 shows how Wheeldon (1974) depicted this process. His two papers expand the following points now given. Various kinds of specifications exist, each having a different purpose of definition.

Systems user and systems designer relationships

- Operational requirements specifications
- Functional and technical requirements specifications
- Design specifications (to implement and check design)
- Factory test specifications
- Acceptance test specifications (Factory)
- Documentation specifications

Systems designer and component vendor relationships

- Standard item specifications
- Modified 'Standard' items
- Special subcontract specifications
- Incoming inspection specifications (system designer)
- Incorporation of vendor specifications in system design specifications.

The designer is the person who has to provide specific detail to the factors presented by the various groups. A realistic producible design at a satisfactory cost must be achieved. Value judgments are needed about what the customer says is needed (which is often what is then *thought* to be needed); what the vendor can offer (or what is *said* to be available); the designer's own ability and facilities for design; and the permitted time and money available to complete the task.

Unfortunately, to specify a product completely before it is made requires powers of prediction and enormous effort in attempting this virtual impossibility. To attempt to create a total specification that gives the user complete assurance of being absolutely safe from faults and failures of compliance is an unreasonable expectation. The cost and time needed to get even close to this are prohibitive. A compromise is therefore struck that specifies the product in a short-form manner in reasonably standard 'shorthand' statements.

Specifications, therefore, attempt to portray what both the designer or maker and the purchaser or user expect to produce and receive, respectively. Owing to the small cost level associated with the smaller systems and the stand-alone instrument, the verbal interface is poorly developed and exploited. In larger extensive instrument systems, the complexity there makes better assessment necessary, but then the complexity still prevents absolutely adequate statements from being realized.

3 PROBLEMS OF SPECIFICATION

In practice, dissatisfaction often arises between the parties to the contract and, in cases where the financial implications are large, independent arbiters are called in to make judgments. The art and science of contract and specification writing are now extensive; specialists exist to cover the needs. It is beyond the scope of this article to go much deeper, but here are some simple rules to follow.

Try to use specifying statements that are the result of past experience. Examples are Codes of Practice and the various Standards specifications. For instance, reference to the BS code for dimensional tolerances will show if those called for are reasonable for the size of the part.

Always watch for 'minor' details in a statement that may be more significant than they are thought to be. For example, surface finish to be within a given limit may be specified for a pressure cell capsule, yet nothing is given about the fluid tightness of the material. Further, never leave important factors out because they seem so obvious. The converse also holds; if they are not given, check them out.

All statements in a specification should be carefully studied *before* signing an agreement; it is of little value to look into it afterwards. Look carefully for fundamental inconsistencies. Does the frequency response called for exceed that of any mechanism yet produced? Does the required or specified noise level fall below the thermal control errors? Suppliers cannot make an instrument that refutes the known physical laws; but they have been known to offer such for sale – unwittingly, of course!

Make clear what specifications apply to what, and at what stage. Care is needed to prevent them 'creeping' in the hands of enthusiastic clerks. There was a case of an optical shaft encoder that had to read to arc-minute accuracy when mounted on a radar tracking head. By the time the specifications were transferred through several stages of contract writing and then into the maker's plant, they had crept to stated need for arc-seconds performance. The manufacturer, not wishing to be caught out, went one better. The result was that the encoder cost about a hundred times the price of one that would have done the job. Furthermore, the full encoder accuracy could not be used because the radar head was not designed for better than arc-minute use.

Specifications can also come to the designer as the result of the so-called 'horse-camel' syndrome. The end user collects data sheets of the various products offered by several different sources. From each of these he picks out the individual good points, adding these together to raise his own specification list. This process entirely ignores the fact that these special features are often the result of the designer trading off one feature to allow another to be enhanced. The result of this combinational method is a specification of an instrument impossible to make. Unfortunately, there are many suppliers in the instrument manufacturing industry who lack enough experience to recognize that such tenders may be impossible to make, and they take them on only to find later (to their and the purchaser's regret) that they had been attempting a virtually impossible task. The use of independent expert consultant groups, a well-trained in-house team, study contracts, and part-stage costing may help.

At all times, it is vital to 'clear the air' between all groups involved. If the user believes the designer cannot do what is suggested, then it should be challenged very early. Similarly, the designer should state what is unclear early in the negotiations with the consumer. Change becomes progressively difficult as the designer is gradually forced to freeze the parameters in order to make concrete progress.

When writing specifications, considerable care must be given to the provision of statements that are meaningful and not ambiguous. Unfortunately, to write a reasonable specification requires the use of abbreviated statements. For example, statements of accuracy or linearity are used very loosely. Graphs could be used much more to define such parameters as frequency response, linearity, and the like. When in doubt, seek further detail about the meaning of a parameter.

There is no harm in verifying the self-quoted performance of subcontractors and vendors.

All too often, the user does not adequately think out the task for the instrument that is called for. The designer should be expected to ask poignant questions of the user, for the designer will often know the design problems more closely than the user. Very often, discussions show that the user really wanted something quite different from what was thought to be necessary. Take, for instance, the person who once asked for a thermometer to measure length changes of a component because he did not see that it could be measured directly as a dimension.

Each case stands on its own merits. In measuring instrument design, the spread of applications is so broad and the design becomes so complex that poor performance

often results. The ongoing state of instrument design and manufacture is such that it is suggested that instrument users must constantly be on their guard against the supply of faulty instruments – see Moss (1978) for a relevant report illustrating the potential situation.

Instruments, especially one-offs and those with mechanical elements, are still in a state of low inherent quality capability when compared with the performance that one now expects and usually gets when using electronic systems based on standard integrated circuits. If an IC works, it is going to be in specification and continue to operate. It will also be a very well designed component. In contrast, mechanical systems may continue to operate but with deteriorating fidelity.

4 CONTROLLING THE MECHANICAL DEGREES OF FREEDOM

Mechanical design is fundamentally concerned with providing a system of materials arranged to allow controlled movements, ranging from no movement in any axis, to all six degrees of freedom of an extended object within a defining space.

A theoretical point in space has three degrees of freedom – the three translations that are generally expressed as x, y, z in the Cartesian system; other coordinate methods can be used. The concept of rotation has no meaning for a theoretical point.

A point forming a position on an extended object, however, can have six degrees of freedom for, in addition to the three possible translations, there can be three axes of rotation about the point.

The essence of good mechanical design is to devise a system that restrains as many of the six freedoms as are needed while allowing freedoms. For example, the slide of a traveling microscope must allow one translation, and while doing so, constrain the other two translations and three rotations as perfectly as are needed. Lack of straightness of the slide will cause small translations and rotations to occur as it slides. The degree of precision needed dictates the necessary tightness in the tolerances of manufacture and the method by which this is accomplished in the face of wear, temperature effects, and other error sources.

Some other examples are the framework and sliding axes of a 3-D measuring machine (three translations allowed with rotations constrained) and the surveyor's theodolite (constrains all translations allowing the rotations).

An equally important case is where all degrees of freedom are to be constrained. This occurs when mounting a component to stay in a chosen position relative to another; for example, a method of locating a survey-leveling unit that is to be used repeatedly around a series of test lines.

At times, measuring machines are sometimes specified as, say, $3\frac{1}{2}$ axes, meaning that they have a rotation allowed within the movement provided along one translation axis. It does not mean that the rule of six degrees of freedom for an extended point has been broken.

Two extremes of design philosophy exist for realization of a suitable mechanical structural relationship. Each has its advantages and disadvantages and often the design makes do with a compromise between the two extremes. These extremes are called *kinematic* and *elastic designs*; in between them is the semi-kinematic arrangement.

5 KINEMATIC DESIGN BASICS

When all parts of a structure are held in such a way that they retain positional relationships without being in a state of variable stress except at their points of contact, the design is said to be kinematic. In other words, effects such as a change in size due to temperature or material creep will not stress the frame. Clerk-Maxwell in the *Handbook of the Special Loan Collection of Scientific Apparatus* 1878 wrote this:

> When an instrument is intended to stand in a definite position on a fixed base it must have six bearings, so arranged that if one of the bearings were removed the direction in which the corresponding point of the instrument would be left free to move by the other bearings must be as nearly as possible normal to the tangent plane of the bearing.

Strong (1938) defined the principle of kinematic design as being applied when a body has at least 6-n points in contact with a second reference body when it is to have n degrees of freedom.

A spherical ball sitting in a triangular hole, as shown in Figure 2(a), rests on three points of contact while it is under the force of gravity (which acts as the 'locator'). Thus, it has three degrees of freedom constrained with respect to the datum block (the translations) yet is free to rotate about three mutually perpendicular axes.

The classic example, demonstrating constraint of all six freedoms, is the so-called 'hole-slot-plane' or Kelvin-coupling arrangement. This is easily understood by reference to Figure 2(b). The hole constrains three translations (three contact points), the slot constrains two rotations (two contact points), and the plane constraints the other rotation (one contact point). Addition of any extra contact points, unless made perfectly enough (as in a ball-race bearing), would add a 'redundancy' causing elastic deformation of the frame due to 'overconstraint'.

It is easy to see that changes to the size of the top plate will cause the legs to move yet retaining the same stress

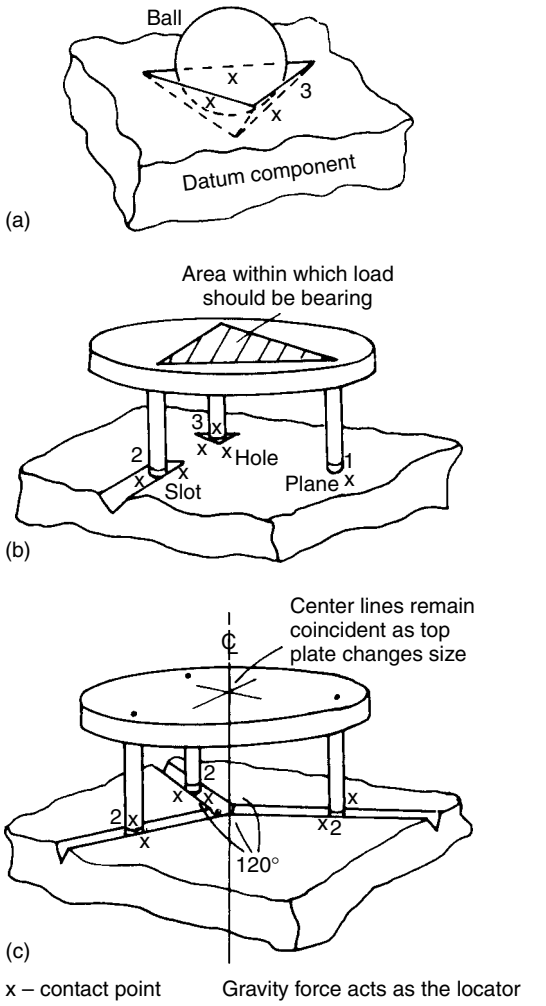

Figure 2. The degrees of freedom in a kinematic design of a coupling are equal to six less the number of contact points. (a) All three translations constrained. (b) Hole-slot plane in which all six freedoms are constrained. (c) Slot-slot-slot variation of case b.

relationships (provided the slotted plane contacts move accordingly). Note that the hole-slot-plane does not, however, retain the center of the top member coincident with that of the lower member should a relative dimensional change occur between the two members. A variation of the 'hole-slot-plane' that uses three radiating slots (Figure 2c) overcomes the center shift defect. Figure 3(a) shows a kinematic form in which one degree (translation) is allowed, this being proven because five contact points exist. Figure 3(b) shows how this form is modified with rolling bearings, to retain point contact while reducing wear. It is typical of the slide of a traveling microscope.

Many arrangements are possible depending on the need to allow or control a given number of degrees of freedom. Sketches of various couplings are given in Whitehead (1934) and Braddick (1954).

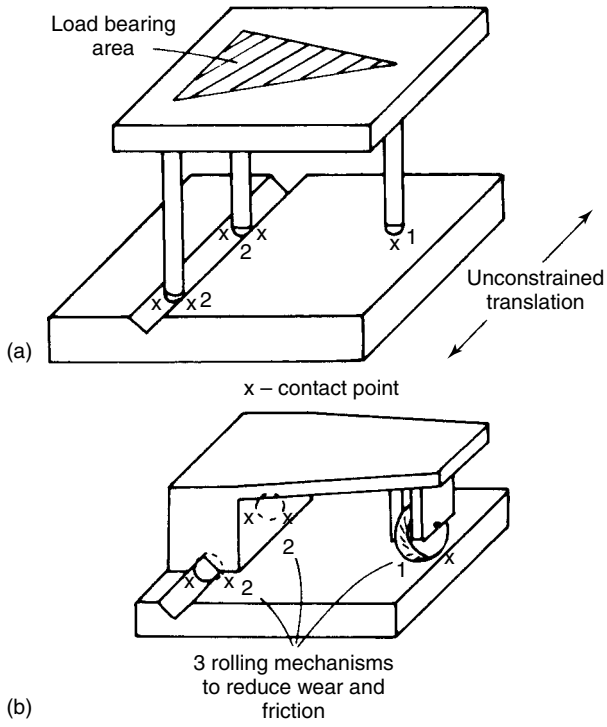

Figure 3. Kinematic design allowing one freedom of translation; (a) contacts subject to high wear; (b) contacts replaced with rolling devices.

The principle of kinematic (or other alternative) design is applied whenever two assemblies need to be coupled. It is necessary, therefore, to break down the whole system into its basic couplings or mechanisms, tackling the design of each in a hierarchical order to ensure that overconstraint does not occur unwittingly at a later stage by the addition of a link in an incorrect way.

Features of the kinematic method are that its parts can be made and installed or replaced without altering the positional system. Once made, the kinematic assembly will be reassembled with the same dimensional performance. Secondly, wear does not induce play in the coupling mode – it may, however, introduce dimensional change. Another feature is that the stresses exerted on all parts are well defined, and they can be designed virtually in isolation from the rest of the system once their contact loads have been decided.

Disadvantages are that there is a need for application of a locator force to hold parts together, such as gravity, magnetism, or small springs. The points of contact are also heavily loaded and consequently operate under conditions of high stress. The pure principle is often degraded by the use of extended contact surfaces to reduce the contact stresses – semi-kinematic design.

A further difficulty arises when it is seen that the systems result in triangular space frames when redundant links

are not present. The three-legged stool is a good example of the possible undesirable features of purely kinematic design. The stool always sits correctly on any reference surface without rocking, but place the load outside the central triangle defined by the leg positions and the linkage is soon lost. The locator should not be designed to withstand such forces.

6 ELASTIC DESIGN BASICS

The opposite philosophy is to join components rigidly, allowing them to flex within their elastic properties: a four-legged stool will still sit on any surface if the top is made flexible. The elastic philosophy deliberately contravenes the 'zero redundancy' law, doing so in a defined manner.

For this method to be designable, the system must be so constructed that the designer knows just what flexes and where. In cases where only limited translation and rotation is desired, the elastic method is probably the best. Purely elastic design is almost an academic abstraction. In practice, the method comes somewhere in between totally kinematic and elastic, being called *semi-kinematic*.

As an example of the two extremes, consider the need to swing a pendulum or the beam of a weighing balance. The pivot may be made using knife-edges that rock on a rigid flat (kinematic) or it may rotate on a single or a crossed flexure strip pivot (elastic). Another example might be the need to support a sensitive tilt meter on a given surface in such a way that the relative length changes, owing to temperature effects on the body of the instrument with no strain on the instrument body. This can be done with either the kinematic hole-slot-plane concept or by the use of three elastic flexible legs that bend a little as the body changes length (see Figure 4). It is important to make specific calculations of the degree of flexing that is needed. What may appear to be a stiff rigid member can be comparatively flexible when the forces are high or the movements small. The designer should regard all components at the onset as being compliant, altering this belief only after calculation of strains due to disturbances shows them to be adequately stiff or compliant as the case dictates.

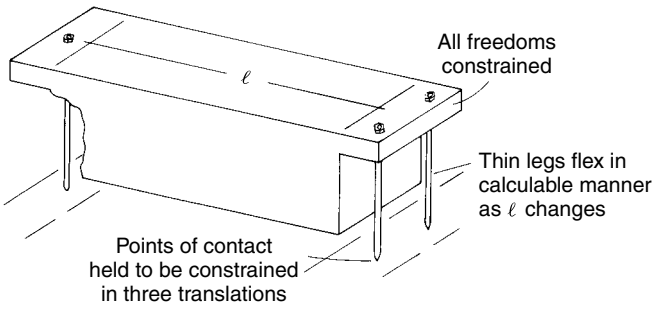

Figure 4. Semi-kinematic design – (ANAC tiltmeter support system).

The mechanisms of the two groups of design – kinematic and elastic – will be dealt with in more detail in later articles.

It is surprising that few texts on general machine design actually discuss these basic design differences. In some of the works that are specifically concerned with instrument design, these concepts are expanded. Greater depth and more examples on the topic can be found in Glazebrook (1922) Vol III, Whitehead (1934), and Braddick (1954). The choice of which philosophy to use and when is very much a matter of training and experience. Where elastic methods can be used, they usually offer considerable cost and assembly advantages. For example, locating one part relative to another with, say, one allowed translation of short stroke can easily be provided with a parallel-strip suspension. It will be virtually free of frictional effects. It will be cheaper to make but does suffer in that a changing deflection force is generated as the 'slide' moves.

1 WEAR-TRUE PHILOSOPHY IN MECHANICAL DESIGN

This article continues the discussion given in **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2** by adding systems issues. Kinematic design is covered in **Article 82, Kinematical Regime – Members and Linkages, Volume 2**; **Article 83, Kinematical Regime – Fasteners, Bearings, Volume 2** and **Article 84, Kinematical Regime – Rotary Motion, Volume 2**. Elastic design is dealt with in **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 86, Elastic Regime of Design – Spring Systems, Volume 2** and **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2**. Errors sources in both kinematic and elastic deisgn regimes are the subject of **Article 88, Error Sources in Fine Mechanics, Volume 2**.

In the Aeronautical Journal of July 1913, Horace Darwin, cofounder of the Cambridge Instrument Co., expounded a concept of design that states that as mechanical elements wear through use they retain the dimensional precision needed. He called it the *wear-true philosophy*.

The use of kinematic principles goes a long way toward this end, and by appropriate choice of proportion and arrangements, it is often possible to achieve a linkage that does not degrade in its accuracy as it wears or deforms.

Darwin illustrated this using the examples of the bearing arrangement of a wheelbarrow wheel. When the axle is fixed in the wheel, the axle ends wear round, and the bearing hole wears oval, yet still round enough to give good location. But fix the axle in the shafts and the shaft wears oval in the wheel and the wheel bearings wear very large and sloppy.

There seems to be no basic statable rule for achieving this and a situation that occurs often is when the designer attempts to arrange wearing surfaces to wear evenly on each contact face of the sliding surface. Another approach is to make the wear or deformation occur at a geometric position that has the least effect on the geometrical precision of the measuring component. Figure 1 shows two designs, one of which does not adhere to the 'wear-true' philosophy.

Darwin incorporated this principle in the design of his very successful 'rocking microtome' instrument of the 1885 period. It was capable of retaining the ability to cut microscope specimen slices to micrometer thickness for a half century of service – see Cambridge Instrument Company (1945) and Braddick (1954).

2 DECIDING THE RIGHT SIZE OF A FINE MECHANICAL INSTRUMENT

Unlike the situation occurring in electronic and in optical disciplines where the size of components usually dictates

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

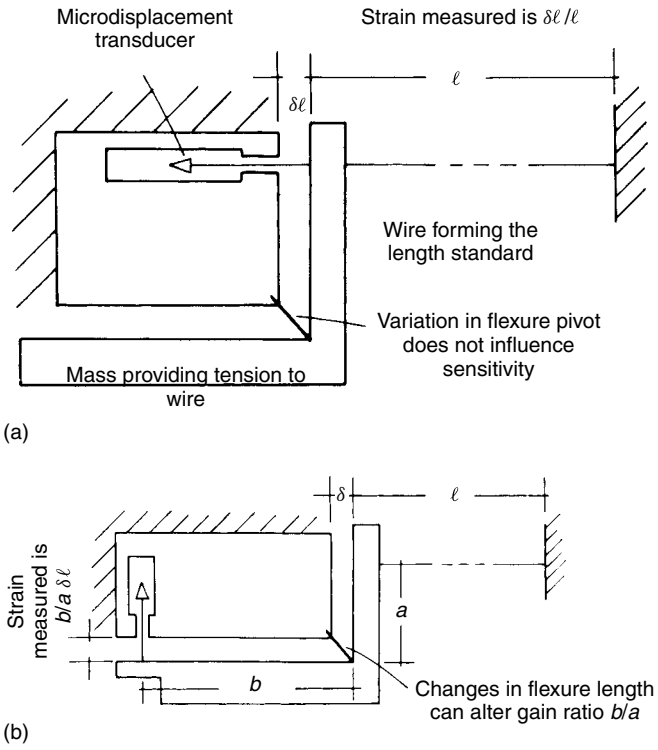

Figure 1. Two balances used to tension a wire length-standard in earth-strain meters; (a) uses wear-true design principle, (b) does not.

the overall size of the instrument system, mechanical instruments may or may not have clear-cut reasons for having any particular size. So, at the outset of design, a choice must be made if progress is to take place that does not need to be completely revised later. Here are a few considerations that may help decide the overall size of the instrument. Braddick (1954) provides specific case studies to illustrate some particular reasons for a given size.

Certain functions, such as a size dictated by a necessary component, may decide the basic size to be used. Examples are the objective size and focal length in a telescope, the length of translation of a measuring machine, the load and volume to be supported or contained, and the need to match a given existing product.

Portability may dictate low weight, but small size often means increased cost and difficulty with assembly and servicing. However, dynamic response rises as parts become smaller. The physical size of a high frequency response anemometer must be very small.

If energy must be stored in mechanical or thermal form, large rotating or static masses may be needed. Examples are the wheel of a gyroscope and the bed of a measuring machine that must integrate short-term temperature fluctuations.

Ergonomic needs dictate that the unit must have manual controls that suit man-size fingers or be mounted at heights that can be easily seen and reached. Whatever the reason, the designer should attempt to find objective bases for choosing a given size. If not, there will always exist the possibility of having to rescale the physical form at a later date.

3 STATIC AND DYNAMIC CONSIDERATIONS FOR A FINE MECHANISM

The static regime of a measuring systems is covered in **Article 57, Static Considerations of General Instrumentation, Volume 1**. The dynamic regime is introduced in **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**. The transfer function of a system block describes the input–output relationship at all relevant frequencies of operation. It comprises a DC gain term multiplied by a frequency dependent term. Although there exists in reality a continuum of performance from DC to the highest frequency of operation, descriptions of the performance are generally split into two domains, the first being the steady state or static characteristics and the other the dynamic behavior that is described by the frequency term.

Mechanical systems are no different from others in that they possess both static and dynamic characteristics.

The design of a direct-reading traveling microscope requires virtually no understanding of the dynamics of movements that the operator imposes on its sliding parts unless it is large, in which case the inertia of the sliding part can be great enough to impart excessive forces restricting the operator's manipulation response. However, if the readout is automated by closing the translation drive loop, the dynamics of the whole system become important if stable and rapid high-speed operation is to be obtained.

Apart from a very cursory statement saying that dynamics do occur in instruments, the majority of instrument design texts give little help with this aspect to the designer of modern multiregime instrumentation. Instead, the designer must read much more widely in order to become familiar with the basics of dynamical systems and then apply the general rules to instrument design where it is needed.

Definition of static performance involves specifications being stated about such parameters as resolution of readout sensitivity to a given variable input, linearity, accuracy, precision, repeatability, and many more concepts. These concepts, which are unfortunately not totally standardized in terminology, are described in most works on instrumentation and therefore need not be developed here. Doebelin

(1975), Foxboro (1972), and Bell and Howell (1974) are examples. They are terms generally describing only the static behavior, the results of tests measured after the systems come to rest. During transients, the performance can be very different indeed. In many cases, the manufacturer provides no statement of dynamic behavior.

In the dynamic mode, the designer must be aware of the effect of friction in its various forms, of the effects that the various kinds of slop between couplings produce: backlash, dead zones, and other nonlinear operation. Where the best acceleration is needed from a motor driving load, the load inertia must be matched to that of the driving source. A gearbox is often needed to obtain this match. The transient performance of electric motors is generally compared by the magnitude of their ratios of torque^2/inertia. This is called the '*power-rate*' (West and Leonard, 1955, and Rothwell, 1966). The same term can be applied to any form of motor (spring motors, gravity feeds, and other mechanical motors), in a similar manner (Sydenham, 1969), giving the designer a chance to assess the relative merits of various mechanical or electrical drives. Where high acceleration is concerned, the diameters of rotating parts should be kept as small as possible; rotational inertia increases rapidly with an increase in diameter, sometimes as the fourth power of the radius. The problem of matching mechanical loads to sources is identical to the problems existing in electrical power transfer.

When resonance is to be invoked, or appears unwanted, the designer needs to know how to enhance or reduce it. The role of damping must be understood. In some instances the designer attempts to design for the highest Q conditions so that the system constantly 'rings' by noise excitation (a relevant example being one form of gravity wave detector that uses large freely supported blocks of aluminum as detecting resonators). This provides increased sensitivity to signals at or near the resonant frequency. The dimensional changes, transduced to electrical signals, are then inverse-filtered to remove all but the varying amplitude of the frequency at which the system is resonating. This variation contains the signal to be detected. In this case, damping is deliberately kept to a minimum.

In many applications, however, the aim is to introduce damping deliberately to produce a certain response to input excitation. This is done by adding damping to the resonant system with suitable mechanical, or other regime, dissipation elements. Consideration of the means to reduce the effects of mechanical hysteresis suggests that the addition of damping is not always the best approach to use, because vibration to rest can often improve the static precision of such elements as bellows, springs, and diaphragms.

Thorough study of the dynamic performance of an instrument is far more complex and time consuming than is the case for the relatively simple static domain. Certain mechanical parts may not be stiff enough or may possess too much mass when under the rapidly changing movements existing in velocity, acceleration, and jerk conditions. The first step to designing for the dynamic mode in a machine linkage begins with studies that provide the designer with maximum values of velocity, acceleration, and jerk. The kinematics of linkages is a topic well covered in texts on the design of mechanism, see, for instance, Beggs (1955) and Mabie and Ocvirk (1958). This leads to the stress levels that occur from which the deflections can be calculated (although often with considerable difficulty, for the maximum deflection and dimensional change points are not always in obvious positions). Inertia force considerations calculated from knowledge of the moments of sections of components, coupled with the velocity and acceleration data, lead to other dynamic considerations.

4 MECHANICAL SYSTEMS MODELING

The above description of the static and dynamic aspects of instruments is not based upon an overall unified systematic understanding of the topics but is typical of the ad hoc approach that many designers use. Each of the above observations can be better explained and calculated using a common fundamental mathematical basis for dealing with the performance of physical systems. The mathematical description of mechanical linear systems is the same as that for electrical, thermal, and fluid regimes, *see* **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**. By the use of appropriate coefficients, the performance equations of one regime can be interfaced with those of another. Figure 2 is an example showing how the moving coil meter can be expressed in a common electrical regime, which can then be studied as an electric circuit to obtain its dynamic behavior. This means that electromechanical systems can be represented by a single mathematical expression. The actual performance will closely be as predicted from this model (in so far as the real situation matches up with the model used).

This understanding is represented in the systems approach to physical system – see Finkelstein (1977) for its use in measurement. This is not to be confused with the much more widely applied 'general systems theory' that attempts to take in far more experiences, including such topics as biological and sociological phenomena. The latter is similar in concept but has to operate without the same degree of mathematical rigor and formal representation that is present in the former.

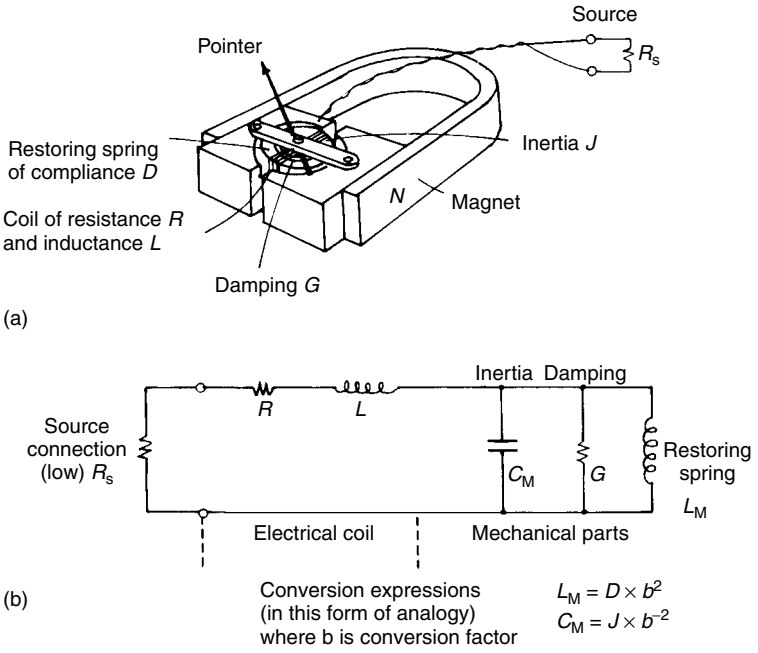

Figure 2. Unified representational model, made in the electrical regime, of electromechanical moving coil indicator; (a) physical electromechanical system; (b) electrical model.

The systems approach for physical systems has been steadily developing from roots emanating from the early radio era when microphones and loudspeakers were first being developed. Various papers were written on what were later seen to be constituent parts of this integrated topic. Eventually the basics were assembled together as a single methodology in such books as Olson (1943), where the 'analogies' were presented as a systematic approach to the design of linear dynamical systems. Initially, the approach was developed for the design of electromechanico-acoustic devices. It gradually found its way into the description of electromagnetical machines in general; see Fitzgerald and Kingsley (1961) and Koenig and Blackwell (1961). The material was later presented as a method to cover the dynamics of all physical system regimes, Shearer, Murphy and Richardson (1971) being a well-presented and extensive work; it also lists other books of relevance.

Each of those above mentioned works was in general written for the study of energy conversion devices. Instruments are a class of those specifically concerned with the conversion of information into knowledge, that is, using an energy conversion transmission path to convey meaning between points in a system. The foregoing theory of physical systems can be condensed somewhat when instruments are the prime interest.

Modern finite element CAD tools are now able to support sophisticated design development, moving from basic element representations, stress and strain calculations, and graphs, onto CNC software files for manufacture. These tools, however, still require the user to have a well-developed sense of the metrology aspect of the system being developed.

Mathematical models, *see* **Article 71, Modeling Methodology, Volume 2** are only as good as the numerical values that give the workable boundaries to the system of equations used. These are invariably obtained from experimental procedures; thus, there will always be a decision to make about whether it is more expedient to generate a mathematical model or to build the device and test it.

Models may also take the form of scaled physical versions or analog simulations in another regime. For example, an application required the development of a small linear vehicle for robotic research. Testing its linear movement performance to check out the circuitry, the braking, acceleration, and control circuits was more conveniently done using the drive system to operate, as the final stage, a rotary equivalent of the linear mass to be driven. Digital simulation is another choice for modeling the system.

A word of caution must be given, however, on the use of models. It is all too easy to become used to the idea that the model that has taken so much hard work to develop is a true and entirely faithful representation of the final instrument. Models are rarely more than just adequate because the effort needed to improve them beyond a certain point is not seen to be further productive in low production rate instruments. The user often decides to compromise model precision in order to make progress.

A model, although it may well simulate the correct input–output relationships, may not do this by the same internal mechanisms as the original system. The field is covered by the discipline of 'systems identification' and 'simulation'. This point is demonstrated by thinking about the fact that there are many technological ways to achieve an end: fuel gauges in a car can be electronic or entirely mechanical. Models must be so constructed that any internal data that are desired are available to the user of the model.

The united 'analogies' approach to instrumentation also shows that the performance of an instrument system can be tailored by the use of any appropriate discipline. In setting up an instrument design, the degree of mechanical proportion needs consideration in the light of what can be achieved using alternative electrical, optical, and fluid regimens. For example, several years ago the design of gauges for dimensional measurement generally required the designer to incorporate as much mechanical sensitivity as possible in order to obtain an adequate mechanical signal output. Today, the electronic alternative allows virtually unlimited dimensional sensitivity: fractions of nanometers can be routine (Sydenham, 1972). Mechanical stages no longer have that constraint imposed on them; the trading off of sensitivity usually allows higher frequency response.

A second example of the use of alternative regimes arose when a radar-tracking turret was assembled and found to have an unexpected resonance in a drive shaft. It was more easily overcome by adding electronic compensation circuitry to the control systems than by replacing the shaft with a stiffer design. Instrument design is no longer the matter for a single approach, nor does electronics always offer the best solution.

Design is the procedure whereby a mass of general facts are gradually sifted to sort out which combination will achieve the specification. There is seldom a unique solution and the designer is constantly required to make choices, knowing that a whole range of other possibilities are then omitted from future considerations. Finkelstein (1977) and Bosman (1978) discuss this in relation to instruments.

1 GENERAL INFORMATION ON KINEMATIC COMPONENTS IN FINE MECHANISM

Mechanisms act as links, called *pairs*, that couple parts of a system together. Although not a classification generally used, it is convenient (and logical) to divide mechanisms into two groups: those based mainly on kinematic concepts and those that operate via elasticity. For our purposes, links that are strictly semikinematic because of their bearing area being greater than a point contact, including those which are manufactured to perfect enough tolerances, will be placed in the kinematic class forming the first group. Both types do use elasticity to spread the initial load but do not rely on compliance to allow subsequent deformations to take place. For example, a bolted joint deforms as it is tightened but does not flex to the extent as would an elastic cantilever beam that it could be holding. Ball bearings also deform at the points of contact, but the degree of yield is generally smaller than the component they might be supporting.

The various kinds of mechanism that might be employed include such devices as members, columns, bearings, linkage arrangements, wobble pins, gears, belts, cams, fasteners, flexures, shaft couplings, and clutches. There are very many of these, and in the past they have always been ordered into logical groups. Today, it seems from the published material, no satisfactory classification has been achieved. Authors still differ widely in the way that their works are organized.

In this account, they are ordered to reflect the design process: how the designer moves from one stage to the next, gradually completing the detail of the system being created.

Kinematic and semikinematic mechanisms are divided into members, linkage arrangements of members, fastenings that join members rigidly, bearings that are used at the joining points of linkages to allow motion, and the transference of motion across a linking point where rotation is required at a given gearing ratio. This article addresses members and linkages.

Texts that contain information on the various types of mechanisms are from the time when there was considerable interest in fine mechanism. It is apparent from inspection of the interiors of such equipments as printers and copy machines, that this design expertise still resides somewhere, but not in recent texts. The useful source books include Beggs (1955), Braddick (1954) for which a 1966 edition exists, Faires (1955), Mabie and Ocvirk (1958), which was reprinted in 1975, Peatfield (1951), Doughtie (1966), Reliance Gear (1972 and subsequent years), and Trylinski (1971). The many publications of Geary (1955, 1961, 1962, 1964) may also be of use in

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

the general selection of mechanism. Beggs' work contains a 'repertory of mechanism' that is provided as a source of ideas. Of these books, Trylinski's work is the most theoretical general work that is specifically on instrument mechanism. The date of publication of works on mechanism is not very significant, for mechanisms have been known for centuries. Little has changed in the principles used. They have just become more sophisticated in implementation. Very few new mechanisms, in fact, have been invented in recent decades. A key paper by Furse (1981) is relevant to kinematic design.

2 MEMBERS IN FINE MECHANISM

Here, the discussion centers on three-dimensional materials that are fashioned to have significant length over radius of gyration ratios. Included are columns, beams, plates, and shafts.

A slender member can be used in tension with the dominant failure mechanism being when it yields beyond its elastic limit in tension. The way it is fastened to another member is another design issue to be allowed as a connection (*see also* **Article 83, Kinematical Regime – Fasteners, Bearings, Volume 2**).

The elasticity and the strength of a slender member are calculated from the usual strength expressions relating Young's modulus of elasticity to compliance and the material parameters that define the limits of tensile load. Compliance remains the same for all conditions of a material; tempering and other treatment does not alter the elasticity, only the ultimate point at which yielding begins; where Hookean elasticity ceases.

There is an exception to this rule; that is, when the material is formed as an extremely slender fiber; the mechanical properties may change significantly. It is good to remember that the end connections may need to be of a much larger section than the member to keep bending stresses low. In instrument design, where dimensional change is important, the compliance of apparently adequately strong members may be too high and they need to be made well over the strength needed. Calculations should be made to verify that it is adequate from the viewpoint of its compliance.

3 COLUMNS AND SHAFTS COLLAPSE STRENGTH

In tensile use of a member, the longitudinal forces on it act to stretch the member; in this case the force system is stable. If, however, the force is reversed so that it now compresses the slender member, the first failure mode to appear will not be compressive yield but collapse due to the column buckling as it bends to form one of several possible modal shapes of a bent member.

This form of collapse is quantified by use of Euler's column formula (Timoshenko and MacCullough, 1959). The formula gives the value of load at which the fundamental mode, for the given end connections, begins to appear.

Euler's point of buckling depends upon the end conditions of constraint that are applied to the two ends of the beam. These may be so-called *pin-connected* (that allows rotation at the end in any direction) or be firmly clamped so that perpendicular rotation is not possible at the point of connection. The first case is also referred to as *simply supported*, the latter as *built-in* or *fixed-ends*. Another condition of Euler buckling can also occur when the end is not constrained in translation, being free to move sideways under the load.

An interesting feature about the two sets of key beam formulae (Eulers' buckling and deflection) is that although each has a different basic expression, within each group the expressions vary only by their numerical coefficient. The stiffness of a column or beam increases as the ends are made more constrained and the end point loading made more central. Figure 1 shows the various cases of collapse that can occur.

As a guide, Euler collapse begins to occur when the slenderness ratio rises to reach around 100. The value must be calculated for the smallest radius of gyration when the member has an asymmetric cross section.

4 SECOND MOMENTS FOR COMMON MEMBERS FORMS

Figure 2 provides information about the moments of typical sections of structural member as they are then needed. These formulae are needed for many mechanical member designs. They assist selection of cross-sectional shapes for suitable column and elastic members.

5 USE OF SHAFTS AND PINS IN FINE MOTIONS

Rotating shafts also have a performance failure that can be likened to the column collapse characteristic. A shaft that is free to turn in bearings that do not constrain its rotation at the bearings will reach a critical speed at which it begins to whirl – the central region attempts to move outwards owing to centrifugal forces. It takes up a bent profile while it rotates. This, too, depends upon the elasticity of the material and the slenderness ratio of the shaft. The expression giving the lowest whirling speed is given in Figure 1. Attachment of loads along the shaft alters this value (Faires, 1955; Mabie and Ocvirk, 1958).

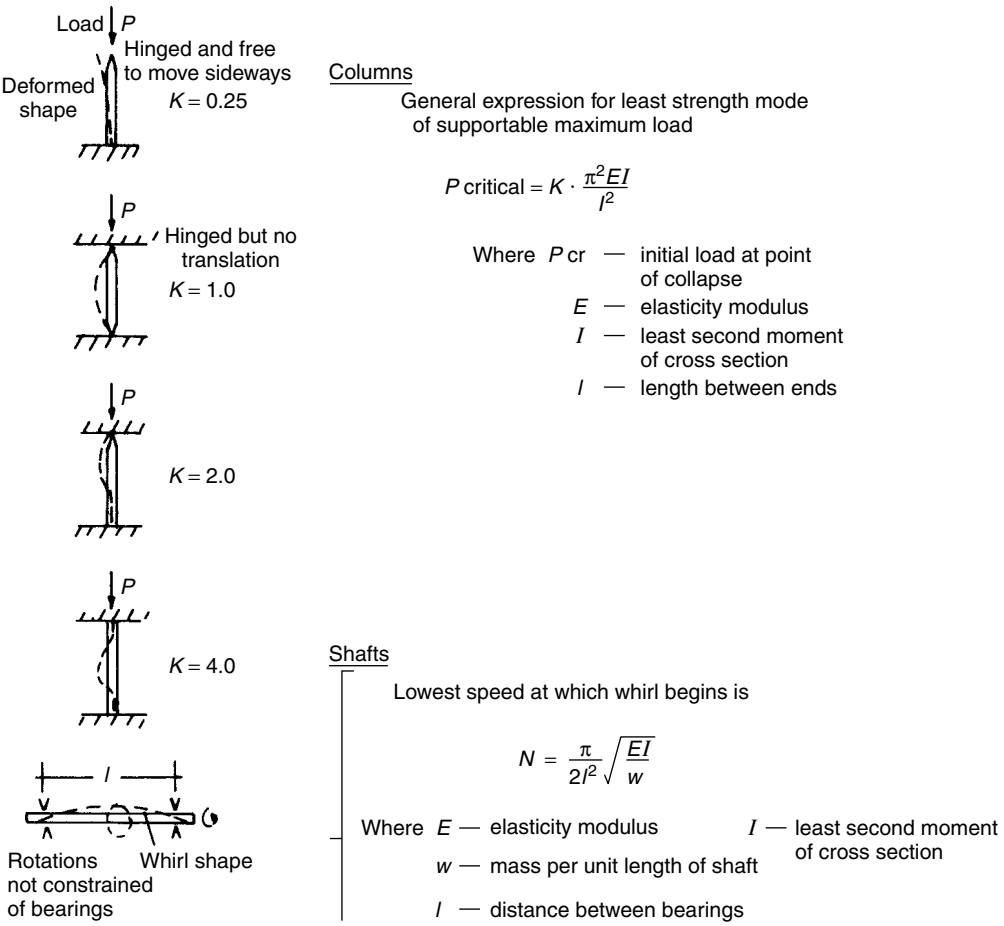

Figure 1. Columns and shafts – collapse point.

Slender members might be used as shafts coupling motion, or as parts of a linkage to produce a given motion. They can also form wobble pins that transfer linear motion without forcing any constraint on the freedom of translation that occurs at the end of the members forming either side of the drive.

Wobble pins, Figure 3, can only be used to transmit compressive force, since the compressive force keeps the point contacts mating. Ends are usually formed to be small radii hemispheres. Another use for slender members is where thin legs are used to support a tiltmeter while allowing freedom of expansion of its body. If in tension, drive can be transmitted by relatively thin wires or rods, for in that situation the Euler's collapse mode cannot occur.

Slender members (often called *beams*) used in the horizontal direction to support loads are the usual subject of texts on the strength of materials; origins are largely for civil engineering structures analysis. The various cases of point load at a given position along the beam, a uniformly distributed load or of a mixture of loads are each well developed for the various free- and clamped-end connections.

The formulation extends to cover the two-dimensional plate having freely supported and built-in edges to which is applied a central point load or a total area distributed load. These latter cases cover the needs of most diaphragms in pressure gauges. Intentionally designed deflection of shaped diaphragms is discussed in Trylinski (1971).

No difficulty should be experienced in obtaining the various formulations. In the case of very complex loading, it may be necessary to develop the expression from the basic approaches that are used to obtain the quoted equations; see Timoshenko and MacCullough (1959) for a full treatment of the equations of beams and other components. Texts containing tables giving the common expressions are Braddick (1954), Faires (1955), Neubert (1975), and Timoshenko and MacCullough (1959).

Beams that are curved and have to carry linear tensile or shear loads, such as a hook, will experience high bending stresses in the region of the bend. Areas around rivet and pin connections can be unexpectedly weak near

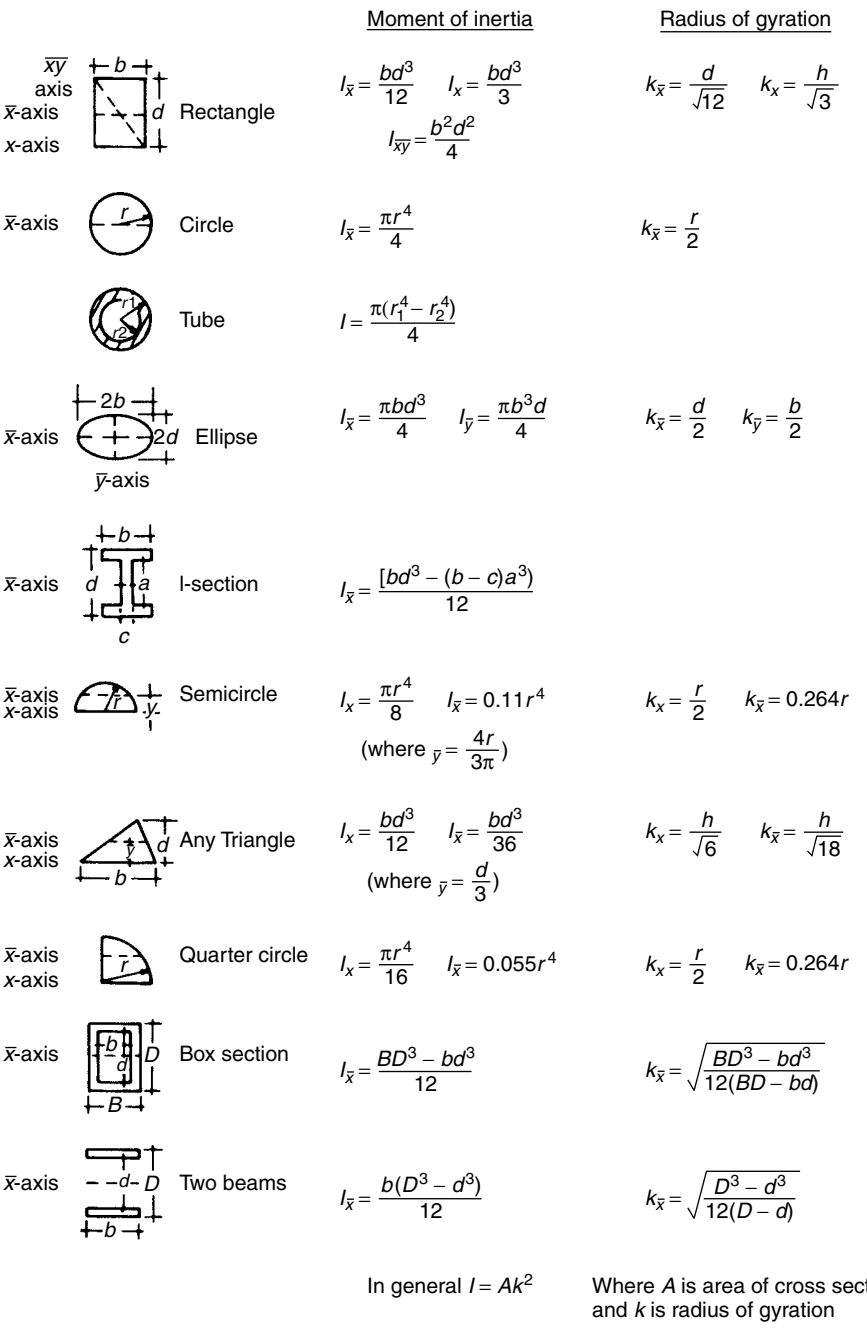

Figure 2. Second moments of commonly met sections (composites can be built up by addition of these sections).

the joint if care is not taken to increase the section size.

Beams find use in instruments as structural members and as sensing members; they may, therefore, need to be appropriately inelastic or elastic. Successful design rests on choice of material, design of the member shape and size, and the connections used.

Shafts also can be made elastic or rigid depending upon the need. They should be large in section and short in length to increase the frequency of resonance when they transfer rotary motion in closed-loop systems.

The torsional elasticity of a shaft is calculated from the torsional or shear modulus for the material, the process of calculation being analogous to that for analyzing linear elasticity of a member.

Dynamic balancing of rotating parts is needed where vibration levels must be kept low.

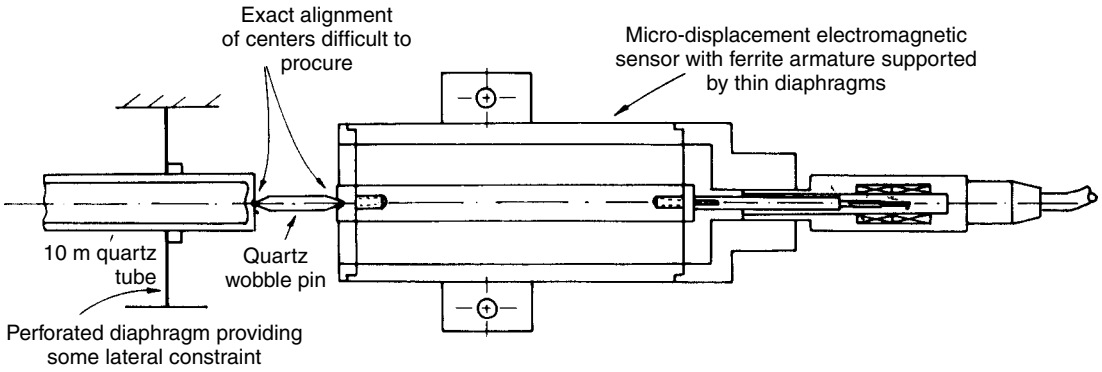

Figure 3. A wobble pin can be used to couple a moving member to a more constrained point. It will buckle if too slender for the compression force (Sydenham, 1974).

6 LINKAGES

Members connected together can be used to provide conversion of motion of various kinds – from linear to rotary, from linear to linear, and from rotary to rotary. The range of possible linkage functions is vast.

Linkages, Figure 4, may form a mechanism for geometrical size conversion such as in the pantograph, or as the method by which a balance scale can be made insensitive to the position of the load in the scale pan (seen in the so-called *static enigma* by Roberval in 1669, which appears to contravene the laws of the lever). Linkages have found extensive use in the classic typewriter, pneumatic controllers, weighing scales, in mathematical calculating instruments, in recorder pen drives, and numerous other applications.

The method of analysis of linkages can also be used to study the action of solid components, such as cams; the instantaneous contact points form geometry that can be considered to form hypothetical members. Linkages become structures under certain conditions of constraint.

7 DESIGN OF THE IDEAL LINKAGE

The mathematical analysis of linkages has fascinated academics for centuries. Many of the defined fundamental problems are still to be solved in theory. The rise and development of the kinematics of linkage is described in Ferguson (1962). To a large extent, analysis, the method of breaking down the action of a given linkage and motions of its members, has succumbed to methodology that can be used to ascertain the positional motion of linkages of reasonably simple nature. As the number of members in the linkage rises, the problem becomes more difficult. The four-bar linkage begins to present a significant theoretical challenge.

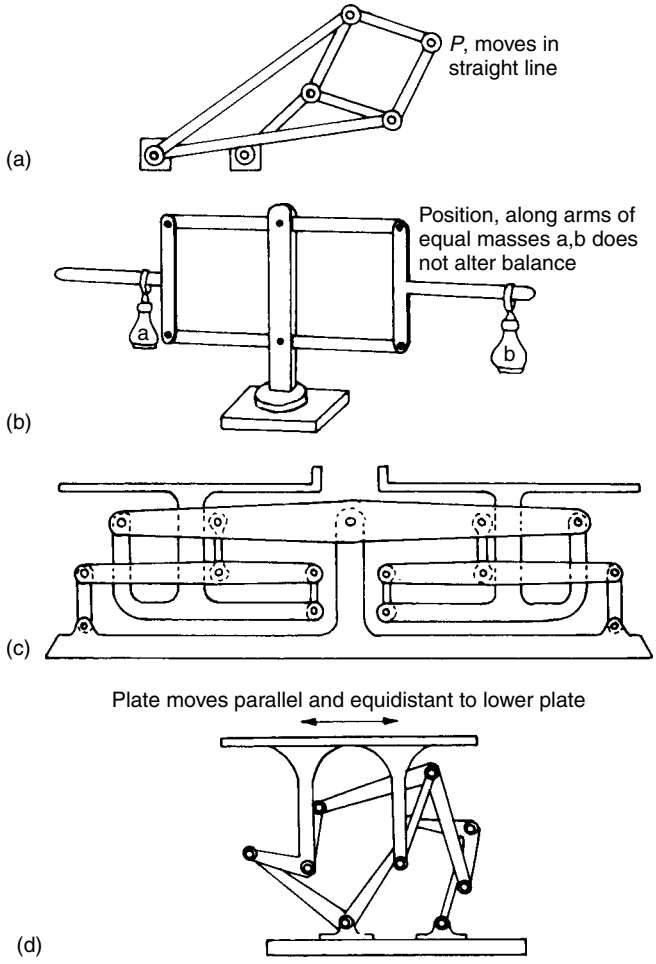

Figure 4. Some linkages used in instruments: (a) Peaucellier's straight-line generator one form; (b) Roberval's static enigma; (c) Beranger's use of Roberval's static enigma in a scale; (d) Sylvester–Kempe parallel translating linkage.

As there does not seem to be a simple general theory that can be applied to decide the motion at the various parts of a linkage system, the problem is often tackled by the use

of graphical procedures in which the motion is generated in incremental steps. To assist the designer, several authors over the centuries have published hard copy catalogs that show the motion of variously constrained linkages. Today, appropriate CAD tools can carry out this function.

What designers would rather have is the means to systematically synthesize – rather than analyze – a linkage system, in order to obtain a required motional relationship. This is, however, still in development; only relatively simple cases can be handled. A computer solution of the equations involved has extended the use of synthesis methods. Usually, the designer resorts to the use of models (in the computer or real), makes use of the above-mentioned catalogs, or iterates toward a suitable linkage arrangement using analysis of each choice.

It is sobering to realize that the theoreticians sought for many years, the theory by which a perfect linear action can be produced by some point in a system of rotating links. Unexpectedly, out of this and other similar interests has emerged useful mathematics for other disciplines (such as the Chebyshev functions now used in electronic filter design, but first compiled for steam engine linkage behavior). This linkage was finally produced by Peaucellier (Figure 4a) in the 1870s.

Many useful systems for instrument work have been invented. The 'static-enigma' balance mechanism made simple-to-use, accurate, top access scales feasible (Figure 4b, c).

The 'Sylvester–Kempe translating linkage' (Figure 4d) allows one platform to move parallel and equidistant from a second surface.

Johnson's 'converting motion' provides two revolutions from a single reciprocating translation.

Other systems related directly to linkages are the Geneva stepping mechanism, the Scotch yoke, the Oldham coupling, and many more.

Ability to analyze a linkage might be necessary to establish the clearances needed as the members move, to assess the velocities and accelerations of the various parts and points, to predict the input–output functions, and to study the action of systems like cams and gears.

The methods of analysis of linkages are discussed in Beggs (1955), Faires (1955), Mabie and Ocvirk (1958), Zimmerman (1962), and Lent (1970). Trylinski (1971) uses the procedures in his discussions of the kinematics of various mechanisms used in fine mechanics. Ferguson (1962) includes several references to linkage theory. The journal *Precision Engineering* (first issue, January 1979) is a source of papers. Burstall (1970) discusses the history of linkage development giving several references to early works. This book contains illustrations of linkages that were invented during the history of man's involvement with technology. Pollard (1929), on the design of couplings, also might help understanding of the procedures.

1 FASTENINGS IN FINE MECHANISM

The purpose of fastenings is to join components together in a manner that will provide a firm constraint of all degrees of freedom at the joint. Available designs vary greatly, the choice largely depending upon the magnitude of the forces and torques involved, whether the joint is permanent or needs to be detachable, the degree of vibration experienced, and the level of dimensional accuracy needed. The design of joints is as important as the other factors of a fine mechanical system.

An introductory, nonmathematical catalog of fastenings can be found in Peatfield (1951). A thorough treatment of many of the possible types is given in Trylinski (1971), this being a key work of reference. Machine-design texts such as Faires (1955), Lent (1970), Shigley (1988), Erdman, Sandor and Kota (2001), and Juvinall and Marshek (2002) generally treat only the joints used in power machines, that is, bolted, riveted, and welded arrangements.

In some applications, the dimensional stability of the joint can be very important. One view suggests that in such cases, it is better to avoid using joints, making the whole unit from a single piece of material. Examples are the manufacture of flexure pivots in which the flexure part is formed by thinning down the piece of material. There is, however, very little substantive evidence to prove that this is necessary. To the contrary, it has been found that remarkably crude joints, such as knotted metal wires, rings placed over a shaft and in tension, small magnets holding a part to a surface, and bolted joints (Jeffery and Sydenham, 1973), will each hold dimensional relationships across the joint to less than micrometer level. Couplings working at the very small tolerances of nanometers or less may well exhibit instability, but it is far from easy to verify where such a drift actually occurs. Errors of this magnitude can come from so many sources. As an example of the many forms of spring-gravimeter that have been made, units using bolted metal arrangements have shown as small a drift rate as others with mostly continuous parts.

Joints forming part of a mechanical resonance loop can, however, seriously alter the Q-factor because of the damping inherent in the jointed faces. Joints should be avoided where high-quality factors are needed.

In instruments, the joints must provide adequate strength but also they must usually be stiff in compliance. Because of the small sizes of the metal work in instruments, many ingenious joints can be used that would not be practical for large-size machine construction. Joints divide into permanent and detachable methods.

2 PERMANENT JOINTS

Figure 1 illustrates examples of some methods of making a permanent joint. A commonly used permanent joint is formed by passing the metal of one part through a hole

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

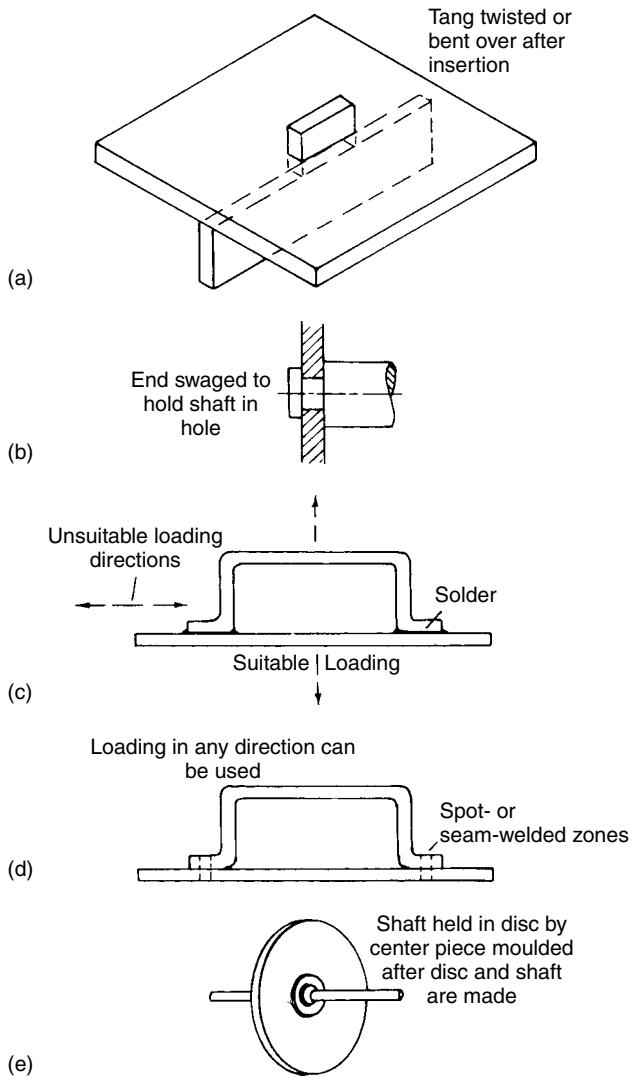

Figure 1. Some permanent fastening methods; examples of each type: (a) bent tangs; (b) swaged after insertion; (c) soldered or glued; (d) resistance welded; (e) molded in place.

in the other and by swaging or twisting it to lock the two parts together. The tang can be twisted, bent over, swaged flat, center punched, or crimped. Trylinski (1971) gives illustrations of many types.

Force-fit joints that rely on friction and a certain degree of cold welding as the parts are forced into unison can also be used. For these, the tolerances of the mating parts must be carefully controlled. These give good dimensional control.

Welded joints are often used, the smallest possible area of welding being at micrometer size. Fine pressure capsules are often welded using focused laser radiation. Gas or electric welding is also used. Distortion due to the heating must be allowed for. Not all materials can be welded.

Adhesives can be used to form permanent joints, epoxy formulations having considerably changed the role of adhesives in instrument construction. Work at the former Sira Institute in England has resulted in several publications on the use of adhesives, Shields (1976) being a substantial account. The slow setting rate of cements and adhesives can make them unsuitable for mass production methods. In some cases, using cements, those substances that fill a gap without stressing the parts that are held together, may be the most suitable method of securing components, for example, holding a lens in a holder.

When using glued or cemented joints, it is necessary to ascertain whether the joint will have adequate heat transfer or electrical conduction across the joining layer that is interposed between the parts. Cements and adhesives are often hygroscopic; they may also creep in dimension. In some instances, however, gluing may be the only satisfactory method of making a fastening. A good design attempts to form a fillet of glue over a large contact area. The glue should not be used to form a dimensional link but should be used to adhere two creep-free materials in close contact. Trylinski (1971) contains a large bibliography on the subject.

3 DETACHABLE JOINTS

Figure 2 shows some examples of detachable methods of jointing. These can be made using screw threads, which hold flanges together or which are formed on the end of rods to be jointed; using pins holding a shaft in a hold (tapered, parallel, roll-pin, shear-pin); using keys that hold a shaft in a hole; and as press-fit combinations. Where the jointing forces are low, such as the holding of a dust cap over a socket, the use of the lids and caps held by simple turn-lock devices can be used. Trylinski also covers these in detail.

When bolts are used to hold a flange, the designer has the choice of either making the bolt hole with close-fit tolerance to ensure the correct dimensional relationship or using some other method of location, using the bolt only as a clamping device. Locating methods in use are spigots or taper and parallel cylindrical pins. It is not good practice to use a large clearance hole in which the actual position is set up on assembly. This may suffice for a one-off prototype, but in conditions of vibration or where service personnel may not understand what is needed, the position can be lost. Where positional accuracy is vital, the joint can be drilled and pinned after assembly. A spigot is used where the location is predetermined. Where the bolt is used to retain position, its shaft should define the location, not the thread diameter. To ensure that this is done, the thread is made with a smaller outer diameter than the shaft next to the head of the bolt.

Screw threads are used extensively and numerous forms of thread profile and diameter are found in applications. The

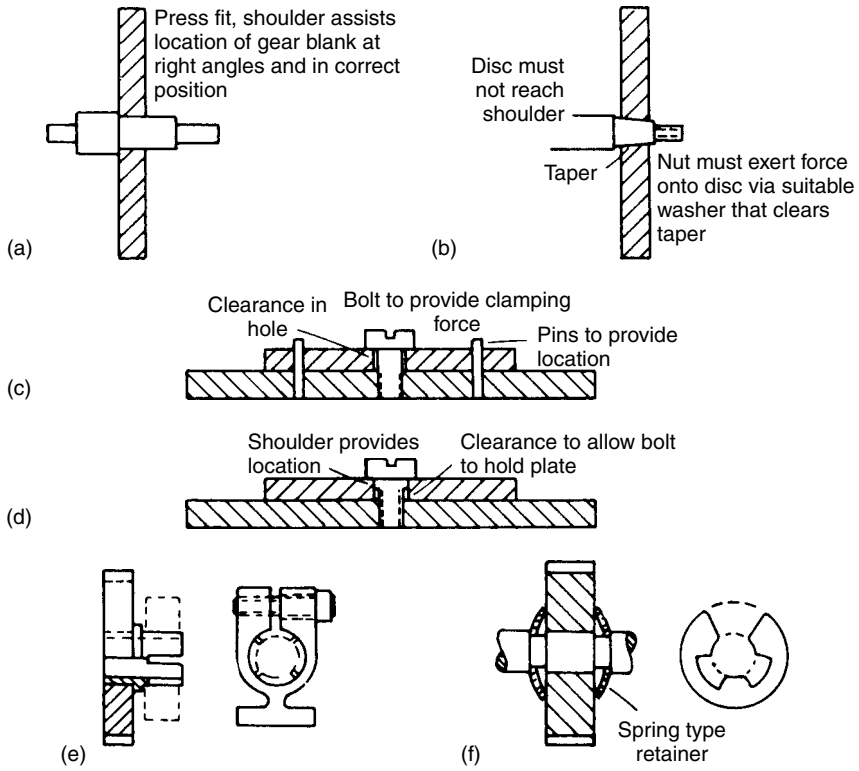

Figure 2. Some detachable fastening methods – examples of each type: (a) press fit; (b) taper shaft; (c) pinned; (d) screw thread; (e) clamp-hub; (f) retainer ring.

designer of a production instrument should strive to use a standard thread where possible. Different disciplines have their own threads – cameras and microscopes being examples. Multiple start, special thread profile, taper threads, and others are sometimes used in instruments. Threads can be locked with some form of lock or tab washer or can be pinned. Where the joint must be secured against unauthorized opening, the shaft outside of the nut is drilled to take a small wire that can be sealed. Special proprietary fluids are available to lock threads; paint is sometimes used. Here again, Trylinski (1971) is a definitive reference work.

4 INSTRUMENT BEARINGS AND PIVOTS

Joints between two parts that allow motion, such as rotation or sliding in translation, are generally called *bearings*. Trylinski calls them *supports*. They are also referred to as *pivots*.

The relative motion may combine both rotation and translation through the bearing axis. They may be included either to limit end-float in a thrust bearing or to allow an arm to turn about a fixed shaft pin. Figure 3 shows a collection of bearings that can be used in instruments.

Selection of bearings begins by a definition of the role that the material support has to play. All bearings are imperfect and will add some measure of freedom at the pivot-bearing point. System sketches realize the degrees of freedom that are needed; study of the system's operation decides the tolerances that are permissible. Other factors to be considered will be the relative speed of the two surfaces involved, the kind of lubrication that can be used, the coefficient of friction, the life needed, assembly requirements, cost and market availability, effect of temperature changes, and the degree of stiffness needed from the joint formed in the bearing. It is quite possible to produce a usable bearing (using preloaded rolling balls) that is as stiff and as backlash-free across the joint as is the rest of the structure.

Supports that allow movement by virtue of elasticity of a flexure are discussed in **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 86, Elastic Regime of Design – Spring Systems, Volume 2**; and **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2**.

Bearings for rotating shafts have been in use since the earliest times. Rawhide was used by the Egyptians around 1500 B.C. Bronze bushes were used in wagons of Roman times. Crude ball bearings date to the same period. Caligula

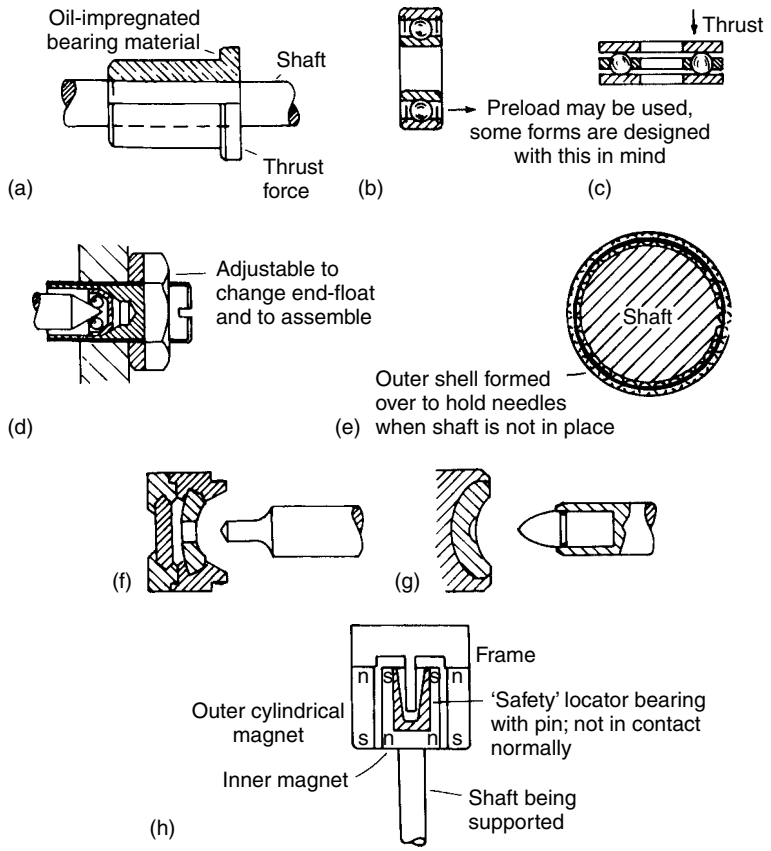

Figure 3. Selection of passive bearings used in instruments: (a) plain bush; (b) radial ball race; (c) ball thrust race; (d) pivot type ball; (e) needle roller; (f) jewel with thrust; (g) center support; (h) magnetic.

had a ship with turntables running on large bronze balls. These early ball systems were not strictly freerunning, for they were constrained so that the balls also slid while turning; Burstall (1970) gives more detail.

Around 1770, Count Carburi used a system of metal tracks and balls to move a 1.5×10^6 kg granite mass across the frozen Russian land (Turner, 1973). The tracks were laid end to end as the statue was moved.

5 REDUCED FRICTION PIVOTS

Friction was recognized as the limiting phenomenon in many an elegant mechanical apparatus of the early times. In those times, ball races, as we know them today, could not be made to the degree of accuracy and quality control that was needed. Many methods were used to minimize the effects of friction in bearings. A particularly interesting one is the so-called *frictionless bearing* arrangement attributed to Sully (1680–1728). This used a system of wheels and shafts running on the periphery of overlapping support wheels held in the prime bearings (Figure 4) effectively to increase the torque that is placed onto the bearing areas. The constraining moments of the bearing have less effect on the output in this arrangement. A number of well-known instruments of that time used this bearing – Atwood's falling machine, Michell's and Nairne's dipneedles being examples (Turner, 1973; Sydenham, 1979).

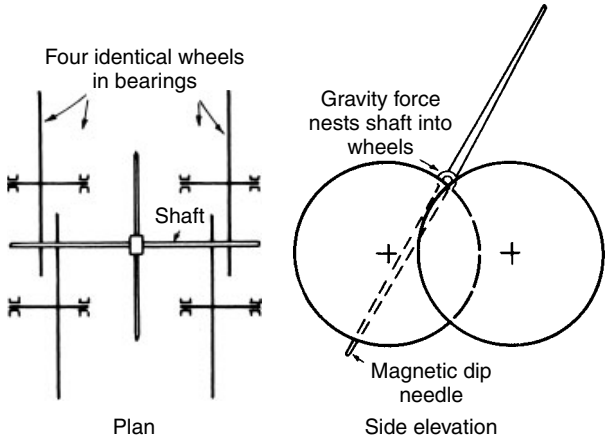

Figure 4. The Sully (*c* 1700) frictionless bearing arrangement as used by Michell in a late eighteenth century dip circle instrument.

6 SURVEYS OF INSTRUMENT BEARING INFORMATION

The design of bearings is a very well developed aspect of instrument construction. Considerable theory now exists to complement the highly developed fine mechanical production capability. Low-friction precision bearings can be as small as a millimeter in outside diameter. The designer who wishes to be sure that his or her choice is justified and is within the requirements of the task has a wealth of theory and experimental data to fall back on.

Manufacturers provide considerable design material to assist application. Permissible load, run-out, clearances, speed, friction force, life, and assembly arrangements are all well documented.

Since the various forms of bearings are generally familiar, this account will only introduce each kind, giving references to where in-depth information can be found. An excellent work on each type is Trylinski (1971). It provides information about the small and miniature-sized bearings that is not generally given in machine-design texts. It covers jewel bearings; direct in the base bearings used in clock mechanisms; conical and tapered supports, which use a tapered shaft end running in a hole in a suitable bush; spherical ends; hydrostatic designs; center supports in which a spherical shaft end runs against a concave plate; cover-plate type thrust bearings, including the shock-resistant Incabloc arrangement; mercury supports; knife-edges; rolling-contact bearings, such as the very easy to use cup-and-cone miniature and subminiature ball bearings; and wire track bearings in which the rolling contact ball is used to form its mating track by being pressed into soft metal wires. The chapter in his text on 'supports' covers friction and bearing area stress calculation, errors in location, and many other theoretically based explanations of behavior. Eighty-two references are included. A further chapter on guides covers the design of sliding arrangements, which are usually of rectilinear form.

Further in-depth works on instrument bearings include the series compiled by Geary of the Sira Institute (then called the British Scientific Instrument Research Association, BSIRA). His second booklet (Geary, 1955) was a bibliographic survey of knife-edge bearings. It gives an illustrated technical introduction, followed by 166 references. Geary concluded then that knife-edges should be considered as blunt or rounded edges, for, in practice, deformation occurs, resulting in a less than ideal knife-edge. He also wrote that there was a general dearth of research and objective data available, especially in the English language, and that the best-written works were of German origin. He suggested that some of these works should be translated. (Trylinski's work was later translated, helping to fill this gap in available knowledge.)

Geary's fourth report of the series on instrument parts (Geary, 1961) covered instrument ball bearings in a similar way, providing a specific account on the small series of precision-quality ball bearings. It is a key document where information on the use and choice of small ball bearings is required. Harris (1966) is also relevant.

Applications requiring zero clearance and a large measure of stiffness across the ball-bearing joint can use specially designed ball races – the angular-contact series. In use, the shaft and housing dimensions are chosen to force the balls to ride against one side of the race. This is known as *preload*. Ball nuts, those drive nuts in which balls run in contact with the lead screw thread, are often used together in pairs, one being rotated against the other to preload the nut into the shaft. Ground leadscrew shafts can provide remarkably stiff, yet resistance-free, joints.

For nonmagnetic applications, beryllium–copper ball races can be used. Stainless-steel bearings are also sold. Bearings capable of 300 000 rev min^{-1} are used in dentist's drills.

Each application dictates careful choice from within the various classes of bearings if best operation is to be achieved. The fifth report (Geary, 1962) covered fluid-film bearings. This provides a general introduction to this bearing type and gives details of liquid-lubricated bearings using external pressure generation, of gas-lubricated bearings, and of less well known bearings such as fluid-squeeze films, mercury globule, and acoustic radiation pressure supports.

The frictional force of the different kinds of bearings varies considerably, ball-bearing systems exhibiting considerably less frictional torque levels than simple liquid-fluid bushes. As an indication of the magnitudes involved, oil-filled gyroscope ball bearings having five balls running at 4-mm diameter might exhibit a breakaway torque of 8×10^{-6} Nm. Running torque is generally about 30 to 50% less. Very small, three-ball pivot bearings breakaway at 1.0×10^{-7} Nm torque. Torque figures increase with load on the pivot. In contrast, a small plain bronze bush needs about 6 to 8×10^{-4} Nm to move from rest. A small radial ball race will need around 3×10^{-5} Nm torque before it begins to rotate. These figures can only be used as a guide – the actual value varies greatly with bearing form, preload, shear load, and shaft size. They must be calculated or measured for the support to be actually used. Misalignment can introduce considerable frictional loss, unless designed as a self-aligning arrangement. Suspensions for electrical indicating instruments use knife-edges, jewels, bushes, and elastic bands. Drysdale and Jolley (1924), Part 1, include an extensive discussion of these, most of the material given being about jewel bearings. Geary (1964) covers magnetic and electric suspensions. Permanent magnetic suspensions

for instrumental use were surveyed by Fremery and Doden (1978).

1 TRANSFERENCE OF ROTARY MOTION IN FINE MECHANISM

As in electrical systems, mechanical information machine counterparts require means to transfer signals between subunits of the system. These signals may have to be transmitted at the direct unity ratio or be operated upon to alter this ratio up or down. The motion may need to be converted into such motions as intermittent, quick return, and others.

Transferring signals and forces over large distances in mechanical equipment is more difficult than with electrical signals. Generally, in practice, we convert mechanical information into the electronic form for long-distance transmission. This was not always so, and there are still some applications where direct mechanical transfer is more secure, more reliable, and more easily serviced.

This article discusses those components that, while not generally being thought of as computing elements, nevertheless, might be used in that manner and should be regarded in that light. It is important to see coupling systems in this way, for there are many traps to fall into because of imperfections in components and mechanism concepts. Covered here are the shaft coupling devices, gears of various kinds, cams, flexible belt-type drives, and electromechanical gearboxes. The general principles of mechanical design are to be found in **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2**. The use of kinematic design methods for members and linkages is covered in **Article 82, Kinematical Regime – Members and Linkages, Volume 2** and for fasteners and bearings in **Article 83, Kinematical Regime – Fasteners, Bearings, Volume 2**. The design method using the elasticity of materials to obtain controlled motion is covered in **Article 85, Elastic Regime of Design – Design Principles, Volume 2** and **Article 86, Elastic Regime of Design – Spring Systems, Volume 2**. Errors of all kinds is the subject of **Article 88, Error Sources in Fine Mechanics, Volume 2**.

The form and design of these components are well covered in the general machine design texts such as: Peatfield (1951), Faires (1955), Beggs (1955), Mabie and Ocvirk (1958) and Lent (1970). Information specifically relating to instruments is given in Trylinski (1971) and Reliance Gear (1972). Because of the extensive use of gears and other couplings in industry, there are many national standard specifications.

2 COUPLINGS

When coupling two shafts together as a direct drive, the factors to be considered are the amount of misalignment that must be tolerated, the constancy of the velocity and

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

positional form transmitted within a revolution, the torque level, the distance between supports to reduce shaft whirl, damping of vibration, stiffness needed in closed-loop control, allowance for end-float and more severe longitudinal movement, ease of assembly, and such factors as availability and cost. A sample of the range is shown in Figure 1.

Constant velocity couplings began with the design of Hooke reported in 1674. The single Hooke joint, however, does not give a constant velocity (or position) ratio between the input and the output as the coupling rotates through a turn. However, two units can be used together in series so that the modulation imposed by one is canceled by the other. Other more compact forms of constant velocity joints were later developed for the automotive industry, examples being the Bendix–Weiss, Rzeppa, and Tracta joints. These, in general, have not been produced at instrument size. They all have the advantage of providing constant velocity from a single coupling joint. The above coupling stages require the two coupled shafts to be positioned such that their extended center lines intersect in the coupling center. A double Hooke joint can, however, also take up translational as well as angular misalignments.

Where two shafts are parallel but not longitudinally in line, the Oldham coupling can be used. This allows for misalignment by a sliding, cross-shaped connector.

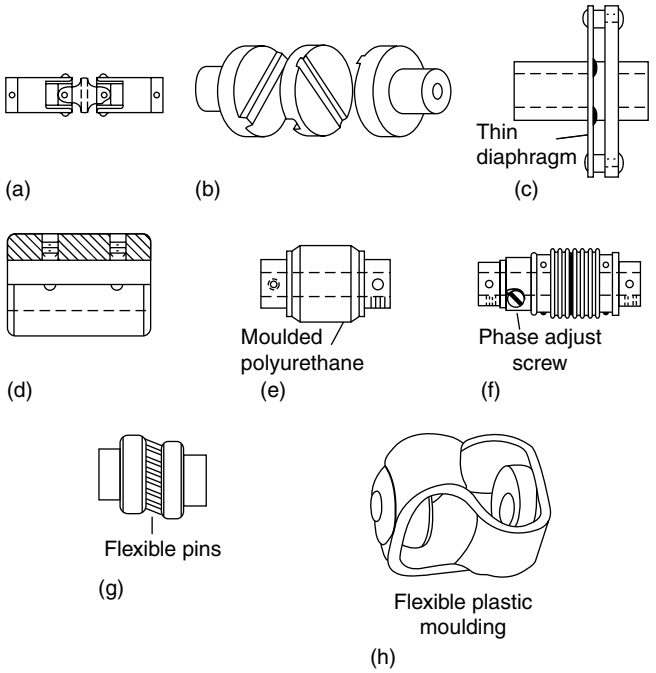

Figure 1. Selection of couplings used in instruments: (a) double Hooke joint; (b) Oldham; (c) membrane; (d) rigid; (e) molded flexible; (f) bellows with phase adjust; (g) Flex-thane; (h) Kudriavetz.

A solid or rigid coupling can only be used where the two shafts are aligned to exacting tolerances. If they are not, the coupling will 'work' on its screws or bend the shafts, causing looseness or failure to occur.

Coupling drives come in many forms; see Reliance Gear (1972) and Trylinski (1971) for illustrations of the various kinds of instruments. The latter definitive work presents the geometrical theory for many designs. The following names are used in the literature for various kinds of couplings; slip joint and slip couplings, membrane, spring and self-locking spring, antibacklash, bellows, molded plastic flexible, universal lateral, Kudriavetz, Flex-thane multiple polyurethane pins, multijaw, sleeve, slip clutch, overrunning clutch, and phase adjust (a type where the relative shaft phase can be slightly adjusted by a small screw rotation). There is no shortage of design possibilities; each has advantages and disadvantages and must be matched to the application. It is important to appreciate the motional and stress characteristics of each in any given application.

Where the motion deliberately is not to provide constant velocity or positional adherence to the input form, intermittent drives may be used. These include the quick return, Geneva, intermittent gear drives, and the various forms of clockwork escapement mechanisms. Many couplings make use of elasticity to allow for misalignment. In these instances, it is unlikely that they will be of use if information fidelity or smooth unmodulated drive is needed through the link. Today, industrial drives tend to use electronic control to implement such motions but there is still place for mechanical solutions due to their lower cost for low energy coupling situations.

3 GEARS

Although the toothed gear was in use in ancient times, it was not until more recent times that it could be used extensively because of the relatively low cost resulting from mass production and good quality control of the form and size of the two mating parts involved.

Gears are used to alter (or maintain) the ratio of speeds between two turning or partly rotating shafts. Many forms enable the directions of the two shafts to be placed at any required angle and displacement. The main limitation of gears is that the shafts involved must be reasonably close together; this can be a serious shortcoming. Idler gears and unity ratio stages can be used to couple stages that are not close together. A combination of gears is called a *gear train*; it is housed in a gearbox.

The simplest form of gearing uses two smooth disks running in contact driving by friction force of the contact. Friction gears are necessary in many applications, for example, in converting the linear motion of running strip into

rotation to drive an encoder, as parts of various mechanical computing devices, to subdivide a circular table, to drive paper through a chart recorder, or to drive a record turntable or tape recorder capstan – see also Sydenham (1968), and Jain and Sydenham (1980). Trylinski (1971) includes a chapter on friction gearing. Experience of Sydenham and Brandwijk (1966) indicates that friction gearing (Figure 2) can hold positional division of a 16:1 ratio step-down to the order of one part in 20 000. The variation in ratio is apparently random in nature, and absolutely fixed ratio gearing and, thus, synchronism cannot be maintained over a large number of revolutions. Best results are produced when the drive wheel has a rounded profile running on a flat surface, when the pressure is as light as possible to provide enough driving torque, and when the two materials are very hard, such as steel. High friction coefficient drive surfaces, like rubber, give good drive adherence but poor constancy of gear ratio.

Where absolute synchronism or high torques are needed, the use of toothed gears becomes necessary. Spur gears are made in numerous forms and are generally familiar.

In instrument work, the design of instrument gears closely follows general gear practice – with a few exceptions. One is the need to obtain precision operation. Gear trains in instruments and precision, small-size, closed-loop servo units will possess a certain degree of clearance between the teeth. This small level of backlash can introduce an error of measurement or instability of a servo loop. It can, however, be reduced by the use of antibacklash gears. These use two gears running adjacently that are spring loaded to cause the two halves to clamp around the mating teeth of the other gear. Whereas antibacklash gears do eliminate backlash, this form of device can introduce a degree of elasticity through the train, possibly resulting in a more compliant servo-loop response. The backlash spring must hold the gears in contact against the friction of the train. It is often better to use higher grade gears for which backlash can be reduced by closer tolerances of manufacture.

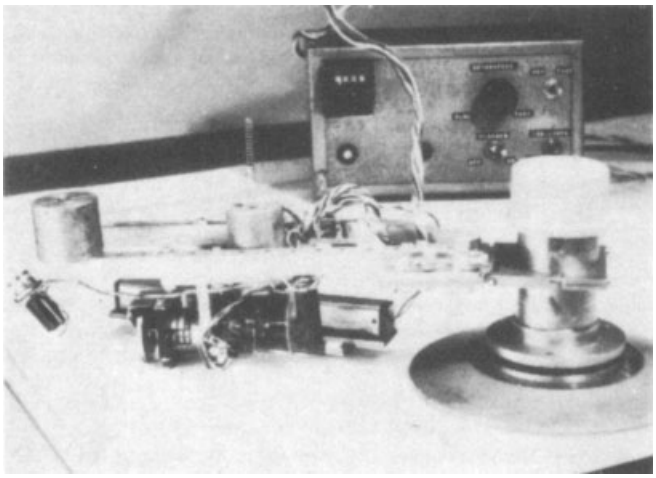

Figure 2. Friction gearing used to subdivide a circle in the automatic manufacture of radial metrology gratings.

The inherent inertia of rotating parts may be significant; it must be considered when designing gear trains for dynamic use. Inertia rises as the fourth power of the gear radius and each stage adds inertia as the reflected inertia seen looking into it, multiplied by the gearing ratio. Multiple stage step-up gears soon accumulate significant inertia. The inverse obviously applies; step-down gear boxes see little inertia. High-ratio step-down boxes, however, will have increased backlash and the wind-up of the train becomes more significant as the elasticity of the gears, shafts, and bearings combine to form a more compliant through-link. As a general rule, the best response servos and the lightest action manual instruments result from the use of a low gear ratio and low tolerance gear wheels.

The choice of more stages of lower ratio to obtain a given overall ratio may be better than using a single large ratio step. Friction of step-down trains is generally of little consequence, but step-up units may load the drive excessively because of the multiplier effect of the train ratio.

A gear train is only as good as the bearings and box structure allow it to be. Considering that high quality gearing runs with around 5 μm runouts of concentricity and with pitch errors of similar magnitude, it can be seen that the bearings and machining must be of the highest quality and the box be very rigid.

Gears are graded according to many codes, examples being the AGMA (old and new – American Gear Manufacturers Association) Admiralty, British Standard Specification (BSS), Mil Specs, and more. Specifying odd, nonstandard, gears can be expensive. It is better to choose from standard ranges of diametral pitch and quality classes wherever possible. Reliance Gear (1972), Trylinski (1971), Mabie and Ocvirk (1958), Beggs (1955), Merrit (1975), and Michalec (1966) each cover the theoretical and practical design of the various forms of gears. CAD tools are for supporting gear designs in power gear trains, but are not as useful for the specialism of fine mechanism gears.

The designer can usually make use of the marketed instrument fine mechanism products that have been properly designed to obtain efficient and smooth operation. Manufacturers provide tables and other information to assist the designer to call up the correct centers, clearances, the lubrication to use, and how to design gear trains with specified backlash. Reliance Gear (1972) contains a practical step-by-step guide to the design of fine-pitch gear trains, suggesting the following hints be followed.

The accuracy of gears can be gradually relaxed as the sensitivity to error reduces. The slowest speed gears are the most sensitive. Use spur gears where possible to make the most of the production precision that is available. Keep the number of meshes to a minimum to preserve transmission fidelity. Preload bearings to reduce backlash caused by bearing slop, which is not eliminated with antibacklash gears. Do not use pinned hub gears for high accuracy work. Sometimes gears can be matched by correct phasing to reduce the overall eccentricity error.

The finest pitch gears, theoretically at least, must produce the most precise gear train but practice limits their production. As a guide, avoid teeth finer than 120 DP or the finest above this that is consistent with the load requirements. Avoid mixing pitches in a train. Cleanliness of assembly and in use are vital.

High ratios are obtained in relatively small volume spaces using worm and wheel gears. These, however, may be inappropriate where the gear train has to transmit motion in both directions, as can occur in some servo drives. They can also be damaged easily in instruments where there are shafts that can be unwittingly forced by the operator or service man. Where this might occur, a friction clutch can be used to allow excessive torque to be dissipated without harm.

The use of gears is not restricted to full-circle wheels only. Part gears can be used where the motion needed is only part of a revolution or where intermittent motion is needed. The Leibnitz carry mechanism used in classic mechanical calculators and mechanical automobile odometers is an example. Where precision length measurement or positioning is needed using gears, a rack and pinion is generally adopted. The pinion must run with little backlash and the guides must be carefully manufactured to keep the system aligned. The pieces of rack must by phased properly when butted together to extend the length range. Precision racks can provide relative readout or positioning to within one part in 100 000 (or a little better) uncertainty.

4 CAMS

This is a two-part fundamental mechanism, in which one part, the cam, imparts motion to the second part, the follower, that stays in contact with the surface of the cam. Cams take the shape of disks or plates turning on shafts, as curved slots cut around a shaft, as eccentrics within a yoke; they can also be formed as linear alternatives in which a follower rises and falls (Figure 3) in response to the shape of a linear plate profile moving relative to it. They are used to provide rotary to rotary, or to linear motional conversion, or linear to linear action. Cams are characterized by the feature that the output motion is only generated over a small relative angular magnitude. Cams cannot provide large strokes or rotations unless made equal or larger in size as the amplitudes needed. They find use in timing, function generation, for compensation, and as a means of producing motion from a source.

Fundamentally, cams are continuous surface forms of linkage. At any instance or position, the point of contact between the two parts and the support forms a linkage. The design of cams is well developed and they can be synthesized as well as analyzed using graphical and computational methods. Shigley (1988), Erdman, Sandor and Kota (2001), Juvinall and Marshek (2002), Sclater and Chironis (2001) Parmley (2000) and Mott (1998) are also sources to use. Mabie and Ocvirk (1958) give a good coverage of cam design; Beggs (1955) and Faires (1955) provide less extensive accounts. Rothbart (1956) is a text devoted to cam design. Surprisingly, because cams are used extensively in instruments, Trylinski (1971) does not cover the subject.

Cam design basically attempts to realize the correct conversion action from the two components, but it is complicated by the fact that high-speed cams will impart significant velocity, acceleration, and jerk to the follower. This can cause the follower to leave the cam surface and produce excessive wear. In other words, the correct functioning of the cam and its follower is lost unless the shape is appropriate for the dynamics involved. Various cam shapes provide different velocity, acceleration, and jerk characteristics. Typical forms used are parabolic, modified parabolic, and simple harmonic for relatively slow actions. For higher speed applications where jerk becomes significant, the forms used are cycloidal, half-cycloidal, harmonic,

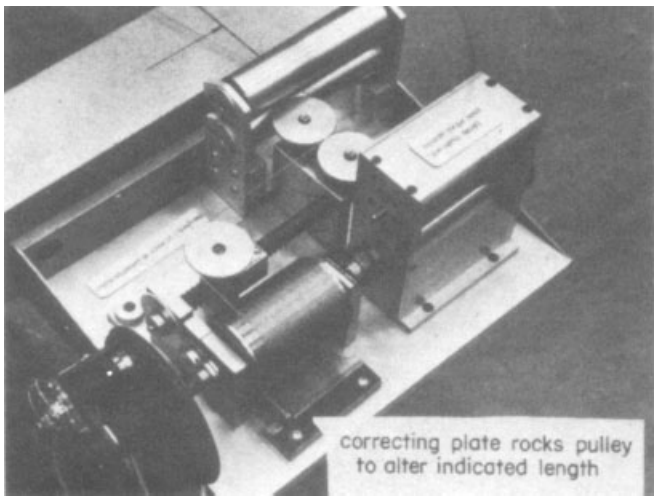

Figure 3. Linear corrector plate used to provide automatic compensation for calibration factor, in-scale nonlinearities and possibly thermal errors in a wire length measuring device (Sydenham, 1969).

and eight-power polynomial. Each offers certain desirable features of operational acceleration and jerk magnitudes; see Mabie and Ocvirk (1958) for more detail.

Cams may run directly against the follower and be constantly in sliding contact. This situation can be designed for by the use of hardened steels and other suitable materials. Alternately, a roller or hydraulic follower may be used. The follower can be a hinged rotating or sliding translating component. The cam in disk or plate form can be shaped to form a function required for applications of compensation or function generation. In these applications, velocity, acceleration, and the higher derivatives generally give no problems. Cams are also used to generate a shape that is 'followed' by optical means. This is used in furnace and other temperature controllers where the temperature must change with time in some specified manner.

Clearly, rapidly changing functions are not readily accommodated by cams because the follower has a finite size and will introduce, by virtue of its aperture width, some degree of integration. Cams are often required to rotate only in one direction. A reversed motion can become locked when the follower comes against a rise rate to which it cannot respond. Cam shaped gear systems also exist that generate specific functions, but these are strictly gears, not cams.

Cams are also made in which the follower responds to the resultant of two inputs. These are referred to as *3-D* or *space cams*. These need a spherical ended follower that is allowed to move in two translations as it is directed by the cam. Space cams are generally of complex 3-D shape and can be made by sintered forming methods or be cut by numerically controlled machine tools. These cams are unable to impart much force into the follower so they are often used with a servo that slaves to the follower's motion.

The dynamic behavior of cams can be complex because of the high value accelerations that can be present. These can cause the cam to appear elastic and can induce resonance in the cam body and in the follower and its spring. Beggs (1955) reviews this problem.

5 FLEXIBLE CONNECTING DRIVES

This classification is given by Trylinski (1971) to that group of motional transference mechanisms that use flexible elements to transmit motion. They may do this with or without conversion from rotary to linear regimes. Some links use elasticity to provide the freedom of bending; others use kinematic, pivoted principles such as those found in a link chain.

Elastic types will not fail because of the bending stresses being excessive in their outermost 'fibers' if they have slenderness ratios of at least 300 : 1 (ratio of radius of bending to the thickness of the flexure in the direction of bending). This figure is only a guide. A calculation should be made of the stresses in the outer layer when the member is bent over the smallest radius, in order to see if the material is not near to the yield point. There may be a jockey wheel or a guide pulley added to keep the system taut; often these are made too small in diameter. The stress level is as important as designing for adequate drive forces because excessive bending stresses will eventually cause the drive material to fatigue and break.

6 BELT DRIVES

There are many alternatives available, each having particular advantages and disadvantages. Flat belts made of a material having adequate tensile strength and friction coefficient can be used with flat pulleys (actually the pulleys should be slightly curved, rising in the center, to cause the belt to track into the middle). More usually, instruments would use small section vee-belts or continuous round section belts made of reinforced plastics. O-rings make excellent belts; as they are made to tight tolerances, they provide smooth drives. If the forces to be transmitted are high, the pulleys and belts should be designed after calculations are made to decide the ability of the drive to operate with a realistic tension that will transmit the force without breaking. Round and vee-profile pulleys provide increased friction drive force without needing high belt tensions. Their design is laid down in texts on general machine design and is well defined. Trylinski (1971) is a satisfactory source on flexible instrument drives. Figure 4 gives a range of flexible drives used in instruments.

The friction drive belt depends upon the normal force exerted between the belt and the pulley surface in order to develop enough grip. These forces can sometimes be prohibitive and a better alternative may be needed. Furthermore, the drive may need to maintain a strict synchronized positional relationship between the two pulleys. For these cases, friction belt drives are not satisfactory.

7 CHAIN DRIVES

Synchronized flexible chain drive can be obtained by the use of toothed flexible belts running on appropriately toothed wheels. These are generally available only for comparatively large-size drives, the smallest being about 10-mm wide. Metal roller link chains also can be used but these, too, are not generally made for the size drives needed in the smaller instruments. Smaller special chains

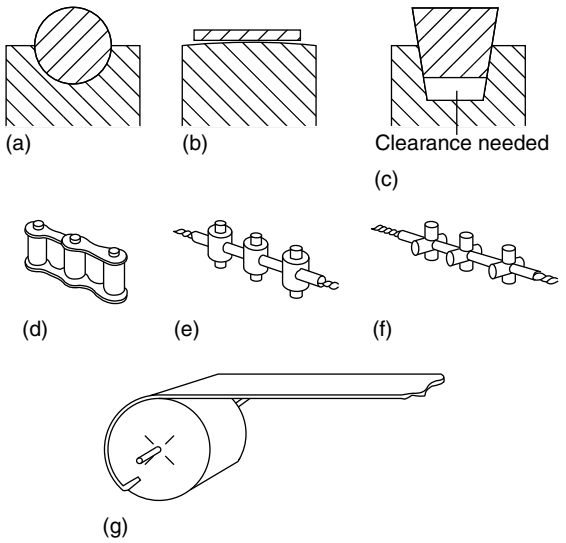

Figure 4. Cross sections of flexible connecting drives used in instruments: (a) round, with or without reinforcement; (b) flat (on slightly domed pulley); (c) vee; (d) metal link roller chain; (e) polyurethane molded – pinned belt; (f) as for 3-D pins; (g) metal strip.

and toothed belts are made but their availability is not widespread. The user will have to search hard for a supplier (see Reliance Gear, 1972, and the British Machine Chain Co, Malden). Examples are the miniature oval-link chains that use specially shaped drive wheels in which the chain links lie keeping its crossed link shape, and the hook-link chains that use sprockets whose teeth pass through the links to provide drive. Fine metal chains can give backlash-free coupling at the force level needed.

Typical working forces for small chains are 1 N, with links of 3-mm pitch. Small, plastic, positive-drive belts are also manufactured. One system uses stainless steel or cord-reinforced polyurethane molded belts, which comprise a round belt having bars formed across it protruding to each side. Another form has its sides shaped like a ladder. The bars nest into a single (or double) row of teeth on the drive pulleys. One Dacron-reinforced belt will take 1 N forces, the unreinforced belt only 0.05 N. Some designs will carry a 15-N tensile load. There is also a toothed plastic belt that will drive sprockets set at 90° to each other without the need for belt twist. For illustrations of the above see Figure 4.

When only a small distance of angular motion is required, the belt need not be endless; further, it can be fastened to the two pulleys to obtain synchronized drive. Examples are the mechanical drive of a tuning dial of a radio in which a cord connects the tuning control with the translating station indicator. Thin steel strips can also be used to couple wheels. As these can only drive in tension, a continuous strip or a biasing spring are needed. Trylinski (1971) gives several illustrations of the possibilities.

Flexible drives can offer extended distances between drive centers and the ability to provide gearing ratios; they can absorb vibration, attenuating it through the link (but they may lack stiffness if this is so); they can allow for misalignment between shafts, they can be designed to allow slippage if the load is too great (or the converse), and they can also be designed to give a continuously variable gearing ratio by the use of tapered pulleys and changing radius pulleys. They are virtually backlash-free and will have relatively low inertia compared with gears trains because they have less mass in motion. They can, however, introduce vibrations from the unsupported belt, which can modulate the drive throughput of force or information.

8 ELECTROMECHANICAL GEARING

The present low cost of digital electronics and the general availability of very reliable and inexpensive optical and other shaft encoders has given the designer the ability to make more use of electromechanical gearing and shaft motion transference.

Combination of a shaft digitizer (Figure 5) that generates electrical positional signals as the shaft rotates and a motor that steps in synchronism with the generated signals forms the basis of an electromechanical gear box.

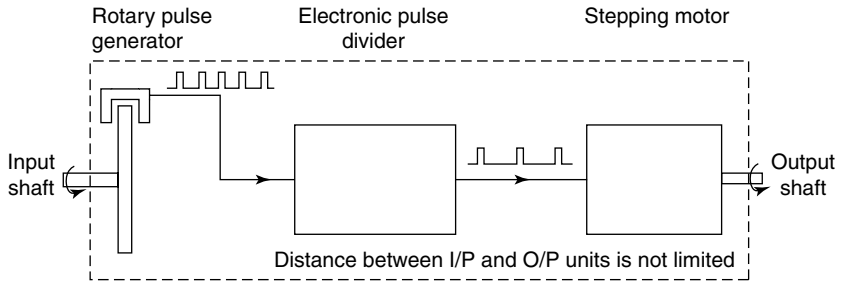

Figure 5. Diagrammatic representation of an electromechanical gear box.

Illustrating the method with the use of the optical radial gratings, the disc attached to the input shaft can conveniently generate around 1000 to 10 000 pulses per turn at rates rising to at least 10^6 pulses s^{-1}; that is, shaft speeds varying from 0 to 1000 rev s^{-1} for low resolution or to 10 rev s^{-1} for high resolution can be accommodated. The digital signals are then passed through a digital divider arrangement to form the required divided pulse rate to suit the speed needed from a stepping motor. Dividers are available as integrated circuits (IC) in which preset switches or electronic signals can be used to set any division number needed. Two ICs can give ratios from unity to 255.

The advantages of this alternative form of 'gear box' are that the input and output shafts need not be in close proximity or in any particular orientation, the power levels of the two sides of the link can be at any level needed, more than one shaft signal can be combined or driven, and the division ratio is very easily changed under computer control. The ratio can be varied smoothly from one extreme to the other. Accuracy can be at any level desired and backlash is not present.

This form of system, however, can be prone to electrical interference, but it is quite possible, with circuitry effort, to make the error rate as small as is desired by the use of coded digital communication transmission methods.

The cost of the electronic parts will be reasonably small and the mechanical parts needed are few – a shaft carrying an encoder disk to couple to the output of a mechanism and an output shaft of the stepping motor. Such gear boxes are cheaper than conventional mechanical units, especially where high precision is needed. These will, of course, need a source of electrical power, which may exclude them from some applications.

1 PLACE OF FLEXURE ELEMENTS IN INSTRUMENTS

Mechanisms used to assemble instruments are divided into two groups, namely, kinematic and elastic. Kinematic elements are made sufficiently inelastic to be unchanging in shape as they are stressed by mechanical forces. Here, the general principles of the elastic group that deliberately makes use of elasticity of components to achieve a given mechanism function are discussed. Flexing action produced by kinematic mechanism, such as a roller chain or belt, is covered elsewhere. Detailed discussion of uses of elastic elements is found in **Article 86, Elastic Regime of Design – Spring Systems, Volume 2** and **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2**. Implementation in microchip form is covered in descriptions of Microelectro Mechanical Systems (MEMS), **Article 162, Principles of MEMS, Volume 3**; **Article 163, Uses and Benefits of MEMS, Volume 3**; and **Article 164, Principles of MEMS Actuators, Volume 3**.

By appropriate choice of compliance, component shape, and method of use, spring elements (often called *flexures*) can provide many of the functions provided by the kinematic forms. Elastic design deliberately makes use of elastic properties of materials to allow controlled movement where needed.

In many instances, a flexure method is to be preferred over a kinematic arrangement. This generally occurs when only limited movement between two parts is needed. For example, a crossed-strip flexure hinge provides a limited range angular hinging action and offers negligible backlash and frictional force. It does not need lubrication and is not affected by dust or dirt. It is very simple to make and often does not require tight manufacturing tolerance.

Flexure elements can be devised in numerous shapes and forms. Good design is always based on proper understanding of the compliance of a flexure element in its various directions of bending and compliance values of other associated elements. In some cases, it needs to have a high ratio of compliance in one direction with respect to another; in other cases, it needs to be the same. The addition of later items, such as protective covers, additional small loads, and further forces from sources other than those designed for, could considerably alter the final performance of an elastic design.

Flexure elements appear to be deceptively simple. They are easy to devise and install and they will often provide quite adequate performance, with only the barest of theoretical understanding being applied. However, a thorough appreciation of the factors involved will assist the user to understand their limitations; they are not perfect elements.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

The necessary relevant basic theory for carrying out elastic flexures design pertains to that of the deflection and stresses of beams and plates – commonly called *strength of material* or *beam theory*.

To this, the knowledge of imperfections of real materials must be added because these introduce such effects as damping, friction, hysteresis, fatigue, fracture, and nonlinear deflection versus load characteristics – subjects not normally covered in beam theory texts.

Fundamental material (which is of civil and mechanical engineering structures design) is to be found in such works as Timoshenko and MacCullough (1959), Timoshenko and Gere (1961), and Roark and Young (1975). Faires (1955) provides a shorter but basically adequate account of the strength of materials theory. Such texts, being written for structure designers and not for instrument applications, generally place greater emphasis on stress than on the deflections that are so important to instrument design.

2 BASIS OF DESIGNING FLEXURE ELEMENTS

Flexure design studies are usually based upon the assumption that the force-deflection characteristics of the materials used are linear. Such a basis can, indeed, give the designer a very wide choice of workable ideas, but on occasion, it might be beneficial to make use of nonlinear materials and processes. Eisley (1963) provides an entry point into the literature in this area of knowledge, giving about 90 references to published papers. Schmidt and DaDeppo (1973) may also be useful in this area.

A considerable amount of published design information is available but it is from earlier times with little being published recently. This should not be taken to imply that the information has become outdated but merely that this field matured several decades ago. There is little likelihood of a basically new flexure element being invented, most having been devised by now. This article provides a comprehensive overview of the many possibilities for elastic design. Combination of several flexure mechanisms leads to more options, many of which are yet to be applied.

The apparent simplicity of flexures can hide the fact that they are not perfect elements. As an example, a parallel strip support for a translating table can easily support a mass of many kilograms, providing translational sensitivity and stability of nanometer order without the backlash being apparent. However, temperature effects may alter the inbuilt spring rate quite considerably, causing errors in other ways. Choice of the wrong material can introduce significant hysteretic backlash.

As flexure systems deliberately introduce spring compliance into a system where mass is involved, it is obvious that linear second-order and higher dynamic systems may be produced (refer to **Article 189, Basic Principles of Flow Measurement, Volume 3**). The natural frequency of such systems becomes an important parameter where the system has to follow dynamic inputs in a faithful manner (Sydenham, 1982, 1983). Damping may be deliberately introduced to prevent resonances from building in amplitude or to make the dynamic response at least critical so as to exhibit response characteristics of first-order nature. It is feasible, by appropriate design and ingenuity, to alter the natural frequency without altering the compliance. For the same reasons, it may be necessary to keep the supported mass to a minimum so that the natural frequency is kept as high as possible.

3 DESIGN PARAMETERS OF THE FLEXURE ELEMENT

Before considering practical flexures and their application, it is appropriate to discuss several basic design parameters of flexure elements since these apply to all shapes and forms of system built with them.

Flexures are formed by the use of a mechanical member (or possibly, other spring form such as electromagnetism), where design deliberately allows the member to deflect in specific directions. It is usually imperative that deflection occurs only within the elastic region of the material's deformation (Figure 1). Although texts on materials give the general impression that the Hookean elasticity law applies in practice, there, nevertheless, is always a small amount of hysteresis; a strained member does not come back to exactly the same strain condition for a given stress excursion. Special materials, those with a reduced mechanical hysteresis, exhibit a lower level of this effect. In many applications of flexures in instruments, however, extreme reproducibility is not important. Tovey (1974) discusses the materials used to form flexure elements.

It is therefore important that the flexure members cannot be deflected beyond the chosen allowable elastic limit. As a rule, the smaller the deflection, the smaller the residual strain error. Plastic deformation, if allowed to occur, will introduce permanent set, with subsequent zero shift errors arising. For this reason, design often calls for mechanical stops and other devices to be incorporated to prevent overdeflection. Assembly and transport can often give rise to the greatest deflections that might be encountered. As a rough rule of thumb, bending flexure elements should not be deflected into a radius of curvature smaller than around 300 times its thickness in the direction of bending. Beyond this level, the outer fibers will be stressed beyond their elastic limit, causing surface cracks to

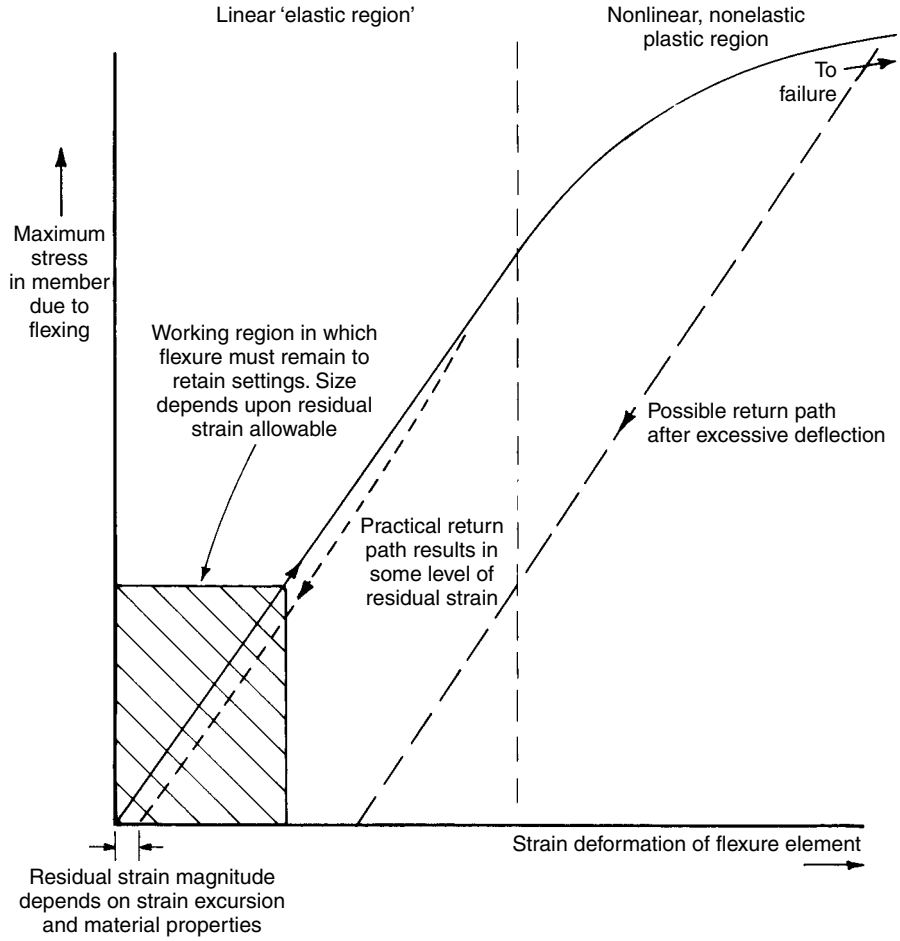

Figure 1. Stress–strain relationships for materials used to make flexure elements.

begin. If this is important, the bending moment caused by expected flexing levels should be calculated for the material used.

As a flexure deflects, it will provide a force reacting with the direction of motion. This is the flexure system compliance. It is produced fundamentally by the elasticity of the material, the effect of which is modified by the total flexure system arrangement. As will be mentioned below, it is possible to devise flexures that provide positive, negative, and even zero forces, as well as nonlinear displacement characteristics.

Using strips in tension will increase the stiffness according to the load (Eastman, 1937). Conversely, they can be used in longitudinal compression quite satisfactorily, provided Euler buckling does not occur. The basic elements still undergo positive or negative deflections toward or away from the elastic limit, but the net effect of the whole flexure system is one of these options.

The fundamental design parameters of a flexure material are its elastic modulus, shear modulus, hysteresis level, elastic limit, endurance limit to constant flexing (especially when in conditions of simultaneous corrosion effects), thermal coefficient of elastic modulus, and such other parameters in any other energy domain. Rolling friction is sometimes a parameter for which more information is published in Minato, Nakafuku and Takemura (1969). Gohn and Fox (1965) discuss stress relaxation in springs. Carson (1937) is about measurement of elastic drift in springs.

When very small displacements are needed, a method used by Jones (1967) might be applicable. It rests upon the principle that an elastic material that is squeezed by a clamp will exhibit a small length change. Poisson's ratio links this action. This method gives fine control to clamping screws on threaded adjustments such as micrometer heads. The same principle was employed by Baird (1968) to temperature-compensate an Invar rod with a steel wire cover soldered to its outer surface.

When flexures are made from thin hardened and tempered strips, they can tear easily at connection points. Careful edge finishing is needed to reduce this failure mode. The material must also be cut to suit any directional grain that exists in the flexure material.

Materials used for flexures are generally the metal carbon springs, stainless steels, copper, and nickel–iron alloys. In some applications, fused-silica (fused-quartz is a term that is usually synonymous) forms the flexure element. In less exacting applications, plastic, rubber, paper, and fiber elements might be suitable.

The above parameters are concerned with the properties of the material used to form a flexure. Having selected the material, it is then necessary to consider the properties of the flexure system as a whole. Some factors that may be relevant include the force-deflection characteristic, range of motion, required parallelity of pseudosliding action, stability of a center of rotation with angular deflection, and effect of load on the system properties because the system may stiffen up, with increasing load being supported. Another important design parameter is to be sure that the system can be manufactured to the tolerances needed and that it can be assembled without damaging the flexure element in some way. Preform in flexure elements can be bothersome at times. Elements may need to be heat-treated to stabilize them before use and be assembled using jigs to prevent overstressing.

4 CARRYING OUT THE DESIGN OF A FLEXURE ELEMENT

Design of a flexure system, like that of a kinematic support system, should always consider the sources of error that might arise in normal operation.

At present, and perhaps it will always be so, the design of a flexure system is initially approached as an art on the basis of experience, with the possibilities open to the designer. A possible arrangement is first selected that may fulfill the need. This is then analyzed as a science to establish the sensitivity, load-carrying capacity, limits of required action, and so on. If the design is not quite suitable, it is then modified. It would be an obvious advantage if computer-aided design programs were available for use in optimizing standard design configurations (of which there are several kinds) in the direction that a designer requires.

Design equations for most types have been reasonably well developed, but the designer usually must spend considerable time in locating the appropriate study. Many reports on flexure elements usage do not include a theoretical account, their design often being apparently raised by intuition and cut-and-try prototype building procedures. Of the references to general accounts given above, those including a well-developed basis of theory to support a design are Chironis (1961), Eastman (1937), Andreeva (1966), Geary (1954, 1960), Thorpe (1953), Trylinski (1971), Wahl (1963), and Weinstein (1965).

5 SPECIALIZED FORMED FLEXURE ELEMENTS

It is stated by some authors and users of flexures that the applications requiring the greatest dimensional stability should use flexures that have end mountings made in the same piece of material. (The usual method is to clamp the flexure end between rigid plates.) This assertion has not been adequately proven by rigorous experimental procedures and it must be left to the user to decide whether this additional cost is justified.

A similar argument exists as to whether metal spring elements give better performance than fused-quartz springs. Experience with both has shown that poor reproducibility of the zero reading with time is more likely to be a factor of overall design than of the material used. It is possible to find evidence that suggests that either material group is the better to use for precision instrument springs. As the problem reduces to one concerning the hysteresis and temperature properties of the materials, it will be found that certain metal alloys are far superior to fused-quartz in this respect.

A key parameter that tends to be overlooked in such comparisons is the level of flexure excursion. Small movements of a spring element, such as those occurring in a tidal gravimeter or a tidal tiltmeter, will give rise to much smaller levels of hysteresis when compared to the performance of an exploration gravity meter or a borehole tiltmeter. In the latter case, the flexure element must range over larger excursions and can be expected to be more severely handled.

6 COMMONLY FOUND BEAM DESIGN FORMULAE

Figure 2 provides the usually needed deflection and stress expressions for a few of the commonly found elements. Note that point load and distributed load cases each follow the same general laws.

For flexures to be theoretically designable, it is necessary that their stress levels be determinable for all parts of the system. In the kinematic design procedure, forces are arranged so that they act at known, well-defined points of interaction. In flexure design, deflection takes place over a distributed region.

To assist design, it is often expedient to structure the flexure elements of the system as members having dramatic changes of size at given positions, so the compliance alters very significantly. It can then be assumed that the flexure member is deforming elastically, with the end mounts being adequately rigid.

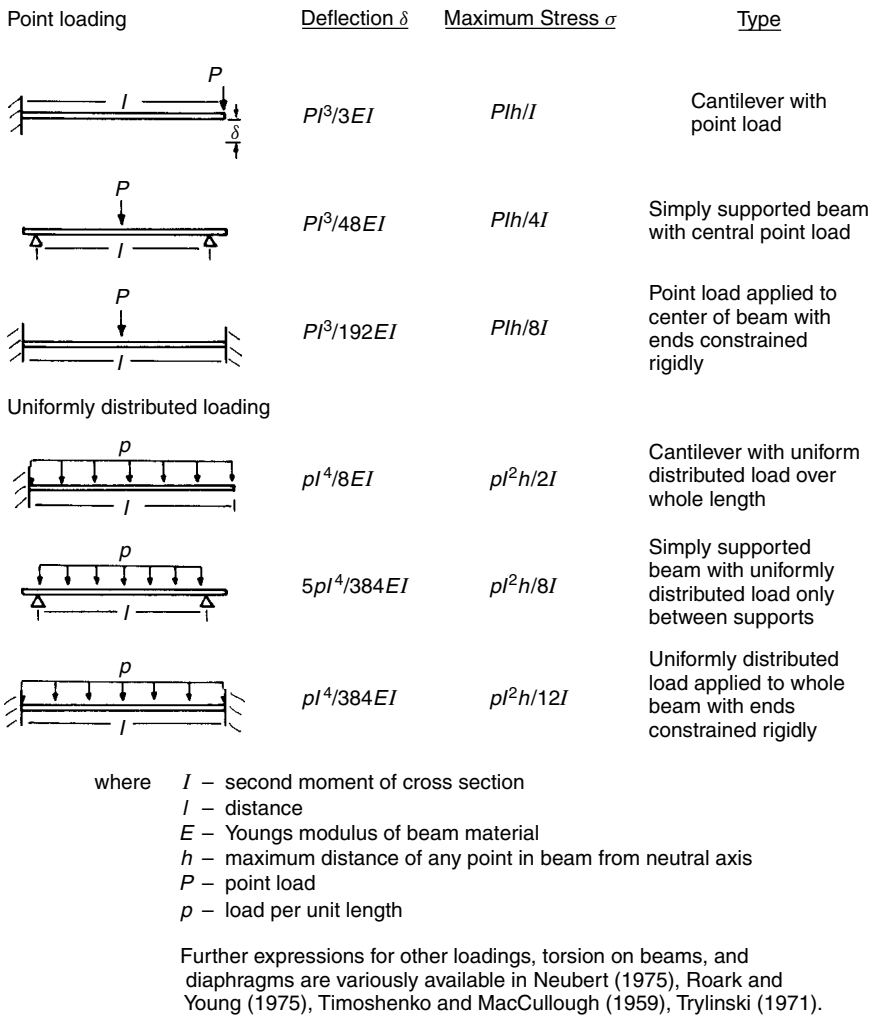

Figure 2. Expressions for commonly found beams.

From the viewpoint of fatigue strength, however, such sudden geometrical changes in shape can give rise to locations in the flexure where stresses can be raised. Flexure designs needing high numbers of highly stressed cyclic movements will require a more sophisticated treatment to allow for graded compliance changes along the flexure element.

7 TYPES OF FLEXURE ELEMENTS

A flexure can provide controlled movement in a system of flexure elements, using one or more of three basic modes of flexure (Sydenham, 1984).

It can be deflected in pure transverse bending, in pure axial torsion, or it might be deformed elastically in its longitudinal compressive or tensional mode (Figure 3a). In practice, combinations of these three actions occur to a lesser or greater extent depending upon the flexure system arrangement. Too often, designers (and quoted formulae for flexure arrangements) do not recognize this combinational feature. For example, a simple single flexure strip being used at the top end of a clock pendulum to allow it to swing in one preferred direction also supports the mass of the pendulum. The flexure element is, therefore, simultaneously stressed in both bending and tension. The tension component can considerably stiffen the rotational compliance in the bending direction.

The helical coil spring is a torsional arrangement in which torsional flexure is converted to provide linear spring-force action. Torsional flexure systems can make use of forms other than strip or other solid members. Two wires, placed apart, can produce a similar action – these are called *bifilar suspensions*.

The third class, wherein longitudinal tension or compression is used without transverse bending action of the flexure, is applicable when stiff flexures are needed. Simple examples would be the use of a bolt to hold two

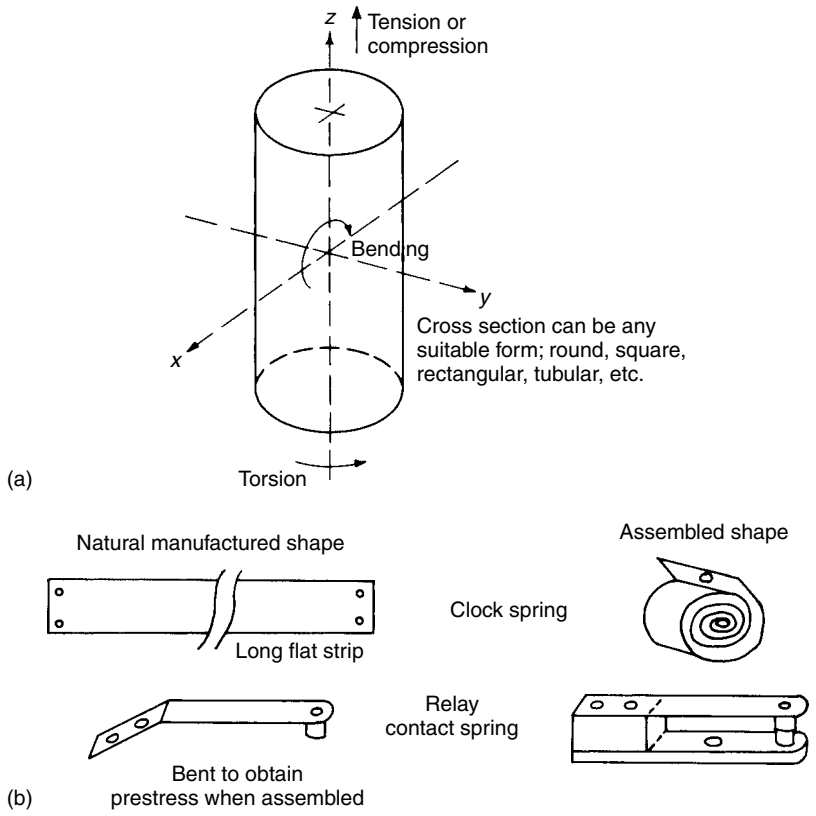

Figure 3. Fundamental flexure design options: (a) modes of flexure deflection; (b) natural shapes used either in some manufactured shape or preformed.

parts together yet allowing some additional elasticity to enable it to cope with excess tension loads or a rubber isolation mount. Torsional systems often stress the individual members this way. Such methods may dictate the use of materials with low values of Young's modulus so that they provide reasonable compliance from practical cross sections of material. Their use is, of course, dependent on the requirement and materials' suitability.

With the basic elastic kind of action being decided, the designer then has a further fundamental option available. Many flexure systems use the element in a stress-free state when the system is at its rest position. For example, a helical spring may be coiled so that the turns just nest together and with no extension, the spring material is in a relatively stress-free condition (see Figure 3b). Elastic energy is then stored as the spring is tensioned.

Another example is the use of clock spring to provide drive energy for a clock. In its unassembled state, the natural shape of the flexure is a long flat strip. As it is wound up, it takes on the curved shape seen in the assembled clock.

The alternative spring flexure arrangement is to prestress the spring material into a natural shape that operates in the reverse manner to the obvious situation exemplified above. A torque motor (that is needed to drive a mechanical clock) can be produced by precurving the strip so that its natural shape is a small radius, that is, the unassembled spring rests as a tight coil that is then unwound as it is deformed to store energy. Springs holding electrical contacts in relays are usually preset to some extent so that their assembled state holds the contact in the correct position, applying a force to the other contact.

Yet another distinction can be drawn between the flexure system that is purposely intended to store energy in order to produce a force on demand and that which uses flexure action as a mechanical linkage. In the latter case, it is often necessary to design for minimum stored energy as deflection occurs, storage and its resulting force-producing action being an unwanted parameter. Often, the flexure system simultaneously provides both mechanical linkage and energy storage functions; for example, a cantilever flat strip spring provides return action and guidance.

Through the use of a suitable design of spring, it is possible to obtain mechanical magnification of small displacements. Such springs are generally of the type in which a small change in length of a tensional spiral spring produces a rotational motion in the center or at the end of the spring element. The rotation can then be used to operate a

suitable length output arm or the mirror of an optical lever. Torsional magnifiers are discussed in Geary (1960).

In practice, there are a very great number of possibilities, so it is not feasible to list every combination and arrangement that has been reported.

8 INFORMATION ON FLEXURE SYSTEMS

Collectively, the literature (when reviews included within several of the citations are also recognized) provides a very large range of diagrams and applications of flexure elements in the design of instruments. What constitutes an instrument is a matter of personal definition in this area, for flexure elements find as much use in power-supporting applications as they do in fine mechanisms.

Young (1989) is a definitive source of formulae for mechanical situations. The design of springs elements, which commonly concentrates upon helical and flat power springs (*see* **Article 86, Elastic Regime of Design – Spring Systems, Volume 2**), as opposed to instrument springs, is dealt with by Chironis (1961) and Wahl (1963). Spring suspensions and flexure devices, for which the emphasis is upon fine mechanism, are covered in Eastman (1937), Geary (1954, 1960), Andreeva (1966), Trylinski (1971), and Sydenham (1984). The definitive reference work is Howell (2001). It covers the wide range of topics introduced here.

Geary (1964), Frazier, Gilinson and Oberbeck (1974), and Fremery and Doden (1978) cover another type of spring suspension: that provided by magnetic and electric fields. Dorien-Brown (1971) is one review of air springs.

Many other works include mention of flexure arrangements in sections ranging from chapter length down to a few paragraphs. These include Rolt (1929), Whitehead (1934), Thorpe (1953), Braddick (1954), Beggs (1955), Weinstein (1965), Jones (1967, 1968), and Neubert (1975). Hugill (1978) compares several spring-mass systems used in gravimeter designs. Equations of sensitivity are given in each case. Gast (1974) includes discussion on flexures. Dratler and Block (1972) is an interesting report. Sclater and Chironis (2001) is a useful source of ideas.

1 HELICAL SPRINGS

Elasticity of mechanical components is used to obtain necessary degrees of freedom in the elastic regime of fine mechanical design. The general principles of elastic design are given in **Article 85, Elastic Regime of Design – Design Principles, Volume 2**. Comparison with the alternative kinematic methods is made in **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2** and **Article 81, Principles of Fine Mechanics – Systems Considerations, Volume 2**. Spring element design has regained interest in MEMS applications, *see* **Article 162, Principles of MEMS, Volume 3**.

The design of spiral (helical, coil) springs is well covered in numerous commonly available sources because they form part of the training of engineers in the general design of machines. For example, each of the following authors Chironis (1961), Andreeva (1966), Faires (1955), Geary (1960), Trylinski (1971), and Wahl (1963) can be consulted for the theoretical design of the familiar cylindrical coil spring. Howell (2001) is the definitive source in elastic mechanism. Such springs are generally intended for use as pure tension or pure compression flexure elements (Figure 1a and b), but they can also be used as torsional or bending elements.

The above references discuss the key spring design parameters to obtain a spring with a given spring rate (compliance, stiffness), adequate range of deflection, adequate fatigue life, and given maximum stress levels in the material, each applying for the range of materials normally available. The more general machine design texts, however, do not usually consider such factors as the effect of temperature on the spring rate or the need to reduce the inherent mechanical hysteresis effects – two factors that are vital to instrument design.

Figures 1 and 2 show several of the many shapes and forms that fine mechanism elastic spring elements may take.

Helical torsion springs (Figure 1c) are formed into shapes that are similar to the coil spring, but the forces are applied to the coil as a torsion, rather than as longitudinal extension or compression. In this use, the basic mode of flexure of the spring material is not torsional, as it is in the tension helical spring, but occurs as bending action.

In this use, the turns are required to rotate with respect to each other; practical design has to allow for any friction (the binding effect) that may occur when the coils slide against each other. Such springs are often made with spacing between turns. Another factor to be considered is that as the spring is twisted tighter in torsion the effective radius reduces. Long torsional helical springs may buckle; guides are often employed to support the spring, in which case the added effects of friction must not be forgotten in sensitive system design. Wahl (1963) suggests that buckling is

avoided if the spring is not turned at the torsional input by more than 0.87 of a turn for length to diameter ratios that are short, the input rising to 1.25 turns for longer springs having the same diameter. This can only be taken as a guide; references cited by Wahl should be consulted for more detail.

2 SPIRAL SPRINGS

Spiral springs are those wound springs in which flat material is used (Figure 1d) that is curved in a decreasing radius and where all turns lie in a flat plane. The clock and electromechanical indicator restoring spring are in this group of springs. These are generally referred to as *hairsprings*; when the turns do not come into contact and are particularly fine in dimension. Hairsprings can also buckle at high deflections.

It is in this class of springs that the Neg'ator spring design fits. This preformed spring was invented and reported in 1952 by Votta (1952). It has the interesting and somewhat hard to visualize characteristic that it can provide linear tensioning action, exhibiting constant force with displacement (as opposed to most springs in which tension increases with displacement). By choosing a suitable bush size to support it (Figure 1e), it is possible to tailor the design to provide very slight negative or positive spring rates on the basis of unusually high base loads. It is particularly useful as a means to counterbalance gravity-acting masses in instruments. Arranged as a torque producing device, Figure 1(f), instead of giving purely linear action, it forms a constant-torque drive motor with a large range of output turns. It is marketed as the Tens'ator™ spring. Typical commercial design data is available in AMETEK (1973).The dynamic performance of this spring has been analyzed as a dynamic motor in Sydenham (1969), where the commercially offered width to thickness ratios and suggested spool diameters that lie far from the optimum values needed to obtain minimum rotational inertia are shown. Given the optimum spring material thickness and width, the use of small diameter spools in such motors can provide very responsive torque sources; energy stored can be dangerous while in use, and protection is needed to prevent damage, should a spring break or come away from its end constraints.

The design of spiral springs is covered in Andreeva (1966), Geary (1960), Trylinski (1971), and Wahl (1963). Each of these sources covers some of the same material, but additionally it provides a somewhat different design information. It is necessary to select the appropriate work for the task in hand. None of them appears to give a coverage that caters for all likely needs; there are just too many spring options in existence.

Trylinski (1971) concentrates on fine mechanism springs, that is, those including hairsprings and main springs for instruments such as clocks and watches. Geary (1960) is useful for its general introduction and for the bibliography provided. It provides the theory of torsional systems using bifilar and multifilar suspensions. Wahl (1963) and Andreeva (1966) cover in general all types of springs.

Several highly sensitive scientific instruments make use of a spiral form of spring, in which the turns are not in contact and lie in a helix. Figure 2(a) gives an arrangement used in one gravity meter to suspend the proof mass. Figure 2(b) is that of a somewhat similar use, but where

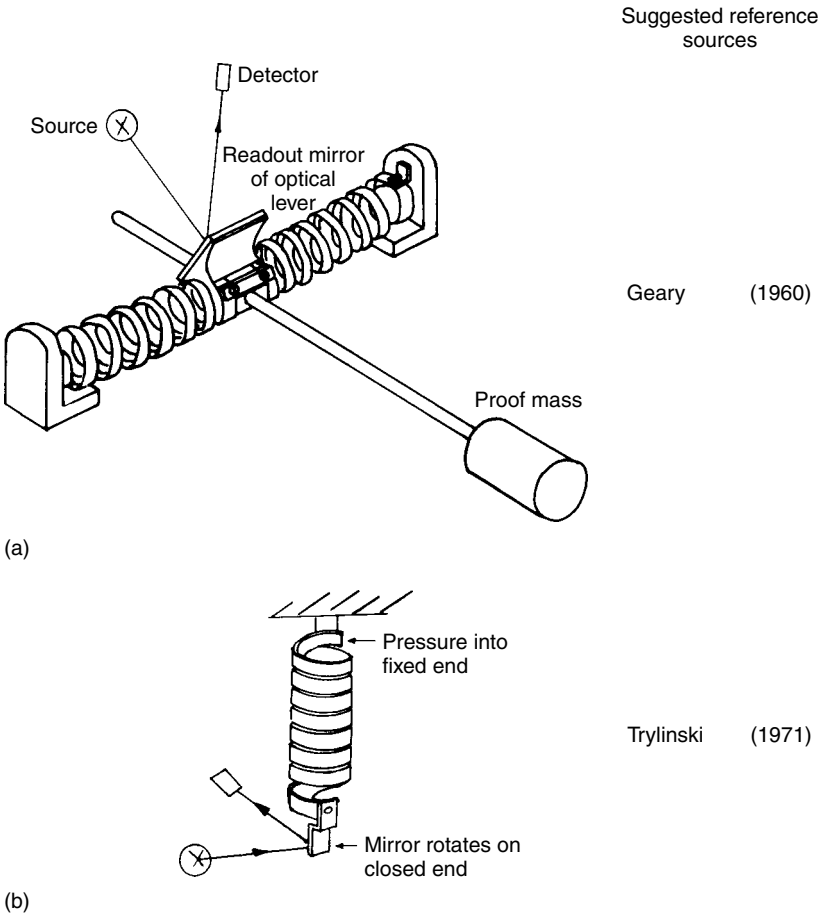

Figure 2. Examples of coiled spring: (a) helical torsion in gravimeter; (b) helical Bourdon tube.

the form of a spiral quartz Bourdon tube is used for ambient pressure measurement. Reference sources are given in the figures.

3 FLAT-STRIP SPRINGS

Flat strips used in bending and torsional modes of basic flexure, as with previously treated springs, can also be used as energy storage elements or as supportive mechanisms. In many applications, they serve both purposes together.

With so many options reported, it appears most expedient, in this brief introductory review, to present schematic illustrations of a selection of options describing some of them in detail to bring out certain design features. Figure 3 provides various views of flat-strip springs used to provide energy and support. Several applications use the flat strip in a coiled fashion; it is not possible to entirely separate spring forms into unique groups.

The first type shown in Figure 3(a) is the use of a strip in which one end is secured so that rotation at the fastening is prevented. Deflection progressively occurs along the strip, increasing in amplitude as the force moves outward. The force-deflection characteristic depends upon the shape and thickness of the strip. It is nonlinear for a parallel, uniform strip. To linearize the spring rate, it can be tapered in thickness and width. Leaf springs used in vehicle suspensions are actually a very tapered cantilever spring that is cut into sections and stacked in a pile. Their sliding contact also provides damping. Early expensive vehicles further tailored the characteristic by tapering the spring material in thickness as well as in width. The design of these is straightforward. The strip can be regarded as a beam with one end (or two ends if needed) fastened rigidly. Another option for altering the rate characteristic is to let the step progressively lean onto a shaped support as it deforms (Beggs, 1955). Figure 3(b) shows the strip used in the same way as a beam with both ends supported. In this option, the ends can be simply supported so that rotation is allowed at the ends. Deflections are not linear with load unless the beam is suitably proportioned in thickness by the means mentioned above.

When cantilever springs are used as small rotation locating mechanisms, the effective pivot point, called the

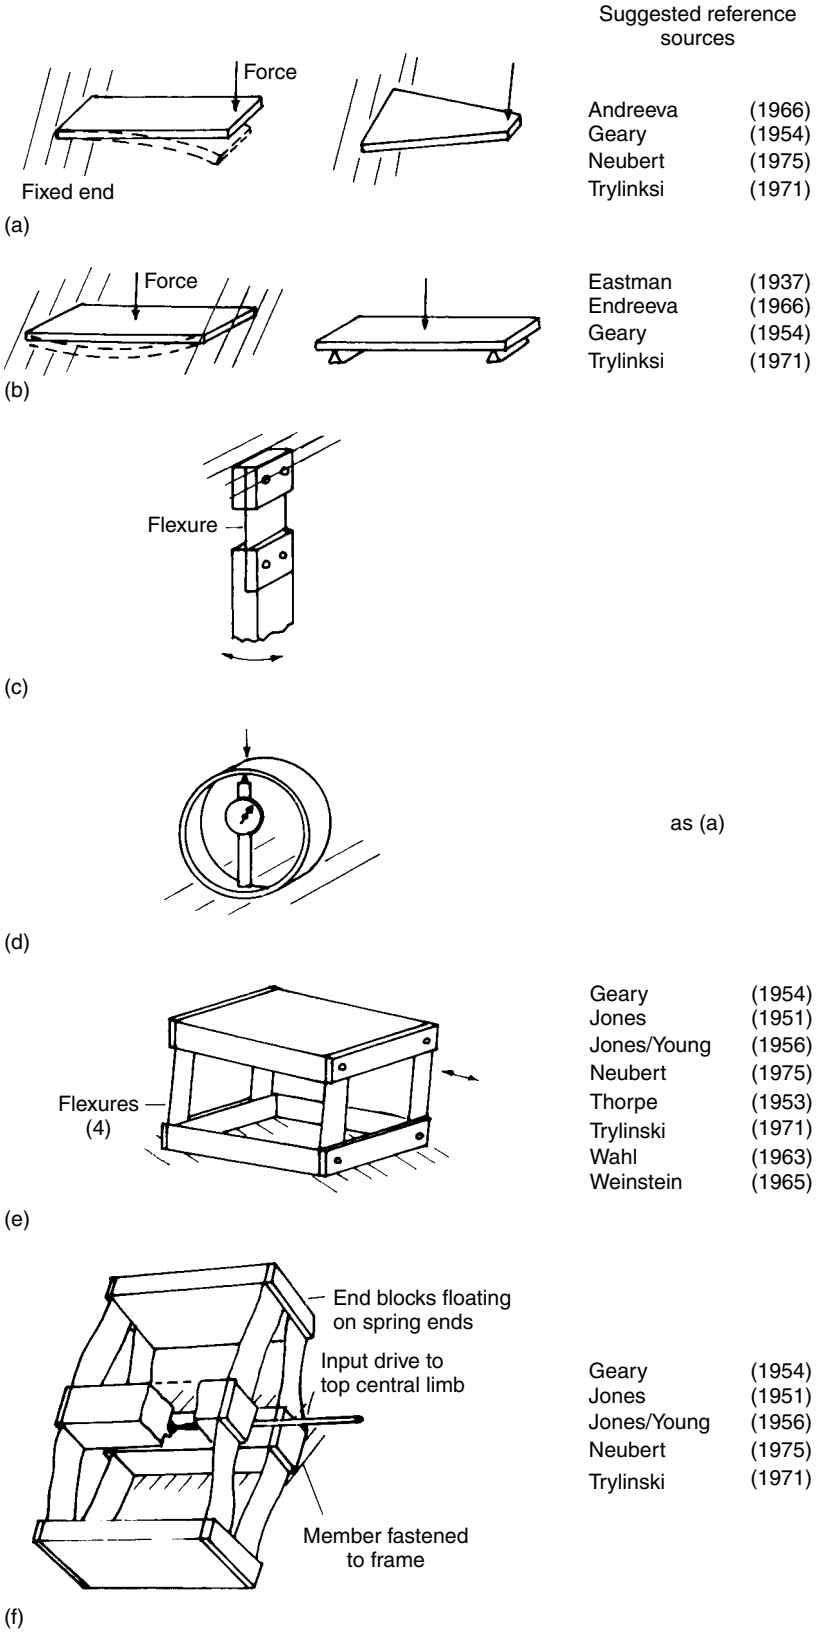

Figure 3. Examples of flat-strip springs: (a) cantilever; (b) beam; (c) single flexure pivot; (d) load cell; (e) parallel-strip slide (uncompensated); (f) parallel strip (one form of compensation).

instantaneous center of rotation, moves in a curved path. Cantilever flexures can also be used with the end of the beam being placed in torsion. A tensioned beam used this way with long length and narrow width is called a *taut band suspension*.

Figure 3(c) shows a strip that bends while supporting a load. As has already been mentioned, the bending stiffness increases as the load supported is increased. Many expressions given in texts do not allow for this. The pivot action provides an instantaneous center of rotation that moves in a circular path, as does a cantilever support. Geary (1954) should be consulted for reference sources on this design. Trylinski (1971) and Eastman (1937) are also relevant.

Proof rings, which form the force to displacement conversion element of a load-cell type, are formed of shaped rings, tubes, rods, and more, to which are attached a displacement sensor. The sensor might be a simple mechanical indicator or an electrical output device. In either case, the design aims to obtain linear or other specific conversion characteristics by suitable choice of mechanical force load-cell element. Figure 3(d) shows a circular proof ring formed from a thick strip by machining it from a solid or by forming a flat plate.

4 MANAGING THE DEGREES OF FREEDOM IN ELASTIC SYSTEMS

Displacement of a table in one axis, while the other five degrees of freedom are substantially held in constraint, can be obtained by use of a parallel-strip suspension shown in Figure 3(e). These take several forms of which the simplest variation is shown. Study of a given four-strip suspension will reveal that, as the amplitude of displacement rises, the table being supported does not follow a perfect linear translation but traces out a curved path in which it rotates and rises and falls. These effects reduce as the length of the strips increase with respect to the amplitude of movement needed.

Introduction of a symmetrical but oppositely applied suspension, Figure 3(f), produces a differential error compensating system that can provide almost pure translation. These are called *eight-leaf* (or *strip*) *parallel strip guides*. Jones (1968), Trylinski (1971) and Neubert (1975) show alternative physical arrangements of the compensated method. Jones (1951) and Jones and Young (1956) are basic reading about parallel-strip suspensions.

It will be apparent that the suspension produces a reacting force as the table is displaced from the central rest position. The force to deflection ratio is constant over small ranges of travel for both the four- and the eight-strip suspensions. The ratio follows cubic relationships for thickness and spring length and is linear with width of spring material and elasticity modulus. Designs sometimes use two adjacent strips that are merged across into one strip. If the suspension has to bear a downward acting load, the flexures can be stiffened with plates (to avoid Euler's buckling) added to the central length of the strip (Geary, 1954).

Parallel-strip suspensions will deflect according to the inverse of their stiffness values. Thus, a series connection of a stiff unit driven by a more compliant unit acts to reduce motion in a positive, accurate, and stable dividing manner. Figure 4(a) shows the layout of strip flexures used to obtain displacement reduction of 1000:1, with negligible friction and force requirements. It was designed for displacing an optical grating to a discrimination level of 0.08 μm, (Sim, Ross and Taylor, 1971). This application is typical of many in which ingenuity is applied to obtain very effective mechanical mechanisms using flexures.

Having replaced the kinematic slide with a flexure equivalent, at least for small amplitudes, it may seem obvious that there might also exist a limited action replacement for the rotating bearing. This does exist and is known as the *crossed-strip pivot* (there are numerous name variations with 'crossed' used in each). Figure 4(b) shows the four-strip hinge. This may take on the alternatives of three strips when two are combined inside the center of the other two, or a two-strip form in which they do not cross within their physical length, doing so at the theoretical extension of the strips (see Geary, 1954).

The springs are generally arranged to cross at 90°, but this is not vital. Considerable design options are available with these. The instantaneous center of rotation moves such that the support can provide positive restoring or collapsing moments (negative restoring force) when excursion reaches given points.

Added to this feature is the possibility of preforming the springs, altering the crossing point from the center to higher or lower positions between the two surfaces, and by forcing the springs into nonflat shapes by their clamping end conditions. Haringx (1949), Geary (1954), and Trylinski (1971) give in-depth treatment of the crossed-strip pivot. It would appear that only one company has marketed off-the-shelf crossed-spring assemblies as OEM (Original Equipment Manufacturer) products, see Bendix Corp (1975). It is necessary to design and manufacture them to order.

5 BUCKLING EFFECTS IN FLEXURE ELEMENTS

So far it has been suggested that care is needed to prevent buckling through the application of a load greater than

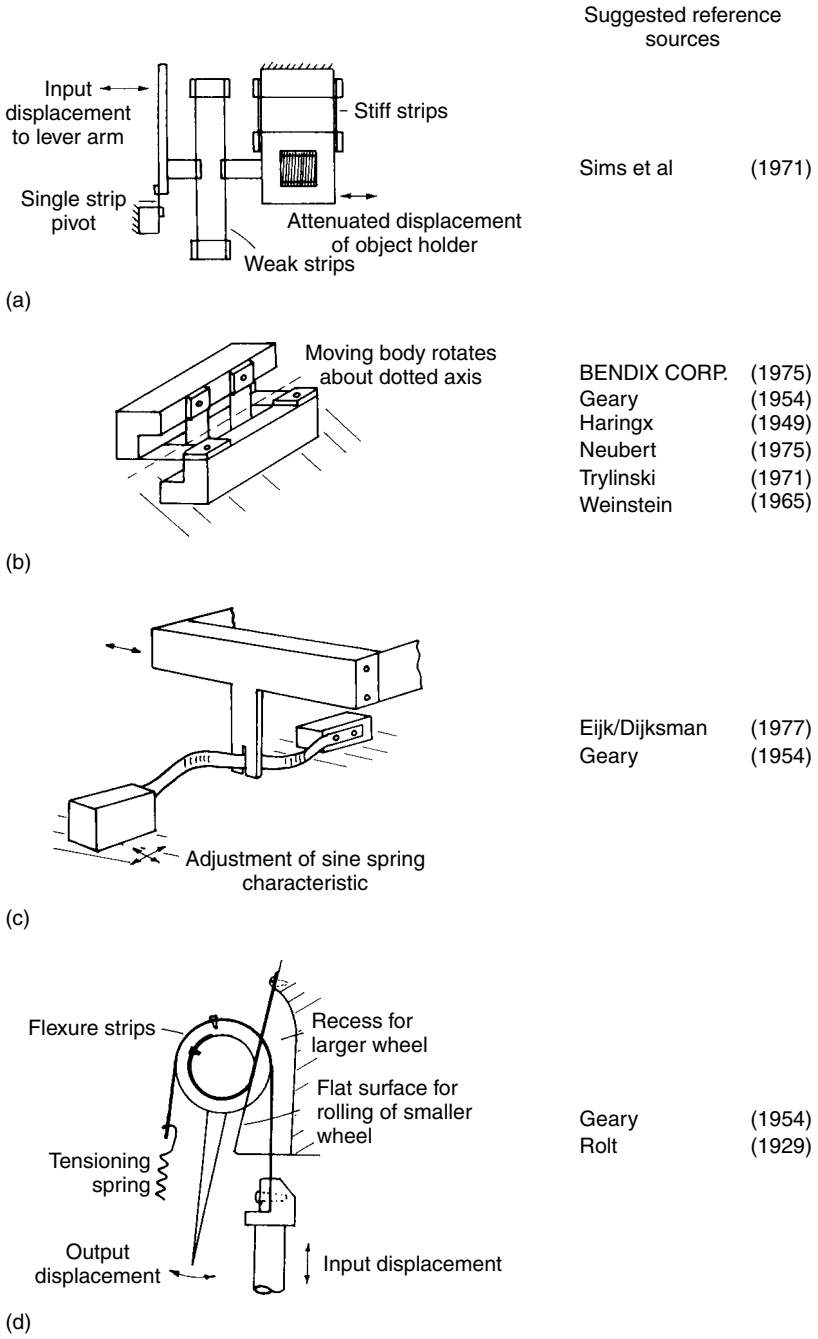

Figure 4. Examples of flat-strip springs: (a) displacement attenuator using strip suspension; (b) cross-strip pivot; (c) sine spring (used here to reduce the restoring force of parallel-strip suspension); (d) rolling suspension.

the Euler buckling limit. This effect, however, can be put to good use to form yet another spring element that can support considerable loads with very small spring rates (including negative) without incurring the penalty of a large initial deflection that occurs with a simple helical spring. Figure 4(c) shows how Eijk and Dijksman (1977) used the buckled-beam spring strip (also called a *sine spring*) to provide a negative restoring force to cancel the force provided by a parallel-strip support; Geary (1954) also discusses these.

Geary (1954) describes a buckled strip arrangement used by the staff of the National Physical Laboratory. Their application made use of the feature that a buckled beam provides a rotating surface on which a mirror can be mounted. As the end of the beam is buckled further by translation, the mirror rotates to form an optical lever.

6 SPECIAL SHAPES OF FLEXURE ELEMENTS

A strip can also be employed to form a rolling suspension. Figure 4(d) shows an example adapted from Rolt (1929) (see vol. 1, p. 333 for greater detail). The strips here act to hold the roller onto a flat surface while allowing the system one rotational degree of freedom. One spring strip must be tensioned (by a spring or a gravity mass) to keep the system taut. As is illustrated, the linear motion of the input is converted into a rotation that also can be given gain by use of different diameter input and output rollers.

The bifilar suspension has already been mentioned; Figure 5(a) shows a form of this. These take numerous forms in practice, ranging from the two round section wire filaments shown to systems using multiple filaments. As a first approximation, these can be considered to have completely flexible filaments, but a more detailed design would be needed to consider their elasticity. Trylinski (1971) and Geary (1960) discuss their design in detail; numerous scientific instruments have been built using such suspensions.

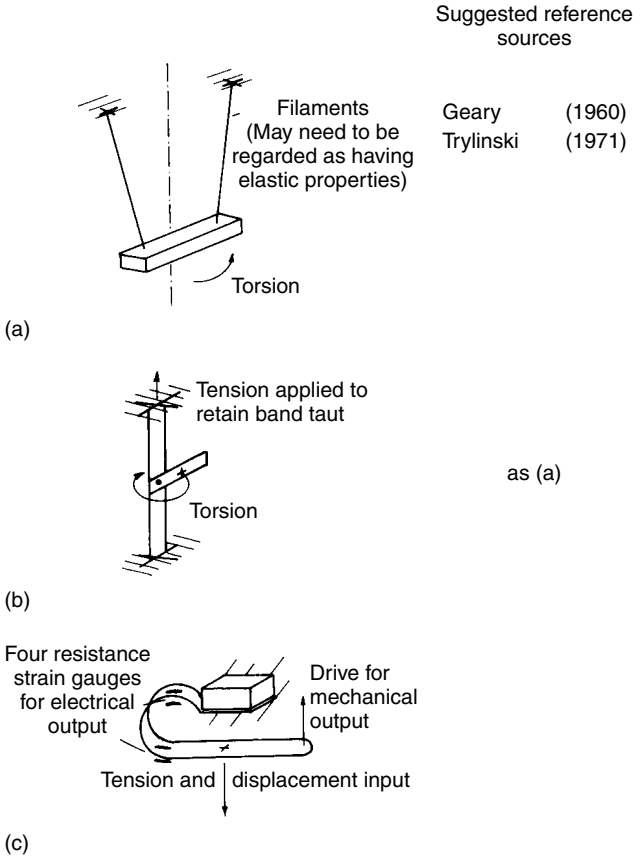

Figure 5. Examples of flat-strip springs: (a) bifilar suspension; (b) taut band torsion; (c) special design used in a relative humidity meter.

A similar torsion action can be obtained using a tensioned taut band Figure 5(b).

7 EXAMPLES OF SPRING FLEXURE ELEMENTS

Finally, in this short review of the innumerable possibilities of spring systems it must be stressed that special shapes can often be devised for special purposes. Figure 5(c) shows one case employed in a low-cost commercial humidity meter to simultaneously provide tensioning force to a stretched hygroscopic membrane and, as the membrane forces the flexure to bend, to provide load-cell action by driving four resistance-strain gauges mounted to its external curved surfaces.

Flexure elements can play a very important part in instrument design and offer an alternative to kinematic design, that is not always the best option to choose.

1 FLAT-PLATE FLEXURE ELEMENTS

Relatively thin plates can be used to provide precision guidance of the center point of the plate; the plate can also simultaneously act to contain pressure of a fluid.

The simplest arrangement (Figure 1(a)) uses a flat, thin, flexible sheet of material that is fastened around the periphery either as a fixed or a simply supported edge in which edge rotation is allowed. In the center, the member to be guided is fastened. As these provide a rapidly rising restoring force with deflection, they are generally only applicable to guide very small motions. Trylinski (1971) provides expressions that show that those provide a linear force–displacement relationship for small movements.

Two basic methods may be employed to obtain a linear force-displacement characteristic over a larger range of movement with a reduced spring rate; that is, those that are more easily deflected.

The first method is to slit the membrane in some appropriate way so that it can deflect further. Figure 1(b) shows several possible shapes. As a very approximate guide to estimating the compliance, designs can often be regarded as providing the net effect, summed in the center, of one or more cantilever beams. The spiral case shown can be mentally unwound to form a long thin beam supported only at one end. In some designs, the plate is not supported around the periphery but at points within the plate. There appears to be no published analytical design information on their design. Trylinski (1971) and Neubert (1975) devote space to these guides but do not provide analytical expressions for other than the simple continuous plate with point or distributed loading. Gibbs (1957) appears to be one of the few reports specifically devoted to the subject, but it contains little more than is given in Trylinski (1971).

Thin plates used for this purpose are called *slit membrane guides* or *diaphragm spring guides*. They are used extensively in such applications as loudspeaker moving-coil supports, geophone suspensions, vibrator suspensions, and anywhere that relatively small amplitude, frictionless translation is desired. By careful design, they can operate for millions of cycles at high frequency, providing high stiffness across the diaphragm and low stiffness in its plane.

They do not appear to be marketed as a stock item and like most flexures have to be manufactured as needed. Slits are formed by photomechanical etching methods, by spark machining, or by plain stamping where quality does not need to be very high and the production run is large.

Slits may well provide greater compliance and range but they remove the property of the plate to retain fluid pressure. In cases in which guidance alone is needed, this may be an advantage to prevent air pressure pumping. Some applications may deliberately use a closed membrane to exclude moisture and dirt.

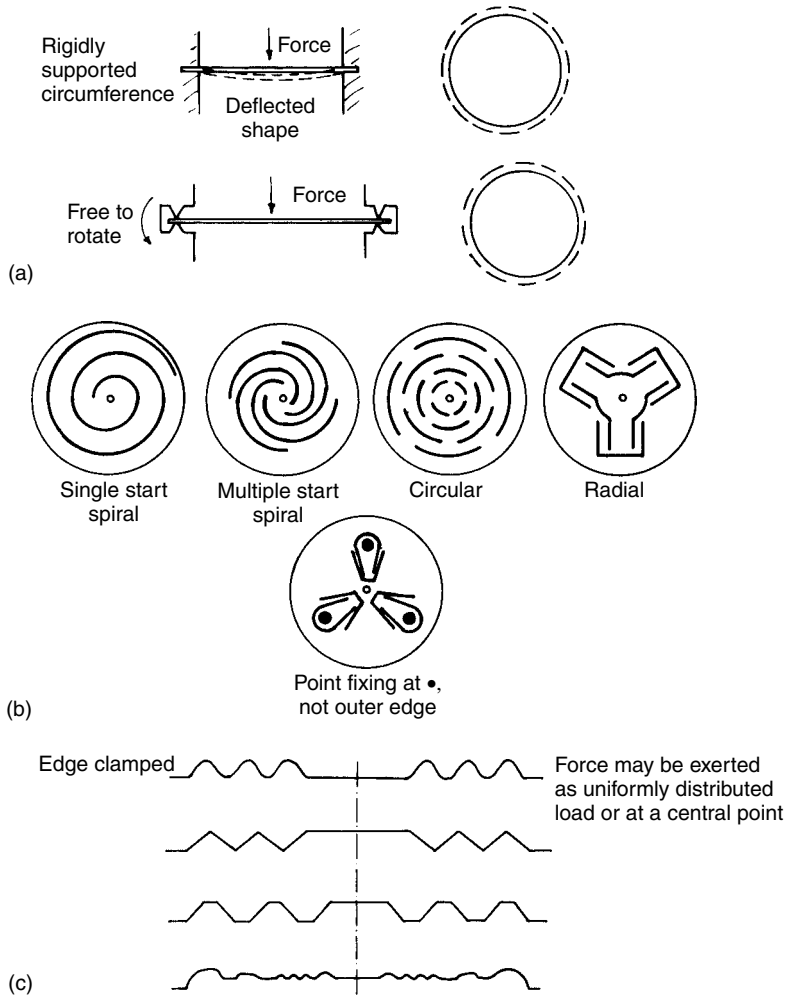

Figure 1. Flexure membranes: (a) solid diaphragms, (b) slit diaphragms, (c) corrugated plates and capsules.

2 PRESSURE-BELLOWS DIAPHRAGMS

If pressure-tightness is essential, as it is in pressure gauges, some other method of making the diaphragm more elastic is needed. It can be obtained by pressing corrugations into the plate. Several commonly used cross-sectional shapes are shown in Figure 1(c).

Sealed diaphragms are also called *membranes*; Trylinski (1971) calls them *pressure controlled elastic elements*.

Presumably, because sealed diaphragms are used so extensively in pressure sensors, a product line that forms a large part of process instrument sales, there has arisen the extensive need of pursuing their design in considerable depth. Design is reviewed in analytical terms in Trylinski (1971). CDA (1953) provides practical detail of application as do Beggs (1955) and BELL and HOWELL (1974). Computer-aided procedures developed in the Department of Applied Physics of The City University, London have made the design procedures of compliant plates considerably simpler to implement; work previously needing much actual prototype manufacture and testing has been bypassed by the use of rigorous mathematical modeling of the profiles needed.

3 CAPSULES FOR PRESSURE SENSING

To obtain greater deflection for a given force, the diaphragms may be joined to form capsules and stacks of capsules, as shown in Figure 2(a). Bellows also provide a similar increase in rectilinear flexibility (Figure 2(b)). As the characteristics of the materials that must often be used – because of temperature limits and the required high strength levels – do not always have the desirable low thermal coefficient of elasticity, pressure systems often need some form of thermal compensation built into the stack assembly. Aneroid barometer bellows and capsules are sealed with internal pressure; the choice of fluid, pressure, and quantity

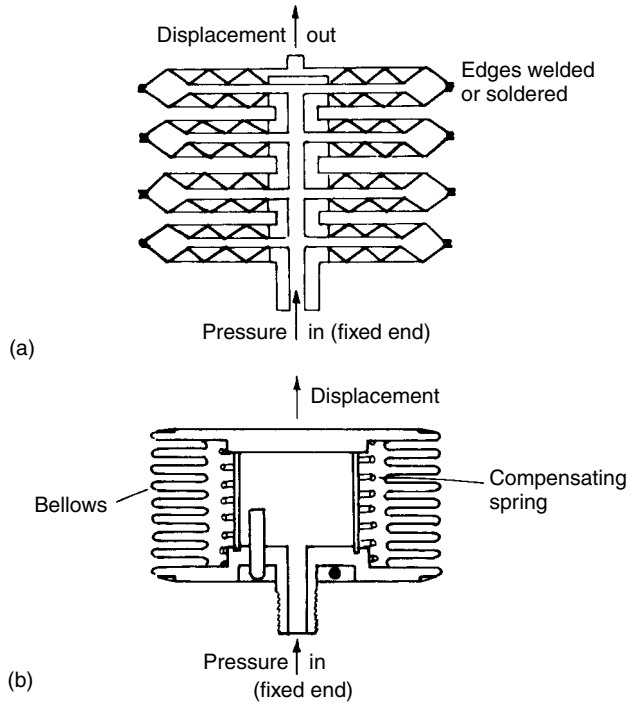

Figure 2. Flexure membranes: (a) capsule stack and (b) bellows.

can be made to assist compensation; internal helical springs are sometimes used.

In pressure sensors, diaphragm deflection is transduced by direct linkage to a mechanical device or a sensor might be actually attached to the membrane. In the latter case, membrane design must allow for this.

Although not made from plates, the subject of this section, it is appropriate to include mention of Bourdon tubes. These are flexible tubes formed such that pressure differences between the inside and the outside cause the tube to deflect. Trylinski (1971) provides design formulae for these. Deflection is harnessed to drive a pointer or an appropriate electric sensor.

4 NONMECHANICAL ELASTIC SYSTEMS

Electric and magnetic fields have been used to provide variable spring rates and so have columns of air. Fluids that are easily compressed are more suitable (where springiness is needed) than the virtually incompressible fluids such as water and oil. Thus, an oil hydraulic bearing is very stiff, having little compliance, while an air bearing will be softer.

Magnetic suspensions are reasonably common in instruments. They can be formed from permanent magnets arranged in a suitable manner using additional electromagnetic coils so that spring rate and stability can be controlled. In either case, it will be clear that the force of attraction rises sharply as the two magnetic poles of unlike kind come closer together. Magnetic suspension systems need some form of stabilizing arrangement to make them statically stable. Earns Haw, in 1839, showed theoretically that the inverse square law for force and distance fields (magnetic and electric fields are such) cannot inherently support a fixed magnitude pole in a stable manner (Geary, 1964). Automatic control is employed to alter the force with distance as a closed-loop system. Further stabilizing mechanisms may be needed to ensure that one pole does not slide away from the desired position. This can be visualized when attempting to sit (levitate) a pole over the top of another pole of like polarity.

An advantage of magnetic springs is that they can be made to act through sealed walls of containers. An example of an application might be as the connection and weighing medium for a sensitive chemical weighing balance. The process of measurement can be achieved by altering the field strength of an electromagnet so that the balance returns to a given datum in the manner depicted in Figure 3. The electric current needed to achieve the balance state is related to the weight of the mass that is supported.

Electric fields also exert forces so they can be used as elastic elements in the design of an instrument. This method has been used in at least one gravimeter to restore the balance position.

Further detail on magnetic and electric suspensions is to be found in Geary (1964). Weighing balance applications are detailed in Gast (1968), Gast (1974), and Wolsky and Zdanvk (1980).

As the name implies, an air spring is a compliant movement obtained by the use of air, contained in some way, to support a given load. The automotive pneumatic tire is the most obvious example of air spring being used in that application to assist isolation of vibration.

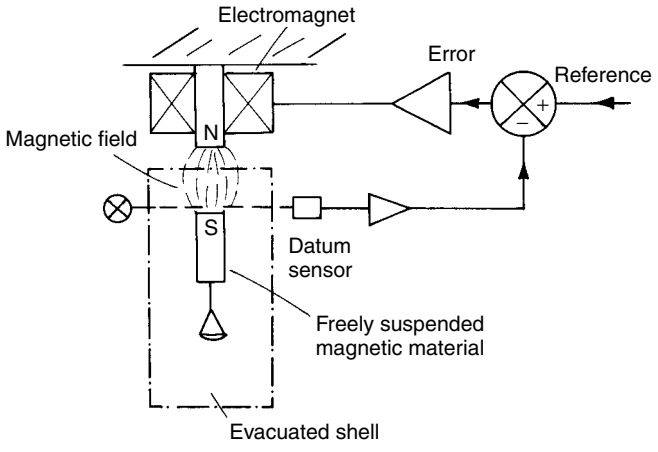

Figure 3. Schematic of force-balance, magnetic suspension weighing technique.

Air springs are capable of substantial load bearing without large deflections, and they can easily provide low natural frequency, second-order suspension systems. They have been used extensively in vibration isolation of machinery. The spring usually takes the form of a round flat flexible bag that is pumped up to a suitable pressure.

Air springs have no resonant effects within the spring itself (as do mechanical coil springs). Their rate can be made to stiffen with increasing load, being nonlinear devices. This means that second-order systems formed with them remain at substantially the same natural frequency with changing load. They are, however, affected by ambient temperature, and they require a relatively large amount of maintenance work. They are generally regarded as being suitable for only heavy load situations. The reader should consult Jones (1967) and Dorien-Brown (1971) for further references and an introduction to this form of elastic system.

5 BIMORPH FLEXURE SYSTEMS

If two materials (Figure 4(a)) having different thermal expansion rates are placed side by side with one end of the parallel combination fixed securely, temperature changes to the element so formed will bend traversely due to differential expansion between the two elements. Such elements are called *bimetallic devices* if made from metals. A similar device can be formed (Figure 4(b)) using two pieces of piezoceramic that are fastened together and have deposited electrodes placed along their outer edges and the central interface. These are termed *bimorph-benders*, or twisters.

Bimetals bend with temperature, converting temperature change into displacement. Bimorphs convert electrical energy into displacement. Bimorphs involve a reversible process – that is, deflection will generate electricity – but bimetal elements are irreversible.

Bimetals are made by soldering or welding thin plates of suitable material together, the final shape being stamped as strips, disks, or whatever shape is needed. The side having the higher thermal coefficient of expansion is called the *active side*; the reverse is known as the *passive side*. As no material has an absolutely zero expansion characteristic and metals generally possess only positive coefficients, the net effect is always that of a combination of two positive coefficient expansions. The forces of this expansion are considerable, and bimetal elements can often directly drive an electrical contact or dial indicator.

To obtain the greatest deflection effect, the metals used need to be, for the passive side, one with the lowest practical coefficient (which is usually Invar), and on the active side, one with a high coefficient (stainless steels, brasses, and special alloys).

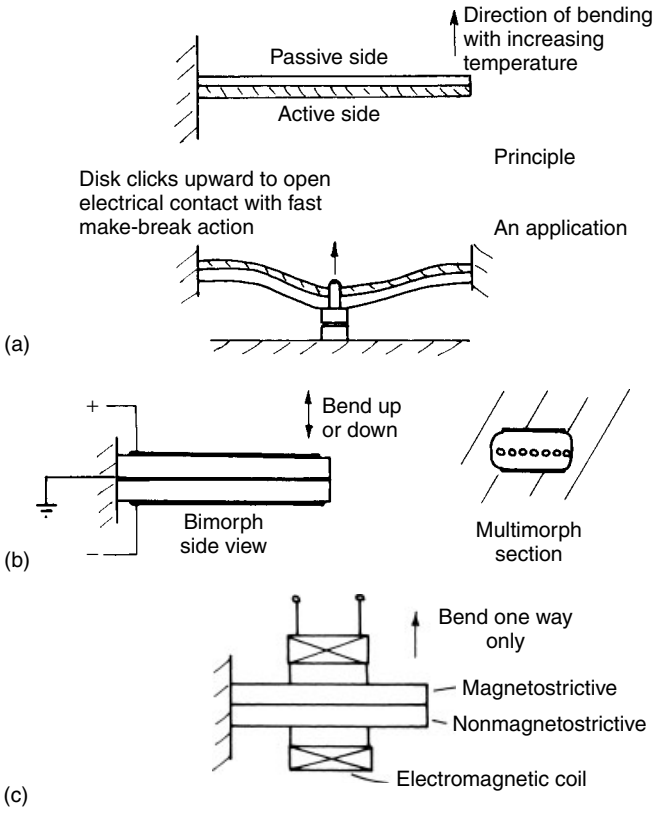

Figure 4. Differential expansion bending and twisting devices: (a) bimetals, (b) ceramic bimorph and multimorph, (c) magnetostrictive bimorph.

Traverse deflection can be converted into rotation through the use of spiral spring forms. These also can be used to obtain greater deflection. However, as the deflection per unit thermal change parameter is increased, it will usually be found that the stiffness of the bimetal element reduces, making it less capable of driving a load without distortion. Preloading the bimetal element against a stop (prop) provides a means of adjusting the datum at the temperature position at which the element begins to respond.

The design of bimetal elements is covered in detail in Timoshenko and MacCullough (1959) and in Trylinski (1971).

Bimorph devices are less common than bimetal elements and information about them is a little harder to locate. Neubert (1975) gives a short account of how piezoelectric sandwiches can be made to provide bending, twisting, and beam deflection action, as well as bending a plate across the diagonal or lifting the free corner of a three-corner mounted plate.

Design information is usually available from the suppliers of the materials, Brush-Cleveite being one source of application notes.

6 MULTIMORPH FLEXURES

A variation of the bimorph is the multimorph. These can provide greater elasticity and are said to be easier to manufacture. Instead of sandwiching two strips together, a single strip is made with a row of fine holes formed through the centerline. These are filled with conductive material to form the inner electrode. The outer faces are coated with electrode material in much the same manner as for the true two-slice sandwich bimorph.

Other forms of differential bending devices could be formed on this principle but they do not appear to have been used. For example, a nickel strip sandwiched (Figure 4(c)) to a stainless steel side would bend in the same direction with an increasing magnetic field of either polarity; the nickel, but not the stainless steel, is magnetostrictive. This is the magnetic equivalent of the ceramic bimorph. It would also give reversible characteristics.

Bimetal and bimorph devices can be used to provide compensation for the physical attribute that suits their input energy form. Bimetal elements are often used, for example, to correct diaphragm-type pressure gauges. They are also used to trip circuits when the ambient temperature produced by the direct true ambient or by the use of a heating coil or direct heating causes the strip to deflect. **Article 88, Error Sources in Fine Mechanics, Volume 2** on error sources and their reduction, provides more information about the use of thermal differential methods.

The dynamic response of such differential devices may be important. Bimetal devices are relatively slow to act since they must transfer thermal energy to obtain deflection. They will be substantially first-order systems in response because the thermal storage and dissipation rate combination is much slower than the rate at which the strain energy transfers. Clearly, the smaller the element the faster the response, and physical size limits would generally provide these elements with time constants in the order of seconds. Miniature thick and thin film devices are able to respond much faster but at the expense of less power drive capability.

Bimorphs are inherently high frequency devices. As the rate of energy change for the electrical and the strain energies transfer is of the same order, these will provide second-order response with high natural frequencies in the kilohertz and higher region; low damping is a feature. They are not, of course, a replacement for the bimetal since the two devices operate with different input energy forms.

1 FUNDAMENTAL LIMITS IN FINE MECHANICAL DESIGN

Having covered the overall design issues relevant to the operational requirements of fine mechanical systems in **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2**; **Article 81, Principles of Fine Mechanics – Systems Considerations, Volume 2**; **Article 82, Kinematical Regime – Members and Linkages, Volume 2**; **Article 83, Kinematical Regime – Fasteners, Bearings, Volume 2**; **Article 84, Kinematical Regime – Rotary Motion, Volume 2**; **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 86, Elastic Regime of Design – Spring Systems, Volume 2** and **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2** it is now appropriate to discuss the error regime of designs.

In any instrument design, there exist certain design factors that cannot be eliminated and must be worked within. All physical processes inherently contain physical phenomena that provide a limit to sensitivity or stability, which ever is the issue. In the majority of mechanical designs, this is not likely to be of great significance. Research material on the detailed nature of fine mechanical errors reached its highs well before the advent of electronic forms of publication. Much of the research material was published before electronic solutions overtook mechanical means from the 1950s. Thus, sources may be hard to locate – but they are often worth finding for they provide a wealth of practical information on less popular topics.

In mechanical systems, the prime fundamental limit to sensing detection is Brownian movement, a random motion of the molecules forming the substance of the parts concerned. The motions of the molecules are averaged by the mass of the part, so larger components exhibit less overall dimensional change due to this source than smaller parts. It has been extensively studied in relation to electrical indicating galvanometers, in the period before the 1950s, and became of interest again in more recent times in the hope of detecting gravity wave radiation. Chapter 17 in Bleaney and Bleaney (1957) provides a basic introduction to the theoretical considerations. Braddick (1966) discusses noise sources in experimental setups. Further references are given in Sydenham (1979) where the importance of this

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

limit in the evolution of electromechanical instruments has been reviewed.

The bibliography given in Logan (1973) contains references to many of the published papers on gravity wave detectors. Jones (1967, 1968) contains useful practical accounts of the limits of measurement sensitivity.

To provide a rather crude estimate of the level of dimensional noise that Brownian motion effects will generate in a mechanical component, some published examples are quoted. These, however, must be accepted only in the full context as given in the quoted reports. Jones (1967, 1970) estimates that the root-mean-square length change of a 10-mm brass block of 1 mm^2 area is likely to be about 10^{-16} m when averaged over a 1 s integration time. This level of change is fine for most requirements, but it will be a limiting issue for those mechanical sensing systems that are taken to the limit of possibility.

As a second example, Usher (1973), a review of seismometer designs contains an estimate that a seismometer with a mass of 10 gm, a natural period of 1 s, a mechanical quality factor, Q, of 100, and operated at room temperature will possess a noise equivalent acceleration of 3×10^{-11} g. He shows that the factor for reducing this in that design is the damping, which should be kept low. The natural frequency of the spring-mass system is not a factor in determining the amplitude of the Brownian motion noise. In these instruments, this noise source must be considered in order to create satisfactory instruments.

Showing up in yet another form, in a sensitive electromagnetic galvanometer, the source there might give rise to noise equivalent currents of around 10^{-12} A. Further examples are to be found in Barnes and Silverman (1934).

2 CREEP AND HYSTERESIS IN MECHANICAL MECHANISMS

Although not strictly a truly fundamental limit, the effects of creep and hysteresis of mechanical materials often act as an effective fundamental limit. There are practical levels to which any amount of better design, external influence parameter control, and material processing cannot better. Despite considerable research effort seeking to quantify the fundamental mechanisms of creep and hysteresis in materials, there does not yet appear to be available an adequate model of the underlying process. Many texts are available that summarize the current state of knowledge. Design to reduce hysteresis and creep is generally based upon experimental data about the material used, its strain history and the experience of the designer.

It is suggested that hysteresis can be reduced by limiting the mechanical stress excursion to the smallest allowable cycle amplitudes and by the use of low hysteresis materials.

Creep is a still more elusive parameter. Clearly releasing locked-in stresses by annealing and other stress relief methods helps. Weathering for prolonged periods is also used where time permits, for it is known that the creep rate generally reduces with time. A part considered to be creep-free, however, may change its creep characteristics quite markedly if remachined or worked in some way. Sydenham (1973) is concerned with the long-term stability of tensioned Invar and fused silica.

The difficulty faced by the instrument designer is that the vast majority of creep and hysteresis data is compiled for highly stressed parts, that is, those operated at high temperatures and large stress excursions, such as are found in aircraft turbine blades. Instrument designers, on the other hand, are generally interested in comparatively low stresses and well controlled, around ambient temperatures. The extreme difference between the two cases makes extrapolation from one zone to the other a very unreliable procedure.

As a guide, it is generally good practice to stress materials (those that must be stable) to no more than a tenth of their elastic limit. Brasses are considerably better than steels in as far as creep is concerned in instrument parts. It is not possible to provide any really worthwhile rule of thumb guides for these two parameters.

Both of these factors are given a very poor account in instrument design texts, very little information is provided on both these factors, presumably because of the lack of general knowledge about them. Trylinski (1971) discusses hysteresis in instruments, but not in numerical terms.

Creep is often finally accepted as a factor that cannot be reduced to the levels really desired. Being largely (an often incorrect assumption) systematic and adequately linear with time, corrections can be made in the measurements using a sensing mechanism that creeps. A prime example is the exploration gravity meter in which an established, return to start, routine is set up with respect to time and position of readings; the drift can be assessed and removed from the data taken in the field.

3 GEOMETRICAL ERROR FACTORS IN FINE MECHANISM

Attention is now turned to these features of a mechanical design that can be controlled in order to improve the performance and accuracy of the measuring apparatus.

A clearly identifiable group are those sources of error that relate to the geometrical features of the mechanical assembly. These are almost all parameters that can be kept in control by careful design of the assembly and through adequate selection of components, materials, and sizes.

Mechanical design of instruments invariably rests upon the assumption that there exist points in the mechanical space framework that are invariant in position with respect to each other. They are often merely drawn as crosshatched lines in schematic diagrams of the system.

In reality, all materials are elastic and change dimension to some degree with force exerted on them. It is, therefore, important to ensure that such elements are, indeed, sufficiently strong, inelastic, and stable.

Stresses occurring in manufacture, testing, transport, and assembly are often far in excess of those experienced by the component in its working state. For example, there is need to finally align a measuring machine in its application, for test bed results cannot be relied upon to be the same. Bolting down stresses can change the geometric shape. Transportation might have imposed distortion of the frame.

A second form of geometric error sources is the dimensional relationship change that will occur because of the actual dimensions of individual parts lying in an error band given by the tolerances to which the parts have been made. Tolerances should be selected for the various surfaces of a component according to the assembled geometry required. There is an art in tolerancing; it comes largely with experience. Whereas, to overspecify may well control the assembly dimensions more rigidly, it makes the instrument far more expensive.

Standards, such as BS 1916 on limits and fits for engineering, provide the starting point to the selection of realistic tolerances for given situations. This aspect is generally included in courses on mechanical engineering. Tolerancing is usually a given feature of mechanical CAD tools.

Related to tolerance error is the gradual loss of accuracy that might occur if a wear-true philosophy has not been adopted. Wear in pivot points and along slides will change the effective geometry of the instrument, thereby possibly degrading the performance.

Such matters, plus other general aspects of design, are gained largely by direct experience. Several authors in the past have endeavored to pass on that experience as descriptive guides to general instrument design. These include Braddick (1966), Glazebrook, Darwin and Mason (1923), Rolt (1929), and Whitehead (1954).

Rather more specific are errors caused by assuming that location points, such as a center or a sliding perpendicular, are provided in a perfect manner by a bearing or a slide, respectively.

3.1 Abbe's principle

Abbe's Principle, although well known among practitioners, does not seem to have been defined in English language texts about instrument design. Basically, it states that a measurement is generally best performed by applying the measuring device to the object in as direct a manner as possible. For example, in the field in which this was first expounded – mechanical dimension measuring equipment – it is preferable to determine the length of a part using a comparison method that introduces as little error due to the comparison process as is practicable. Figure 1 contrasts the use of a scale to measure the length of a part with the method in which a traveling microscope head slides along a scale. Where the scale markings and the interval that must be measured can be placed in actual contact, the reading cannot include any error from the comparison process. (Of course, it could contain error of the scale or from its misreading.) In contrast, the traveling microscope arrangement can introduce error by way of the slide not being straight, causing the microscope to project the scale incorrectly on to the unknown.

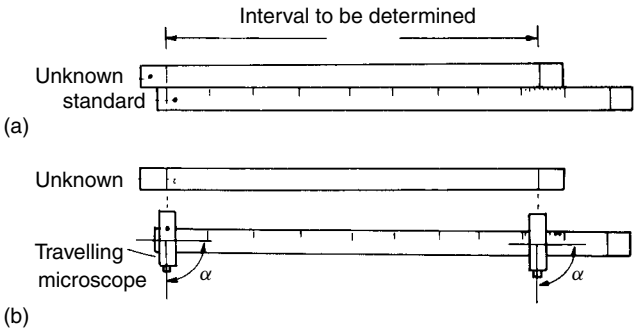

Figure 1. Abbe's principle. In (a), the unknown and the standard are compared in a direct manner but in (b), errors may exist in the projections of the scale by the microscope.

Whereas Abbe's Principle might be the ideal to aim for, it is often not practicable to adhere to it. If not, then other geometrical errors must be considered.

4 SINE AND COSINE ERRORS, AND CENTERING ERROR IN FINE MECHANISM

Angular variations introduced by the mechanism embodied in the traveling microscope example given in Figure 2 need consideration. It depends upon the effect on the length being determined or required to be held constant.

If the same microscope is used at each end of the length and the slide is straight (Figure 2a), any fixed angular error, α, in the mounting of the microscope head will not cause error in the length determination because it is equal at each end. If, however, the microscope mount is perpendicular to the slide at one end and the slide causes the head to rotate

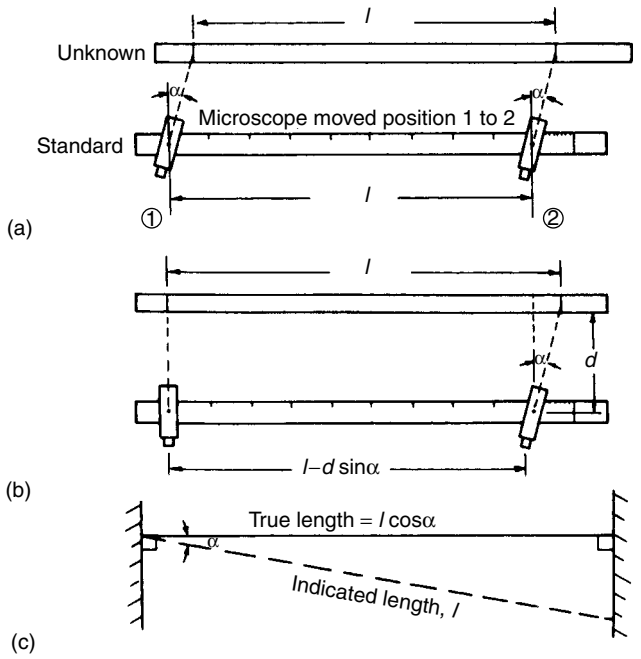

Figure 2. Sine and cosine errors (a) error of microscope mounting not significant, (b) sine error occurs at one end due to rotation of microscope, (c) cosine error.

by angle, α, at the other end (Figure 2b), an error equal to $d\sin\alpha$ will arise. As this error is directly additative, and because sines of small angles are significant quantities in such cases, quite small angular changes can give rise to relatively important error magnitudes.

When measuring a length (Figure 2c) between two end intervals instead, as arises with an inside screw micrometer (the above sine error case occurs in vernier calipers), then a second kind of error source can occur. If the part to be measured is not aligned with the central axis, the length will be $l\cos\alpha$, not l as indicated. This is not as significant as the sine error of the previous case for if the angle α is small, which it usually is, the $l\cos\alpha$ is close to the same as α. Another example where this error arises, is in the setting up of a distance measuring ranger. The actual alignment need not be very accurate, because the error caused by misalignment will not be significant.

Whereas cosine errors are generally easy to control, they must, nevertheless, be calculated to ensure that the approximation holds to the degree of accuracy that is required. Sine errors, similarly, must be controlled by ensuring that the angles remain within tolerable limits under practical use. As d is reduced, in Figure 2b, it will be seen that Abbe's Principle is approached.

Errors of this form are discussed but only briefly under the principle of alignment in Rolt (1929) and in Braddick (1966).

4.1 Centering error

Where the measurement of location depends upon a bearing around which motion takes place, there may arise errors of centering. It is common knowledge that such errors can be reduced by reading the scale on opposite sides, taking the average of these as the correct value. Whitehead (1954) devotes space to this problem, pointing out that it is not always necessary to use the best possible bearing tolerances. He provided an analytical study of the magnitude of errors. Many instruments are made to be read at least at diametrically opposite places. Indeed, some arrange more than this number of averaging processes to be carried out in provision of the output value. Whitehead, however, only considered the use of a centering bearing for a radial scale. In linkages, the error effect must be considered from other viewpoints. Braddick (1966) also provides material on centering errors.

Although the above error sources have been illustrated here in terms of the traditional, manually read instruments, it will be found that these error sources arise frequently in the design of the mechanical features existing in transducers of the modern form.

5 INFLUENCE PARAMETER ERRORS IN FINE MECHANISM

The very best of internal designs can only provide satisfactory operation if variations in external influences either lie within tolerable limits or can be handled by the internal design arrangement.

All systems are influenced by changes in ambient conditions to some extent. It is the relative magnitude of these effects that matters. Temperature, ambient air pressure, relative humidity, magnetic and electric fields, acoustic noise level, mechanical vibration, chemical attack, and more can each possibly give rise to error in operation of the installed instrument.

It is common and established practice to test an instrument toward the end of the design cycle for its tolerance to such effects. Calibration is often accomplished taking into account given levels of vibration of influence parameters. It is, however, often overlooked that the test conditions may not be reproduced in the final use situation, where yet more influence parameters may be in existence.

The designer of an instrument must know which of these influence quantities will exist in use and how to allow for them. There are two approaches. One is to control the internal environment of the instrument by the use of a suitable enclosure; for example, the internal evacuation in a vacuum weighing balance that avoids

errors of buoyancy and provides some degree of thermal isolation. The alternative is to design each element of the system, such that the overall system can tolerate significant enough influence parameter variations. An example here would be to use low thermal expansion materials plus certain mechanical structural arrangements (that will be discussed below) to reduce thermal differential expansion error to within tolerable limits for the expected design temperature variations.

In practice, one or the other, or a combination of these two alternatives is used. Probably the hardest part of the task is probably to properly and adequately decide what influence quantities are relevant and their magnitudes of change.

6 TEMPERATURE ERROR IN MECHANICAL SYSTEMS

Without doubt, the most prevalent influence parameter in the mechanical design of instruments is temperature change. Basic materials with absolutely zero thermal coefficient expansion do not exist. Furthermore, materials with the lowest values are not always suitable for the manufacture of instrument parts. It is, however, possible to produce instruments from the relatively high coefficient materials, which are reasonably temperature insensitive. Before going into the methods that might be used, it is instructive first to examine the general thermal design of a mechanical instrument.

Thermally controlled jacketing and mechanical compensatory mechanisms are often used to overcome temperature error. The value of each, generally, rests on an underlying assumption that the temperature is uniform within the instrument. This is often far from the case. It is not adequately recognized that thermal heat flow is not an instantaneous process. Any change of forcing temperature on some part of an instrument will give rise to changes in temperature of all of its parts at varying rates. If, in exacting designs, the instrument is regarded as being a thermally dynamic rather than static assembly, then better design should result.

If the external temperature does not change, then only internal sources of heat, such as arise from electronic circuitry enclosed in the housing or from friction between moving parts, can cause thermally produced differential dimensional errors. Heat source changes due to adiabatic action on air pressure may be relevant. Design, therefore, should aim to keep internal and external sources of temperature change as small as necessary. They, however, cannot ever be held at an absolute stability. Internal heat transfer mechanisms should be arranged so that temperature uniformity results as speedily as is required. In practice, these simple rules are very difficult to adhere to.

Consider first the problem of thermal uniformity. The materials that are most suited for construction, such as the steels, aluminums, and brasses, do not have very high thermal conductivities. They also possess comparatively high thermal expansion coefficients. Lower coefficient materials generally have still lower thermal conductivities.

Heat is transferred by conduction, convection, and radiation. Knowing the constraints imposed by the materials that have to be used – good thermal conductors are not the best of structural materials – it is possible to arrange for heat transfer to be improved through the use of design layout, shape, cross-sectional size, and similar design possibilities.

7 REDUCING THERMAL ERRORS IN FINE MECHANISMS

As a guide, design for good thermal uniformity will aim to provide good conduction inside the instrument with a high thermal barrier attenuating external changes through the use of some form of integrating enclosure. Enclosure design can also be most sophisticated. Reference will be made to that later.

To obtain good internal uniformity, all parts should be made to maximize conduction through the use of high thermal conductivity materials, large cross sections, good thermally conducting joints, and optimal arrangement to keep conduction paths as short as possible.

Conduction and convection can often be improved by the use of a stirring arrangement such as a fan or stirrer paddle. The internal fluid, in such cases, will be a suitable liquid or gas that will assist heat transfer. The transfer of thermal energy is, however, often decided more by the heat transfer film coefficient existing at the interfaces than it is by the fluid's internal properties.

Sometimes the design aims to prevent convection taking place, thereby aiming to maintain the temperature constant, if not uniform, within the instrument. It is a physical fact that the smaller the convecting cell size, the lower the rate of convection. Below a certain cell size and shape it ceases completely. Because of this, it is often helpful to fill interspaces of an instrument with loose thermal insulation so that the internal convecting spaces are made smaller.

Heat transfer by radiation can be increased by suitable use of surface treatment, blackening being the most used. The actual surface treatment used will be decided by the thermal wavelengths involved. Within the system, parts are blackened and the whole is then surrounded by a thermally reflecting enclosure. The silvered vacuum flask is a good example of this.

It will be appreciated from this account of the possibilities that the thermal design of an instrument can be very complex. Perhaps that is why this aspect of design of instruments has not been adequately researched or organized. Braddick (1966) gives brief mention to the problem. Considerable practical information exists in primary journal literature on temperature controllers, but the basic principles, theory, and design do not appear to have yet been ordered in a didactic manner.

Basic texts on heat transfer, such as Eckert (1950) and Jakob and Hawkins (1957), provide general design principles. Publications relating to cryostat design (White, 1959) and use also delve in these problems. Abachi, Molenat and Malbrunot (1979) provide a useful bibliography of reported designs. Designers of microbalances have given thermal effects considerable attention, Wolsky and Zdanuk (1980) being a key review work. Wolsky *et al*. (1967) discusses how gold plating a quartz balance arm can reduce thermal expansion errors through subtle heat transfer mechanisms. Sporton (1972) is probably the best available paper to consult when beginning a design of an enclosure.

Thermal enclosure design is often needed in the development of the total instrument system. Some applications require the instrument to operate within temperature limits as small as a millikelvin variation. Design aims to form an enclosure in which the walls seen by the contained instrument are uniform in temperature and of the lowest practicable thermal impedance.

Simpler designs generally use an almost point source of heat, which is controlled from a single point on–off temperature sensor. Clearly, this does not come close to the rule of maintaining uniformity throughout and, therefore, only provides crude control. Far better are the designs in which the heater and the sensor are distributed throughout the wall area of the enclosure. Proportional control is generally assumed to provide the best control loop but this may not always be the case.

Parameters of thermal enclosure design are the external variations and frequency to be controlled, the size and shape of the instrument (clearly smaller instruments are easier to control to a given limit than large structures), the limits of control variation required, the internal heat sources, the enclosure design (sandwiched heat conducting and insulating walls), plus judicious use of air spaces have proved very effective (Sporton, 1972).

In many applications, the aim is to integrate the external thermal forcing function to an adequately small internal variation. Thus, it seems an obvious step to use an enclosure that has an adequately long thermal time constant. In practice this can be, with passive methods at least, less effective than might be expected. The thermal time constant (that for a 64% change if the system is assumed to approximate the first-order linear response) for a vacuum flask is around 2 to 3 h; a solid house brick box is similar. When using such methods to average out daily variations, they are barely effective. Daily variation smoothing requires several meters of rock cover.

Active systems, those in which temperature is actively controlled, can be far more effective. Long time constant passive surrounds also suffer in that they must be given time to stabilize before the internal instrument can be used in its intended state. As thermal mass is the dual of thermal insulation, it is possible to construct first-order thermal enclosures from either conducting or insulating material. Each has its advantages. Use of both kinds together raises the order of the enclosure's thermal time response and, therefore, if designed properly, can provide better results.

In the practical construction of thermal controllers, it is far easier to produce heat energy than it is to remove it (compare electric heating elements with Peltier cooling cells, for instance). For this reason, thermal surrounds often are operated at some margin above the ambient temperature so that natural heat loss acts to provide the heat reduction mechanism.

It is the author's experience that a contributing factor to the mechanical instability of materials is the stress brought about by temperature variations of the part. It appears that the more controlled temperature variations are, the better the ultimate stability of creep exhibited. This is further supported by the practice of thermostating gravity meters with a temperature-controlled jacket that is kept energized even when the instrument is not being used.

8 THERMAL COMPENSATION METHODS IN FINE MECHANISM

The alternative method for reduction of thermal mechanical error is the use of compensatory mechanisms.

Most constructional materials possess a positive coefficient of thermal expansion; that is, they expand in length with increase in temperature. Owing to the shortage of suitable, large enough, negative coefficient materials (they do exist – carbon fiber and the silicas), it is not generally possible to counteract the positive expansion with a negative part as shown in Figure 3. This kind of component, however, using two different positive coefficient materials, can provide an adjustable positive coefficient rod by

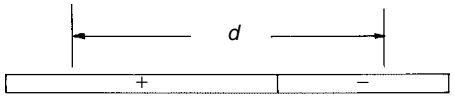

Figure 3. Thermal compensation by cascaded bars.

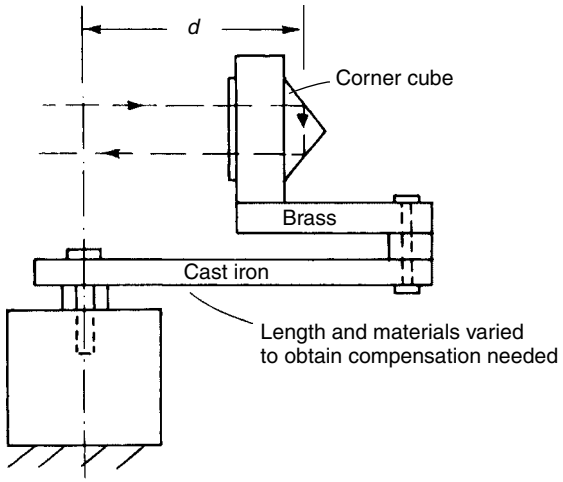

Figure 4. Thermal compensation by reentrant bars.

clamping it with distance, d, spanning the ratio of the two lengths required.

This problem can be completely overcome (within limits) by the use of two positive coefficient materials arranged as a reentrant compound structure. Figure 4 shows the mounting arrangement used to maintain the reference arm distance, d, in a Michelson optical interferometer constant with temperature change to the mount and corner cube. As the cast iron expands outward with temperature rise, the brass expands in the reverse direction at a larger rate, giving a net change of zero to distance, d. Concentric tubes can also be used to form a zero length change bar. Bimetal strips, in which the two materials are joined, can also be used to change dimension in some way through a forcing action.

The choice of materials being limited means that the design of reentrant arrangements must be proportionate to the relative lengths in order to obtain the zero (or other) state using the small range of thermal expansion values that will be found to be usable. In the above mount, the design also allowed for the expansion of the glass of the corner cube.

The assumption that both parts of a reentrant link change (track) temperature together may not hold; during temperature transients the compensation may not operate satisfactorily.

A second method, one that is not used as commonly as the reentrant arrangements (because, it seems, it is not well publicized) is to make use of the stresses set up by temperature change in an element. Baird (1968) used this principle (Figure 5), to compensate a bar of Invar.

In this method, steel wire was wrapped around an Invar rod. It was then soft-soldered to it, so that axial stresses in the steel wire, caused by temperature changes, are coupled into the circumference of the Invar bar. With temperature rise, the steel attempts to form a larger diameter ring around

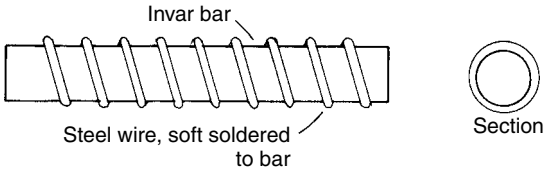

Figure 5. Thermal compensation by counterstressing.

the Invar, causing it to be tensioned outward. This, in turn, via the Poisson ratio shape–volume change effect, causes the Invar bar to reduce in length. The reverse holds true. He provided the theoretical considerations for obtaining the degree of compensation needed for a pair of materials. Clearly, this method can be applied by plating layers or by pressing tubes over the base bar. The thickness and the external material used are the key design factors.

A third method for compensating thermal errors is to measure the temperature change in a part, applying a generated appropriate length change where needed. Many methods exist for the provision of small length changes under electric control. They include piezoelectric crystals, magnetostrictive rods, and thermal heating of rods and electromechanical devices. Measurement of the temperature of a part can be difficult because of transient thermal effects. The control loop, however, may also introduce phase shifts that distort the required behavior.

9 TEMPERATURE ERROR IN ELASTIC ELEMENTS

Temperature changes to elastic elements will give rise to length changes according to the thermal coefficient of length; additionally, however, the elastic modulus will change.

The combined effect is to alter the elastic rate (scale error) of the spring element and also to alter its free length, giving rise to a zero position shift (zero error). If the component is designed to be a flexing spring, then these combined effects can be very serious. Exactly how the spring's combined scale and zero behavior varies with temperature change depends upon the spring's form and geometry. Producing a spring that has negligible temperature error does not occur merely by selecting a zero elasticity modulus material, nor will it occur by using a zero thermal coefficient of expansion material.

It can be shown (see Gitlin, 1955a) that for the common cantilever, helical, and torsional forms of spring the error of spring rate change (scale error) is not a factor of the physical dimensions but it is dependent upon the thermoelastic and linear expansion coefficients and the magnitude of the temperature excursion. Thus, once the material is chosen,

a given level of scale error exists for all designs with that material. Beryllium copper, for example, possesses a scale error of −0.03% per degree Centigrade for an increase in temperature, that is, the spring softens with temperature rise.

Shift in zero with temperature is dependent upon the spring's form. The three articles by Gitlin (1955a, b, c) are key reference accounts about the thermal errors in instruments. Trylinski (1971) includes discussion of this problem.

9.1 Error due to ambient pressure

The mechanical components of an instrument change dimension according to the external pressure exerted upon them by their ambient environment. This has a very small effect, but on occasion it can be significant. It is calculated from the Poisson ratio for the material, which expresses the longitudinal change in length for transverse stress variation. As a guide, metals will lengthen by around 1 part in 10^8 for a typical daily ambient barometric pressure variation.

Error from this source can be reduced by the use of ambient pressure control, which need not necessarily be at the evacuated level as long as the pressure remains constant enough. Alternatively, it can be compensated in some way through the use of some form of pressure-sensitive device. Sealing an instrument inside a container does not necessarily provide constant pressure inside the container; temperature changes to the gas inside it will give rise to significant pressure changes.

10 MISCELLANEOUS ERRORS IN FINE MECHANISM

The above discussion has dealt with sources of errors occurring in mechanical components. Also of importance might be those cross-coupled, mechanically produced effects that transduce mechanical energy into another energy domain. An example is thermoelectrical current, which is generated by the mechanical materials used in combination with thermal effects. Piezoelectric and magnetostriction are electrical resistance-strain changes that are each brought about by mechanical input parameters. They must, therefore, be considered in the mechanical design stages of an instrument as possible error sources in the total system.

It can be seen that there are many sources of error in, or caused by, the mechanical components of an instrument. If good mechanical performance is to be obtained, these must be considered and reduced to satisfactory levels of magnitude. This point needs to be stressed because this aspect of mechanical instrument design is sadly neglected in texts, in courses, and in practice. Scientists involved in the manufacture of their own experimental and measurement apparatus often reach these barriers and they, therefore, are aware of the errors that can arise. Other designers, however, often do not realize that their designs also may suffer from such effects; it is necessary to eliminate them as design parameters by reasonably rigorous study before they can be honestly regarded as insignificant. They are often easily reduced at the initial design stage.

The main error source is temperature and it affects just about every component. It always needs consideration before any measurements are made or instruments designed.

1 BLANK MATERIALS

Optical technique has long been important for measuring and observing instrument design, making its first impact as the telescope and microscope of the sixteenth-century Galilean times. Combined with fine mechanics development, it provided a vast array of mechanical-optical and, since the early twentieth century, electro-optical instruments. They are vital to modern telecommunications in optical fiber technology, in database storage devices, audio recording and playing equipment, and so on. While the pace of development of the technologies involved is truly amazing, the basics of the optical parts remain as it has been for centuries. Over time, the advances have been in understanding the optical theory and in using computers to support design.

Optical methods made significant strides when machine computation reached a state where the previously needed person-years of design effort have been reduced to hours. A further boost came when the traditional optical-mechanical industries combined their expertise with twentieth-century electronics. In this emerging century, microminiature optics will feature strongly.

The eventually realized laser source, in the 1960s, provided more capability for optical methods to be used in more kinds of measurement. In the solid-state form, the laser source has revolutionized many measuring instruments.

Several texts can be useful here – see Musikant (1985), Ahmad (1997), Hobbs (2000), Smith (2000), Weber (2003).

Optical instruments have been extensively used for varied applications in diverse areas and thus have immensely contributed to the science of measurement. During the latter part of the twentieth century, the interest in this branch of physics has further been stimulated and sustained with the availability of high power–coherent light sources and detectors. This era has thus also witnessed many original approaches toward developing sophisticated optical instruments and systems and associated technological advancements in meeting intricate measurement needs for different sectors of the economy. The quite relative newcomer, the miniature optical-array detector, has also opened up remarkable possibilities for faster and better measurement.

This article primarily aims at elaborating the fundamental issues connected with optical technology and understanding the basic principles underlying the construction of important optical measurement instruments and their applications. Mass-produced optical elements still need to use many of these centuries' old methods. Small-scale production, typical of measuring systems, has to employ them as a handcraft needing considerable skill and know-how.

Raw materials used in the optical shop are considered under the categories blank materials, abrasives, optical

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

tooling, blocking materials, polishers, cleaning agents, and optical cements.

The stock material used to form optical elements is known as a *blank*. Glass is the most commonly used blank material for the production of optical elements but other materials, including plastics, are also used.

Glass is a transparent dielectric substance, in which the molecular structure is characterized by an extended network lacking in periodicity and symmetry, but with atomic forces comparable to those present in crystals. Glasses of optical grade, commonly known as *optical glass* are used for quality optics.

As optical materials are commonly used to diffract radiation passing through an element, the effects that will cause distortions of images transmitted need to be identified and kept within limits. Mirror elements, where the radiation is reflected from the surface, are less impacted by defects but they still need to keep their form and shape as residual stresses relax over time or with thermal cycling in operation. Optical glass must be extremely homogeneous, must not absorb gases and liquids and must have negligible residual strain, bubbles, and striae. Striae are optical lines seen in glass due to variations of its refractive index.

The specifications of A grade optical glass state that it should not possess any visible striae or cord, with birefringence less than $10\,\mu m\,cm^{-1}$, that is, no color beyond light gray should be seen in the crossed Nicols test and it should be totally free from bubbles larger than 0.01 mm in diameter. This kind of glass is refined by heating and cooling many times to remove the defects.

Optical glass is characterized by its refractive index and the constringence or Abbe number (or simply ν value). This is defined as $(N_d - 1)/(N_F - N_C)$, where N_F and N_C are the refractive indices of the material corresponding to the F and C lines of the spectrum of hydrogen having wavelengths 4861 and 6563 Å respectively, and N_d pertains to the helium yellow line at wavelength 5876 Å.

The physical significance of ν is that it relates to the dispersion caused by the material: the higher the ν value, the lower is the dispersion. In simple terms, this means that the higher the ν value is the more the radiation is bent as it changes from one index to the next. Glasses with higher ν are customarily called *crown glass* and those with lower ν are known as *flint glass*. Crown glasses, therefore, have considerably less dispersion when compared to flints. This combination is useful for it allows corrected lenses to be formed by the use of two elements placed together.

Optical glass contains silica, which, when mixed with the oxides of potassium, calcium, barium, lead, and more in different proportions, yields a wide range of optical glasses of different properties. Table 1 gives some typical compositions.

A wide choice of optical glasses varying in refractive index and ν value is available commercially. The end use and design considerations govern the choice of appropriate material.

Testing of optical glass involves evaluation of refractive index, ν value, striae, strain, and bubble contents. The test methods are simple and can easily be adopted in actual practice by following standard specifications.

Some other blank materials employed to make best use of the different radiation bands of the EM spectrum are quartz (both crystalline and amorphous varieties), rock salt (NaCl), sylvine (KCl), fluoride (CaF_2), calcite, KBr, ZnS, calcspar, Iceland spar, solid solutions of thorium bromide with thorium iodide, Corning 7940 glass, Mylar, sapphire, and Irtran. All these possess quite different transmission and reflection properties making them necessary for different wavelength operations.

Curves illustrating transmission of light through the atmosphere, as also through some selected materials, can be found in manufacturers data sheets and in works such as the classic work by Hardy and Perrin (1932) and Weber (2003).

The spectral characteristics of optical glasses render them largely unsuitable for incorporation in infrared or ultraviolet imaging systems: other special materials are available for use at these wavelengths.

Plastics of many types are frequently used in optical technology particularly for making inexpensive and not too critical optical elements. Polymethyl methacrylate, in short PMMA or commercially called *Perspex*, has properties like crown glass, and polystyrene is equivalent to flint type. The principal drawbacks in their usage are the nonavailability of materials with wider choice of refractive index and ν value, lack of homogeneity, lower softening point, fragile nature, and proneness to scratching.

Table 1. Percentage composition of some typical optical glasses.

Glass type	SiO_2	B_2O_3	Na_2O	K_2O	CaO	BaO	ZnO	PbO	Al_2O_3	Fe_2O_3
Borosilicate crown	71.0	14.0	10.0	–	–	–	–	–	5.0	–
Crown	74.6	–	9.0	11.0	5.0	–	–	–	–	–
Light flint	62.6	–	4.5	8.5	–	–	–	24.1	–	–
Barium flint	45.2	–	–	7.8	–	16.0	8.3	22.2	–	–

2 ABRASIVES

To create optical elements, the blank must be shaped into flats or curves. The traditional method has been to grind blanks with abrasives and a form. It is possible to cut the material into shape using computer-controlled machine tools with micrometer tolerances, but they are still not capable of replacing grinding in most applications. Plastics can be molded as is done in spectacle lenses but again a mold shape is needed and the method is not capable of producing geometry of adequate accuracy for exacting optical systems.

Glass is quite a hard substance and for working on its surface, special abrasives are used. Obviously, an abrasive must be hard compared to the surface being ground. On Moh's scale, the hardness numbers of diamond, ruby, topaz, and quartz are, respectively, 10, 9, 8, and 7.

Carborundum (SiC), emery, in natural as well as artificial forms (fused Al_2O_3, aloxite, alundum), and boron carbide (B_4C) are some of the abrasives commonly used in optical workshop practice. These are mostly used in powder form suspended in a water medium. Diamond powder is available in almost all grades and is used for impregnation on working tools particularly when large stock removal is necessitated.

The average grain sizes of abrasives used in the optical shop range between 3 to 300 μm. Rough work requires a faster cutting rate, which can be achieved by using coarser grains. Silicon carbide or carborundum powder is most suitable at this stage. Once the desired shape and size have been given to the blank, finer grades of abrasives are progressively employed to obtain better finish. Aluminum oxide or emery is normally used for this purpose.

Grain size grading of abrasives is done in several ways. An example is the elutriation time taken, in minutes, for the emery to settle through a column of water contained in a vessel 30 cm in diameter and 1-m high, using the sieve or mesh size through which that particular grade can pass.

Table 2 gives the commonly used nomenclature of particle size grading and the corresponding average grain size.

The quality of uniformity in grain size is often indicated by numbers 0, 1, 2, 3, . . . , 10; 0 being perfectly graded and 10 being badly graded.

For the polishing operations, extremely fine-grain hard powder free from impurities is used. Rouge (Fe_2O_3), cerium oxide (CeO_2), putty powder (SnO), chromium oxide, and diamond paste are some of the common polishing agents.

Tripoli, diatomaceous earth, chalk, talc, slate, and pumice powder are other abrasive materials. Garnet optical powders have also been used for the particular purpose of ophthalmic (spectacles uses) machines employing autofeed slurry pumping systems.

Table 2. Abrasive gradation.

Mesh size	Other designation	Elutriation time in minutes	Approximate average size (μm)
60	M 60	–	290
100	M 100	–	150
180	M 180	1	85
220	M 220	–	75
700	M 302	5	20
850	M 302½	10	16
1000	M 303	20	13
1300	M 303½	40	10
1800	M 304	60	5
3000	M 305	–	3

3 TOOLS FOR OPTICAL MANUFACTURING

Turning, smoothing, and polisher forming tools are normally made of cast iron. Molten iron treated with meehanite (CaSi) gives a fine structure free from porosity and other defects. Polisher-holder tools may be made of aluminum. Gunmetal has also been used.

A radius turning attachment is used for providing the desired curvature on the tool surface. As the turning process is quicker compared to lapping, it is desirable to produce, as accurately a curved surface from the tool as is possible by turning.

Templates and gauges are generally made of brass, 2-mm thick, the edge reduced to about 0.5 mm. Collets for holding the job during curve generation on automatic machines may be made of brass (aluminum is also used). Clamping bells required in centering and edging operations are normally made of brass.

Test plates, test spheres, polygons, standard angles, optical flats, and the like are made to the required tolerance and durability requirements, from specified materials such as white plate glass, ophthalmic glass, optical glass, or low thermal expansion coefficient materials such as Pyrex, fused silica, CerVit, and Corning ULE.

4 BLOCKING MATERIALS

After smoothing, several optical elements are normally blocked over a tool and later operations performed upon them in situ. This requires a material that holds the optical elements rigidly during working. The blocking material should be hard enough to withstand the pressure and friction of the smoothing and polishing tool, yet be soft enough for easy extraction of the secured optical elements whenever needed.

Pitch is the most common blocking material as it is soft when warm, but hardens on cooling. Normal tar can be hardened to the desired degree by mixing with it additives such as sawdust and cotton wool. Blocking material should be cloth filtered to eliminate undesired hard foreign particles. Beeswax, plaster of paris, and hydrated lime are used for blocking optical flats, prisms, and similar elements. Low melting–point alloys are also used as blocking material.

5 POLISHERS

A polisher is an accurately shaped cast iron tool upon which the polishing medium remains mounted. Polishing of optical surfaces is achieved by lapping the job with a preformed polisher of desired shape and size and applying polishing powder. The accuracy of the surface quality generated on the finished product largely depends upon the quality of the polisher. A polisher material should be hard enough to retain its form during polishing, yet it must be amenable for alteration as and when needed. Pitch, as stated earlier, possesses these properties: a polisher is formed of warm pitch of the desired shape and size. On cooling, it becomes sufficiently hard to retain its character.

Polisher pitch is softer than blocking pitch. Mixing turpentine with hard pitch produces polisher pitch. Polishing grade pitch is commercially available. As the hardness of pitch depends upon the temperature, the viscosity and hardness of blocking and polishing pitch should be maintained in accordance with the ambient temperature of the shop floor.

Felt, cloth, and wax are some other materials used in preparation of polishers. Wax polishers cause less streaks and scratches but are slow compared to pitch and do not produce accurate surfaces so readily. For hand polishing, wood pitch is considered to be best.

For better results, polisher pitch might be prepared to a consistency such that it is readily but not deeply indented by the thumbnail. Thus, it should be neither too soft nor too viscous. Loaded polishers are made by addition of wood flour, cotton wool, or yellow felt to the pitch. These help maintain the shape of polishers. Addition of beeswax to pitch reduces its tendency to scratch the working surface.

Teflon has also been tried with success as a polisher. Different types of polishing pads are also available commercially, and are mainly used for medium grade flat work.

6 CLEANING AGENTS

At various stages of the work, the optical surfaces are cleaned to remove grease, pitch, or wax. Teepol solution is very useful for degreasing. Methylated spirit, isopropyl, and anhydrous alcohol are commonly used for general purpose cleaning of optical surfaces. Benzene, benzol, and trichloroethylene dissolve pitch and are used during the deblocking operation. Kerosene dissolves beeswax efficiently. Acetone is an excellent solvent and is used for cleaning polymerized HT cements.

7 OPTICAL CEMENTS

Optical cement must be transparent, reasonably color free and must not develop much strain on the cemented surfaces. These are normally nonadhesive, but join two glass surfaces after some physical or chemical operation has been performed upon them. Decementing may or may not be possible, depending upon the type of cement used. Some cements set on heating to a particular temperature followed by curing at another temperature.

Canada balsam, a natural oleoresin with refractive index 1.52, is commonly used in optical cementing work. Its unique characteristic is that it has very little tendency for granulation or crystallization on drying from a solution. Cellulose caprate (refractive index 1.47–1.49), which is another that is widely used, is a thermosetting cement.

Thermosetting cements readily release the cemented components upon heating. Many other types of commercially available optical cements, on exposure to ultraviolet light, are set by a polymerization process. These are extremely fast drying, but once cemented, the reopening process becomes quite tedious.

8 MATERIAL PROPERTIES

In an optical material, its transmittance is an important characteristic to be known because it measures how much light can pass through the piece of material. Technically, it is defined as the ratio of the transmitted optical power to the incident optical power when an optical beam is launched into the piece of material. Obviously, the difference, instead of the ratio, between the input power and the output power, accounts for the loss or attenuation of the material. The attenuation consists of reflection, scattering, and absorption of light by the material. The magnitudes of these quantities depend on the wavelength of light in operation. Since the optical material is made of molecules such as silica dioxide (SiO_2) in glass and CH_4 in PMMA polymer, these molecules can be regarded as spheres with certain diameters. If the wavelength of light is smaller than these diameters, it will see the molecules as spheres and when it impinges onto the sphere, it will be scattered into directions

other than the original direction of propagation. This kind of loss is called *scattering loss* and is typically described by Rayleigh's law of scattering:

$$L_{\text{scattering}} = \frac{K}{\lambda^4} \tag{1}$$

where K is a constant dependent on the diameter of the sphere and λ is the wavelength of light. Thus, we can see that as the wavelength shortens, the scattering loss increases dramatically. Of course, if the wavelength of light is greater than the diameter of the sphere, the propagating light will not see individual spheres in the optical material. In this case, the Rayleigh type scattering will be zero. However, if the material is not homogeneous, the resulting nonuniformity will also cause scattering if its period of variation is smaller than the wavelength of light.

Now, the reflection of light at the surface of the optical material also depends on its smoothness. The simplest relation describing the reflection is the reflectance defined as the ratio of the optical power reflected by the surface and the optical power incident to the surface. Mathematically it is defined as

$$R = \left(\frac{n-1}{n+1}\right)^2 \tag{2}$$

This formula assumes that the interface is formed between air and the optical material with refractive index n. It is also assumed that light enters the interface perpendicularly. In fact, if light enters at an angle, the reflectance can be calculated by means of a complicated formula normally found in textbooks of optics such as Hardy and Perrin (1932).

As light passes through the optical material, it is not only scattered but can also be absorbed by the material. The absorption can be divided into two parts: the ultraviolet absorption and the infrared absorption. For ease of explanation, let us consider the absorption of a pure silica (quartz). It is made up of molecules of SiO_2. The Si atom can oscillate at several wavelengths, that is, its resonant wavelengths. Two of them are particularly important to the absorption loss of glass, that is, 0.068 and 0.116 μm. Light with these wavelengths entering into the glass will be completely absorbed to give rise to the oscillations of the Si atoms. Not only so, light with wavelengths close to the resonances will also be absorbed although the intensity of absorption decreases as the difference between them increases. The wavelength range of visible light varies from 0.4 to 0.8 μm. Thus, the influence of the Si atom resonant absorption is significant. This is called *ultraviolet absorption*. On the other hand, the molecule SiO_2 also has several resonant wavelengths. An important one is at 9 μm. It also has harmonics at 4.5 and 2.25 μm and so on. Its long absorption tail extends well into the visible wavelength range causing extra losses. This is called *infrared absorption*.

Roughly speaking, the absorption spectrum of an optical material can be represented by a V-curve as shown in Figure 1.

The left arm of the V represents ultraviolet absorption and the right arm of the V represents infrared absorption. The apex of the V therefore represents the minimum absorption loss and the wavelength at which this occurs. For silica glass, this minimum is 0.15 dB km^{-1} at 1.55 μm. It forms the basic material for communication-type optical fiber. Figure 1 also shows that fluoride glass has a much lower absorption loss of 0.01 dB km^{-1} at 2.7 μm, while the KCl glass has a still lower loss of absorption at 0.001 at 4.7 μm. However, these glasses tend to absorb water and are not strong mechanically.

Figure 2 shows the transmittance of several infrared transmitting glasses.

Another important property of optical material is the wavelength dependence of its refractive index. The

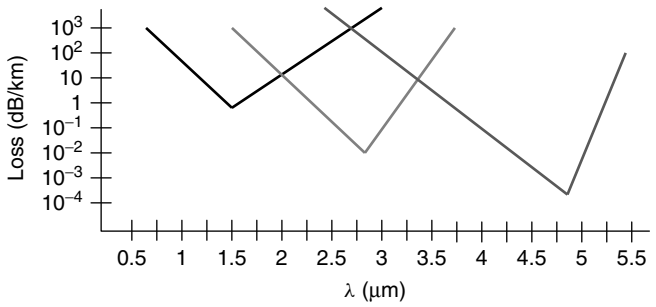

Figure 1. Absorption spectra of SiO_2, fluoride, and KCl glasses.

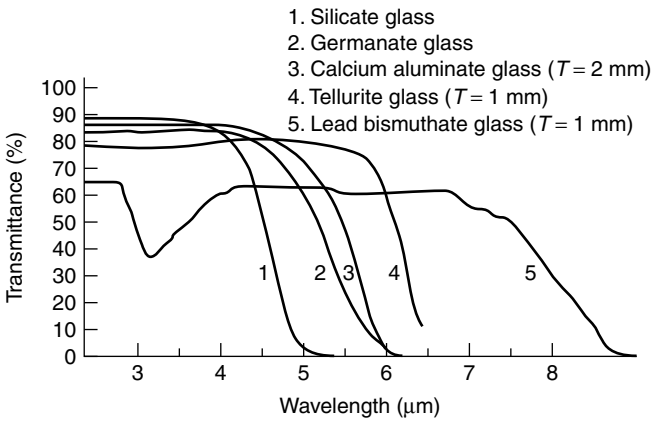

Figure 2. Transmittance spectra of infrared glasses. (Reproduced by permission of Marcel Dekker.)

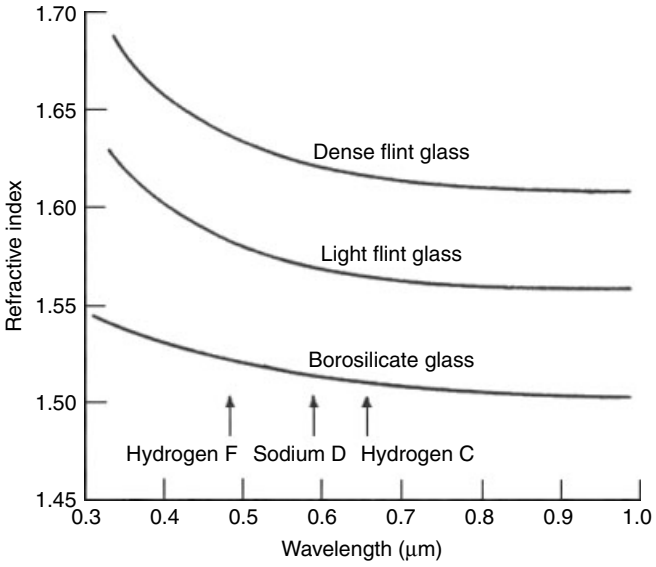

Figure 3. Refractive index spectra of common glasses. (Reproduced by permission of Marcel Dekker.)

dispersion of the material is defined as the rate of change of its refractive index as a function of the change of wavelength, mathematically,

$$(dispersion)_{\lambda} = \left(\frac{\mathrm{d}n}{\mathrm{d}\lambda}\right) \tag{3}$$

Because of the dispersion, a white light passing through a block of glass will spread into many colorful beams. In fact, this is a serious problem in optical fiber because the dispersion reduces the information carrying capacity of the fiber. Figure 3 shows the refractive index spectrum of several common glasses.

1 REFRACTING ELEMENTS

According to the ray concept, a beam of light travels in rectilinear path inside any homogeneous medium. The optical elements interposed in the light path cause a change in the course of the original path by means of

- refraction
- reflection
- diffraction.

On the above basis, the optical elements that can be regarded as the building blocks of any optical system can be broadly considered under three categories:

- refracting elements
- reflecting elements
- diffraction gratings.

Many other miscellaneous optical elements, for example, graticules, filters, fiber-optic elements, polarization components, and optical modulators, are also employed for varied purposes in the optical system design.

This article deals with basic understanding of the function of the various types of basic optical elements.

Refracting elements are made up of an optically transparent homogeneous medium bounded by two or more surfaces. When a ray of light crosses from one medium to another, the path of propagation of the ray is altered in accordance with the well-known Snell's law, which essentially forms the fundamental basis for developing designs of the varied types of refracting elements.

The lens and the prism are two basic types of refractors.

1.1 The lens

The purpose of a lens is to form an image of an object, that is, a lens is essentially an image-forming element. The image may be

- real
- virtual
- formed at infinity.

A lens that forms a real image is called a *positive lens*; similarly, a virtual image–forming lens is called a *negative lens*.

When a lens forms the image at infinity, it is called a *collimating lens* since it transmits a parallel beam after refraction.

A single lens element is characterized by its two radii of curvature, axial thickness, diameter, and type of glass.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

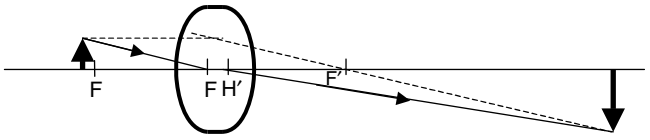

Figure 1. Lens definitions.

The line joining the two centers of curvature is called the *optical axis* of the lens.

Associated with each lens are three pairs of points called *cardinal points*, which are of immense value in analyzing its behavior. These are the

- focal point
- principal point
- nodal points.

When an incident parallel beam of light traverses through a lens, it either converges to an axial point (in case of positive a lens) or appears to be diverging from a point (in case of negative a lens).

This situation can be modeled both for a bundle of rays traveling from left to right, or vice versa (Figure 1). These convergence points of parallel incident rays are called *focal points* F and F′. The planes perpendicular to the optical axis passing through the first and second focal points are known as the *first* and *second focal planes* respectively. Obviously, rays passing through focal points become parallel to the optical axis after refraction. The surface generated by the locus of the point of intersection of the incident and refracted rays is known as the *principal plane*. Like focal planes, there are two principal planes, and their axial intersection points are designated as first and second principal points H and H′.

The effective focal length f (or simply focal length) is defined as the distance from the focal point to the corresponding principal point, while the distance from nearest lens surface to the focal point is called the *back focal length*. Nodal planes are a pair of conjugate planes corresponding to unit angular magnification. Nodal points are the axial intersection points of these planes. Nodal planes coincide with the corresponding principal planes when the lens is immersed in air.

1.2 The prism

A prism is essentially a non–image-forming optical element used for two main purposes, namely, to deviate the light path to any desired direction and to create wavelength dispersion of incident light into its constituent colors.

The incidence angle corresponding to which the refraction angle becomes 90° is termed the *critical angle*, I_c.

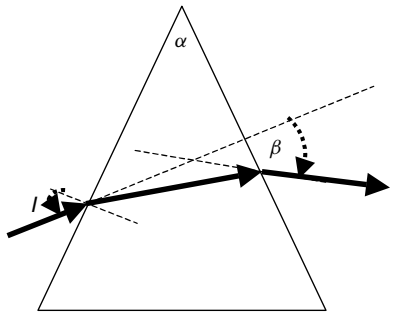

Figure 2. Ray deviation in prism.

From Snell's law, it follows that

$$I_c = \sin^{-1}\left(\frac{N'}{N}\right) \tag{1}$$

where N and N' are the refractive indices of the incident and refracting media respectively. This equation forms the basis of design of many deviating prisms.

The angular deviation β suffered by a ray traversing through a prism (Figure 2) immersed in air, with vertex angle α, can be shown to be given by

$$\beta = I - \alpha + \sin^{-1}[(N'^2 - \sin^2 I)^{1/2}\sin\alpha - \cos\alpha \sin I] \tag{2}$$

where I is the incident angle and N' is the refractive index of the prism material.

In the minimum deviation position ($\beta = \beta_m$),

$$N' = \frac{\sin\left[\frac{1}{2}(\alpha + \beta_m)\right]}{\sin(\alpha/2)} \tag{3}$$

which is a very suitable equation for refractive index measurement.

As the refractive index corresponding to each color (wavelength) is different, the deviation suffered by each of them is different; this causes wavelength dispersion of the incident beam into the constituent colors after refraction. The resolving power of a prism is a measure of its capability for separating adjacent spectral colors.

For erection of an inverted image without angular deviation, the prisms commonly used are Leman, Goerz, Hensolt, Porro types 1 and 2, and Abbe (or Konig). The Abbe prism does not cause lateral displacement. The Schmidt prism erects an inverted image and deviates it by 135° (or 45°). Penta and Amici prisms cause a 90° deviation. A special feature of the penta prism is that the transmitted beam remains stationary even when the prism is turned. Hence, it is also called an *optical square*. A Dove prism inverts without deviation, and on rotation the transmitted image rotates synchronously.

The actual configurations of the various types of prisms can be seen in standard textbooks such as Ahmad (1996),

Jacobs (1943), Levi (1968), Smith (1966), Smith (1978), Smith (2000), Hobbs (2000), and Weber (2002).

In this field, much of the detail was defined a considerable time ago. At that time, more detail was often published than what is easily available today. For this reason, older titles often contain useful information not available elsewhere.

2 REFLECTING ELEMENTS

Reflectors are those elements that reflect back the incident ray in the original medium; they are called *mirrors* or *reflectors*. A mirror may be flat, concave, or convex. Concave and convex mirrors act like positive and negative lenses respectively regarding their imaging properties.

In many specialized applications, particularly in astronomical telescopes, reflector elements of parabolic, elliptical, or hyperbolic shape are used. Parabolic mirrors are also extensively employed in lighthouse and other projection systems.

Beam splitters, which permit only a specified fraction of the incident light to pass through and maintain a known definite intensity ratio between the reflected and transmitted beams, can also be considered as a class of reflectors.

Hot, cold, partial, pellicle, and multilayer dielectric metal mirrors are some other useful reflecting components employed in optical system design.

3 GRATINGS AND FILTERS

Diffraction gratings essentially consist of a large number of closely spaced, equidistant, lines or rulings formed on plane or concave optical surfaces like a prism or filter; it causes spectral separation of the incident light beam.

The efficiency of a grating is determined by the amount of energy diffracted in any desired direction. This is enhanced by control of the groove shape. Sawtooth groove patterns of different step angle enable light concentration in the preferred direction (called *blazing*).

Linear gratings with straight apertures are traditionally produced by mechanically ruling precise parallel grooves, with a diamond tool, on a suitably worked blank. They can then be replicated from a master ruled grating by molding methods using plastics. These may be of transmitting, or reflecting type.

Concave reflection gratings are frequently used for efficient spectral separation. Spectroscopic grade gratings carry extremely fine grooves (of the order of 400 lines per millimeter).

The resolving power of a grating, that is, its ability to separate adjacent spectra, is given by the relationship mN, where m is the order of diffraction and N is the total number of lines.

In recent years, holographic gratings have also become commercially available. Their development greatly extended grating applications and performance.

Another form of manufacture has been developed – the holographic grating. Holographic gratings are produced by recording the optical interference patterns created between two parallel laser beams obliquely set relative to each other. Relative obliquity of the interfering beams enables control of line density. Compared with the ruled grating the holographic grating remains free from periodic error.

With proper choice of the recording medium, blazed holographic gratings can also be made. Other advantages of holographic gratings include a greater number of grooves being possible, up to 6000 grooves per millimeter; large dimension, up to 400-mm diameter; no ghosting; very low level of stray light; recording being possible on concave, toroidal, and aspheric blanks; and a possibility existing for making aberration correction.

A grating formed with concentric circular grooves (or obstructions) is called a *Fresnel zone plate*. It has the property of a lens but with several focal lengths for the various wavelength components.

Metrological gratings, used to determine length, carry identical opening and obstruction widths and are usually much coarser (tens of lines per millimeter). The constructional details of a versatile, low-cost, radial pattern-generating engine suitable for the manufacture of medium accuracy masters of metrological patterns as scales, line gratings, absolute multitrack encoder disks, spirals, circles, zone plates, and variable density and variable width circular tracks has been reported (Jain and Sydenham, 1980).

The Fiber Bragg grating is an important optical signal processing component. It finds applications in optical communications and in optical sensing. In this grating, the refractive index of the fiber core experiences a periodic variation with a period Λ. Any light with a wavelength λ satisfying the following relationship

$$\lambda = 2N\Lambda \tag{4}$$

will be reflected by the grating, where N is the average refractive index of the fiber core. The reflectivity increases with the index variation and length of grating. A reflectivity close to 100% can readily be obtained in single-mode optical fibers. The creation of this grating depends on the photosensitivity of the glass making up the core of the fiber. Boron- or phosphorus-doped germanosilicate glass is normally photosensitive, whereas a simple germanosilicate glass is not. However, the latter can be made photosensitive when hydrogen is introduced into it. To create the grating,

a phase mask with rulings of period Λ is placed close to the fiber and the mask is illuminated by an optical beam of appropriate wavelength at which the core glass of the fiber is photosensitive.

3.1 Graticules

Graticules are fine measuring scales or well-defined patterns placed in the focal plane of an optical instrument. These are employed for determining size, distance, direction, position, or any other attribute of the object that is viewed coincident with them. Graticules are also often denoted by terms such as diaphragm and web or in accordance with their use, examples being sighting scales, cross-lines, (optical) micrometers, and stage micrometers.

Since a graticule is usually required to be viewed in the instrument under high magnification, tolerance requirements in the manufacture of graticule blanks are generally very severe. For example, scratch width and dig or pit diameter should not exceed 0.01 and 0.05 mm respectively; surface accuracy should be within two fringes and sphericity should be within 0.5 of a ring; thickness should be within 0.05 mm; and decentration should not exceed 0.5 to 1 min (Prasad and Singh, 1970).

Graticules are made by several different techniques, namely, ruling and etching, ruling followed by vacuum deposition of chromium or kanthal, photographic processes, and photo etching. Details of the procedures followed in graticule manufacture and compositions of some photoresists suitable for this work are given elsewhere (Horne, 1974).

Health and safety regulations now prohibit the use of many traditional photoresists, so it is important to keep up with the latest information.

3.2 Filters

Filters types fit into the three broad categories:

- absorption or color filters
- interference filters
- spatial filters.

Absorption filters derive their performance from bulk interaction between light and the filter media; the transmission generally being a smoothly decreasing function of thickness. Such filters are made in a variety of base materials: gelatin, glass, and plastic are commonly used.

Selective color transmission is obtained primarily by ionic absorption or by selective scattering. Gelatin filters are low in cost and provide a wide color choice. Glass filters are widely used in photography and colorimetry and also in the production of interference filters for blocking extraneous passbands. Plastic filters are available both in sharp-cutoff and intermediate bandwidth types.

Thin film interference filters operate in the same manner as a Fabry–Perot interferometer. These are usually designed for normal incidence but may be constructed for specific nonnormal applications. Nonnormal incidence results in a shift of the passband towards shorter wavelengths. Two basic types of interference filters are available – metal-dielectric and all-dielectric. These are manufactured by thin-film, vacuum deposition techniques using special manufacturing plant. The experimental techniques adopted are described in Horne (1974), Macleod (1969), Smith (2000), and Weber (2002).

Under spatial filters are included components, which, in a functional sense, are used to modify the spatial characteristics of the incident light. A typical example is the fine pinhole (about 5–10 μm in diameter) used in a Fourier system for filtering out the unwanted portion of diffraction caused by the circular aperture of the microscope objective lens when used in a laser beam.

4 OPTICAL FIBERS

Fiber-optic methods are based on the ability of thin smooth strands of transparent materials to convey incident signal by the total internal reflection process, without interference from neighboring fibers. It is achieved by drawing thin (of the order of 10–100 μm), coated optical fibers having a core and cladding made of different refractive index materials.

Fiber-optic elements can broadly be grouped into two types, noncoherent and coherent. Noncoherent fiber bundles consisting of thousands of thin fibers not arranged in any order are used for transporting light and are often called *light guides* or *light cables*. In coherent fiber bundles, the fibers at the end faces are arranged in the same manner so that optical image can be transmitted without suffering distortion. The fiber bundles are usually made of fibers with relatively high loss. Hence the length of each bundle is about 1 m.

The flexible coherent fiber bundle is the basic component of many endoscopic medical and industrial inspection instruments used in remote examination of internal cavities. The rigid form of a coherent fiber bundle, for example, a faceplate, is the essential component of image intensifiers, enabling high optical efficiency in image transfer. These components have also been used as windows of cathode-ray tubes built for direct recording of high-speed computer printout or other data recording.

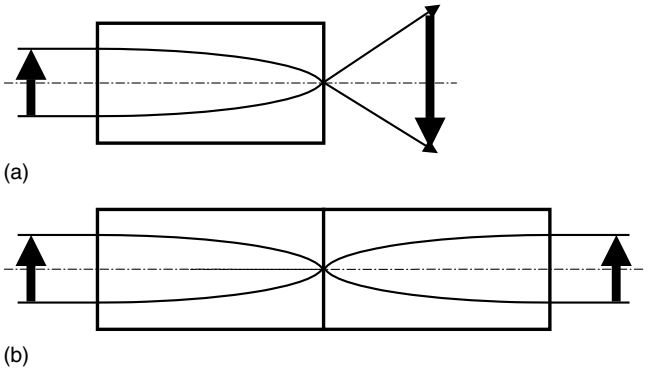

Figure 3. Grin Lens (a) Quarter Pitch Grin Lens, (b) Half Pitch Grin Lens.

Low loss (attenuation approaching $0.2\,\mathrm{dB\,km^{-1}}$ at a wavelength of 1550 nm) single-mode fibers, for use in optical communication, have also been developed.

Another fiber-optic component is the *gradient index lens*, also called *grin lens* (Figure 3). It is essentially a short length of graded index fiber (about 5–10-mm long) with large core diameter (between 1 and 2 mm). The imaging properties of this lens depend on its length. A quarter pitch lens forms an inverted, real, and magnified image of an object at infinity on the opposite end of the lens. A half pitch lens simply inverts the image of an object from one end face to another without magnification.

5 POLARIZERS

Polarizers are used for the production, control, and analysis of light in special polarization states. Their operation depends on the properties of birefringence (double refraction), dichroism (a special case of birefringence), and change in polarization characteristics upon reflection (at, and near, Brewster's angle).

Retardation plates (quarter, half, and full wave), the Savart polariscope, Soleil–Babinet compensator, dichroic polarizers (sheet type), laser-polarizing beam splitters, and Cornu depolarizer are some of the important components.

6 MODULATORS

In communication, display, data recording, and measurement, it is often desirable to control the amplitude, phase, frequency, and state of polarization of the light beam. Optical modulators are the devices variously used for these purposes. They are generally based on basic electro-optic (Pockels, Kerr), magneto-optic (Faraday, Cotton–Mouton) or acousto-optic (Debye–Sears, Raman–Nath) effects.

With the advent of the laser source of radiation, optical modulators have assumed much importance (Hartfield and Thompson, 1978). Table 1 gives some basic information about the various types of optical modulators. A popular high-speed optical modulator that finds application in optical fiber communication is the electro-absorption modulator. It is a reversed biased pn junction similar to a photodetector. Light impinging onto the junction is absorbed and the absorption varies in accordance with the bias voltage. Hence the modulating signal is the electric bias voltage and the light leaving the device is intensity modulated. An electro-absorption modulator is rarely used freestanding because of the high loss associated with the device. Instead, it is part of an integrated optical transmitter, that is, a semiconductor laser and the modulator are built together on the same chip, with the output of the laser being fed directly into the modulator. In this configuration, the additional loss caused by the modulator is only of the order of 1 dB or so.

Table 1. Types of optical modulators.

Type	Principle	Typical materials	Typical applications
Electro-optic	Induced birefringence on application of external electric field	ADP, KDP, $LiNbO_3$, ADA	Amplitude, phase, frequency and polarization modulation, high-speed shutter, laser Q-switching, mode locking, cavity dumping
Magneto-optic	Induced optical activity on application of external magnetic field	Fused silica, dense glasses, H_2O, CS_2, P	Deflection, scanning, spatial modulation, information processing
Acousto-optic	Diffraction and scattering of light waves by sound	Fused silica, GaAs, YAG, YIG, TiO_2	Scanning, optical delay line, heterodyning
Mechanical	Chopping of light beam by rotating sector disc	–	Signaling, IR detection
Electro-absorption	Light absorption in going through a reversed biased pn junction depends on biasing voltage	Semiconductor material such as InGaAsP/InP, dependent on the operating wavelength	High-speed optical communication systems

7 OPTICAL GEOMETRIC ELEMENT DESIGN

In geometrical optics, diffraction effects are neglected and the ray aspect of light is considered. Cophasal surfaces orthogonal to a set of rays are defined as geometrical wavefronts (or simply wavefronts).

An ideal lens produces an image exactly alike the object. However, an ideal lens is only a theoretical postulate since, in reality, there are certain parameters inherent in the refraction process that cause aberrations and deviate the image structure from its ideal shape. The purpose of optical system design is to work out technical specifications of each of its constituent elements, tailoring the geometry such that the entire system gives an adequately aberration-free acceptable image.

7.1 Aberrations

There are five monochromatic and two chromatic aberrations. Spherical aberration, coma, astigmatism, petzval curvature, and distortion fall in the first category, with longitudinal and lateral (or transverse) chromatic aberrations forming the second.

Spherical aberration arises due to the fact that rays originating from an axial object point and intersecting the refracting surface at different heights do not meet at a single point after refraction. In other words, the paraxial focus is different from the marginal focus; the axial distance between them is called *longitudinal spherical aberration* ($\Delta l'$).

When rays from an off-axial object point pass through the lens, the paraxial and marginal bundles again have different foci. A comet-like flare is then seen in the image plane, which is generated by the partial overlapping of circular light patches of increasing diameter. This off-axial aberration is called *coma*. It causes asymmetry in the image.

Astigmatism occurs because rays from an off-axial object point lying in the meridional and sagittal planes focus at different points. The distance between these two foci is called *astigmatism*.

An image of a straight object perpendicular to the optical axis is formed on a curved surface instead of a plane. This is due to petzval curvature.

Owing to unequal lateral magnification throughout the field, the appearance of an image changes from the original object; this occurs even when the above aberrations are not present. Pincushion distortion means that the outer zones are more magnified compared to the inner; the reverse manifestation is called *barrel distortion*.

Any incident polychromatic beam suffers dispersion due to the wavelength dispersive nature of the material of the refracting element. Thus, with incident white light, a point object has different image locations for its different colors. The axial and transverse distances between the violet and red foci are called *longitudinal* and *lateral chromatic aberration* respectively. General accounts of lens types and aberrations are available in Levi (1968) and Smith (2000).

7.2 Elements of lens design

It is possible to reduce aberrations of an optical system by choosing suitable combinations of two or more lens elements. Consistent with the stipulated focal length, f number, image definition, and other requirements, the selection of proper lens combination, their glass types, radii of curvature, thickness, axial separation, and stop specifications falls within the purview of lens design. Detailed analyses of lens design are available in several standard treatises (Buchdahl, 1954; Conrady, 1957, 1960; Cox, 1964). The relationship between ray and wavefront aberrations and their evaluation has been extensively covered in Hopkins (1950). Zoom lens are covered in Clark (1973). Today, much of this foundational theory is embodied into lens and optical system design tools.

The analysis of an optical system requires tracing a large number of rays through it and consequently determining the residual aberrations, which become the basis for further refinement. Depending upon the computational technique adopted, several ray tracing schemes have been developed, Smith (1966) being an example.

Ray tracing schemes require numerous calculations, of simple nature, the whole process being very time consuming and tedious by traditional methods. Electronic computation has been applied to this with great effect.

In either case, considerable experience is required to design even a simple corrected lens system. For this reason, an instrument designer would normally call upon the services of a lens designer or make use of commercially available proprietary lens systems when lens design is a critical feature of the whole system.

7.3 Stop and pupil

To control the illumination and field coverage, certain diaphragms are used in optical systems. An aperture stop determines the maximum cone of light that passes through the system; its location has a marked influence upon off-axial aberrations of the system, though spherical aberration and longitudinal chromatic aberration remain independent. A field stop is the diaphragm used to control the image size.

Entrance and exit pupils are defined as the images of the aperture stop formed by the elements placed on the left and right of the stop respectively. The ratio of the pupil diameters represents system magnification.

7.4 Field angle

Field angle is defined as the angle subtended by the object at the entrance pupil; it specifies the maximum object size that can be imaged by the system. As the field angle increases, the effects due to off-axial aberrations become more pronounced, with consequent increased difficulties in the design process.

7.5 Effects of non–image-forming elements

Non–image-forming elements, such as plane parallel plates and prisms, also introduce aberrations when placed in non-collimated light beam. Such elements are often employed as a corrector for compensation of residual aberrations of the system. In Prasad, Mitra and Jain (1975), the aberrations produced by a single plane parallel plate immersed in air and inclined at an angle with the vertical are discussed. They provide equations for calculating the lateral displacement, tangential coma, and astigmatism of the system.

A parallel plate can also be used to convert large angular displacements into small translational equivalents that can be used on a position sensitive photodetector to sense movement. This has been used in metrology (Sydenham, 1969).

7.6 Performance analysis

Performance of the system can be expressed in terms of residual aberration characteristic curves corresponding to different field angles or in terms of a spot diagram depicting the image plane intersection points of several rays passing through various zones of the system. The resolving power test is based on Rayleigh's criterion of resolution; the Strehl intensity ratio and, as is discussed later, the optical transfer function (OTF) technique are other methods of image quality assessment.

7.7 Optical modules

Illustrations of configurations of often met optical systems are given in Figure 4. Their design clearly becomes progressively more complex as the number of elements rises. Zoom lenses, for instance, were only made economic by the advent of electronic computer methods of design.

8 INTERFEROMETRY

Interferometric measurements serve as a very powerful measuring tool yielding a high degree of precision (within fractions of a wavelength of the radiation used).

Under suitable conditions, two light beams interfere with each other, producing a resultant pattern consisting of alternate bright and dark bands (or fringes). Shape and location of these bands depends upon the difference in total optical paths traveled by the two interfering beams. Accordingly, length and phase variables may be measured directly in an interferometer, while refractive index, displacement, velocity, and more can be evaluated by converting them into corresponding optical path difference OPD.

In the following, we first outline the fundamentals of interferometry, followed by a brief description of common types of interferometers.

8.1 Conditions of coherent radiation interference

Consider two light waves A_1 and A_2 of the same angular frequency ω, given by

$$A_1 = a_1 \sin(\omega t + \phi_1) \tag{5}$$

$$A_2 = a_2 \sin(\omega t + \phi_2) \tag{6}$$

where a_1, ϕ_1 and a_2, ϕ_2 are the corresponding amplitude and phase respectively, at any instant of time t.

Straightforward mathematical analysis shows that superimposition of A_1 and A_2 produces a resultant amplitude A given by

$$A = a \sin(\omega t + \theta) \tag{7}$$

where

$$a = [a_1^2 + a_2^2 + 2a_1 a_2 \cos(\phi_1 - \phi_2)]^{1/2}$$

and

$$\theta = \tan^{-1}\left[\frac{a_1 \sin\phi_1 + a_2 \sin\phi_2}{a_1 \cos\phi_1 + a_2 \cos\phi_2}\right] \tag{8}$$

From this, it can be seen that the resultant intensity pattern is maximum ($I_{\max}$) or minimum ($I_{\min}$), when $\phi_1 - \phi_2 = 2n\pi$ or $(2n+1)\pi$ respectively, where n is zero or an integer.

Fringe visibility (or contrast) is defined as $(I_{\max} - I_{\min})/(I_{\max} + I_{\min})$. For best visibility (or contrast), a_1 and a_2 should be equal or nearly equal.

Summarizing the conditions of interference,

1. the two interfering beams must be of the same wavelength monochromaticity;

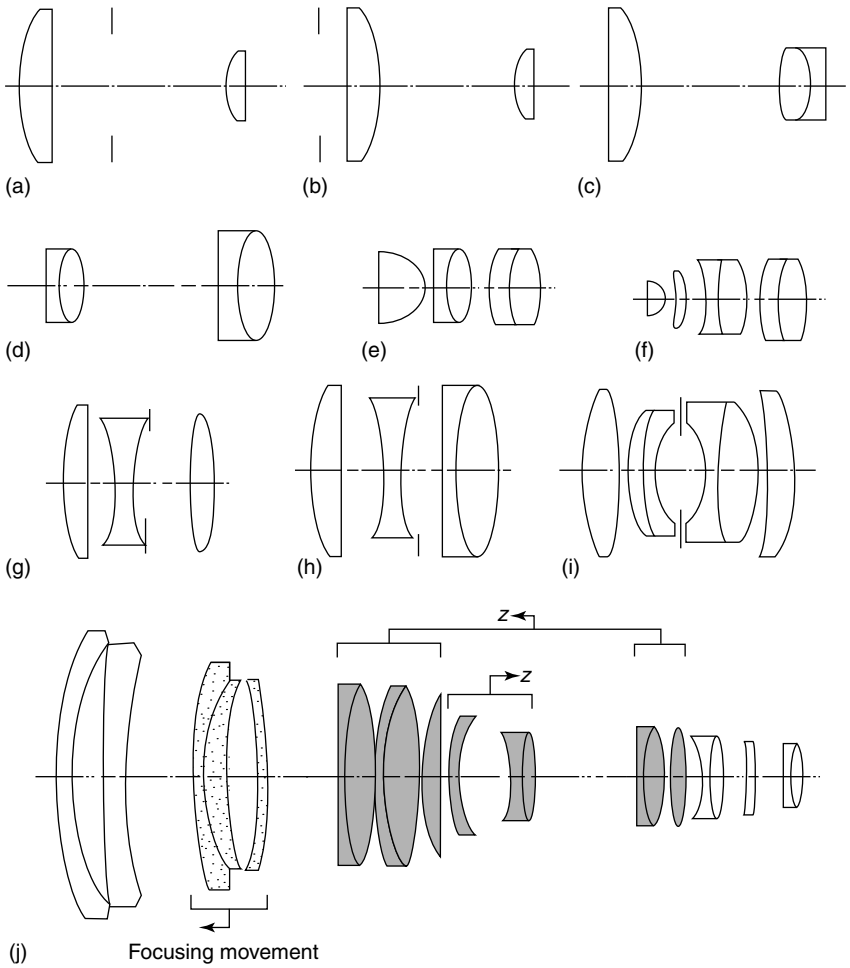

Figure 4. Configuration of some optical systems: (a) Huygen eyepiece; (b) Ramsden eyepiece; (c) Kellner eyepiece; (d) Lister-type microobjective; (e) Amici-type microobjective; (f) oil-immersion microobjective; (g) Cooke triplet; (h) Tessar lens; (i) double Gauss; (j) zoom television lens-Taylor Hobson (Clark, 1973). (Reproduced from *Zoom Lenses*, Clark A.D., Copyright (1983) © Adam Hilger.)

2. the phase difference between them must remain closely constant over the period of observation (otherwise, the fringe pattern would dance around, causing a blurred patch – the coherence condition); and
3. the state or plane of electromagnetic vibrations in both beams must be the same Fresnel–Arago law.

To satisfy the above conditions, light sources used in interferometry generally have a high degree of monochromaticity and are highly coherent so that a large path difference can still produce a meaningful interference pattern. The so-called coherence length is a measure of how long the beam length difference can be to retain coherence.

Further, all interferometers, to a greater or lesser degree, remain sensitive to stray mechanical vibrations. Adequate precautions are needed during their installation to minimize these effects. This makes use in severe vibration conditions difficult.

The principle of interferometry is used in many measuring instruments. Such use is discussed in Dyson (1970), Ahmad (1996), and Smith (2000)

8.2 Michelson interferometer

The Michelson interferometer (Figure 5) is used for the measurement of wavelength of light, slow air drift, calibration of a standard length, and other scientific applications.

Light from an extended source S (white light or monochromatic) is divided into two paths by a beam splitter B (Figure 5). The end mirrors M_1, M_2 reflect back the respective coherent beams 1, 2, which recombine to form fringes in the viewing telescope T. In one of the arms, a glass plate P identical in construction to the beam splitter is introduced to compensate for the inequality of glass path traversed by the interfering beams. In practice, corner-cubes

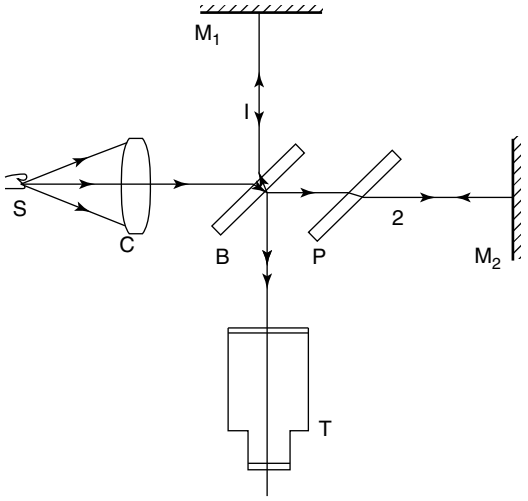

Figure 5. Michelson interferometer: S, source; C, collimating lens; B, beam splitter; P, compensator; M_1, M_2, mirrors; T, telescope.

can be used instead of flat mirrors; this makes adjustment considerably easier.

The Twyman–Green interferometer is a versatile instrument that is particularly suited to optical shop-floor applications. It is similar in construction to the Michelson interferometer. Here, the incident light is formed as a well-collimated monochromatic beam and the compensator plate is dispensed with. The optical job under test is placed in one arm of the interferometer, while the other arm provides the reference beam. In cases of a lens, prism, and the like, the beam passes twice through the test piece; hence the fringe pattern depicts twice the amount of total error, which is inclusive of surface defects, material inhomogeneities, and aberrations.

The invention of the laser source enabled development of an unequal path Twyman–Green interferometer of different geometry that is suitable for testing large optics in a production line.

8.3 Fizeau interferometer

A Fizeau interferometer is suitable for qualitative as well as quantitative assessment of surface quality. In its classical form, it is used (Figure 6) for flat surface testing. A collimator C sends a parallel beam of light from source S onto the test surface T. A good quality plane parallel glass plate F, whose lower surface is of a high degree of flatness (master surface), is placed over the test piece with an air gap. The collimator focuses the return beams onto the observation point O that is suitably located using a beam splitter B. The interference pattern is formed between the rays reflected from the master and test surfaces. Departure

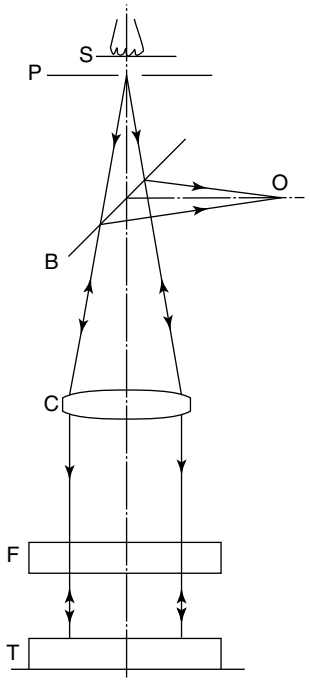

Figure 6. Fizeau interferometer: S, source; P, pinhole; B, beam splitter; C, collimating lens; F, master surface; T, test surface; O, observation point.

of linearity of the fringes expresses the surface error in terms of fractional fringe width (each fringe corresponds to $\lambda/2$ departure).

Numerous modifications of this classical instrument exist. Concave and convex surfaces are tested in a diverging and converging beam respectively, the master flat then being replaced by the complementary master surface. Using a laser source, a spherical surface may be tested against a master optically flat surface. In this interferometer, a converging beam is focused at the center of curvature of the test surface. Another set of fringes is obtained when the beam is focused at the vertex of the test surface, and as such, the radius of curvature can also be measured.

8.4 Rayleigh interferometer

The Rayleigh interferometer is a very useful instrument for the measurement of the refractive indices of gases and liquids and for the control of their composition. Light from a slit source is collimated and made to fall upon two tubes placed side by side, one containing the sample under test and the other a standard sample. Fringes are viewed through a focusing lens and a magnifier. Fringe displacement is measured by tilting a compensator plate placed in the light path passing through one of the tubes. White light sources may be used enabling easy measurement of the fringe displacement.

The Michelson stellar interferometer employs two widely separated slits whose interdistance can be varied. Each slit selects different parts of the wavefront. From the change in visibility of the fringes seen through the telescope, a stellar diameter can be evaluated.

8.5 Jamin interferometer

Used in refractometry, a Jamin interferometer has a thick plate that splits the incident beam into two using reflections at the front and back surfaces. An identical plate recombines the beam. The Mach–Zehnder interferometer is a modification of this. Using beam splitters for beam division and recombination, the separation between the interfering beams is made large. It is extensively used in hydrodynamic measurements.

8.6 Point-diffraction interferometer

Generation of an aberration-free reference wavefront without using high quality optics is achieved in a point-diffraction interferometer (Smartt and Strong, 1972). A pinhole on a transparent substrate is located slightly off-axis at the focal plane of the lens system under test. Diffracted wavefronts from the pinhole produce reference wavefronts. An absorption coating is placed over the pinhole substrate to enable matching of the intensities of the interfering beams.

8.7 Scatter fringe interferometer

Large concave mirrors, as used in astronomical telescopes, are effectively tested in a scatter fringe interferometer. A scatter plate placed perpendicular to the optical axis passing through the center of curvature of test surface splits a converging beam into two components. The specularly transmitted beam, after reflection through a small segment of the mirror, serves as the reference beam, while the scattered component fills the whole test surface and is the test beam. A semireflecting mirror is interposed to superimpose both the beams onto another scatter plate (identical to the first one). The instrument is comparatively less sensitive to vibrations since the interfering beams are closely confined to each other.

8.8 Shearing interferometer

In a shearing interferometer, the test beam is split into two beams, which are compared against each other, thereby doing away with any reference beam, as is needed in comparison-type interferometers. When superimposed, the beams are laterally, rotationally, or radially sheared relative to each other so that different parts of the two identical wavefronts interfere. There exist several techniques for achieving the desired shear. Figure 7 gives simple examples. By employing birefringent crystal elements, such as the Wollaston prism or Savart polariscope, shear is readily obtained. This type is generally called a *polarizing interferometer*.

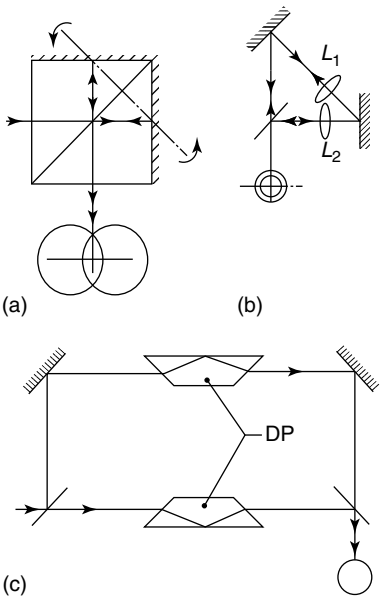

Figure 7. Shearing techniques: (a) lateral shear; (b) radial shear; (c) rotational shear produced by counterrotating Dove prisms (DP).

A shearing interferometer is less sensitive to vibrations (relative to Twyman–Green interferometer) and is suitable for testing a lens, wedge angle, homogeneity of transparent samples, optical flatness, and the optical transfer function.

8.9 Multiple-beam interferometer

If the test surface and the inner surface of the master plate of a Fizeau interferometer are partially reflecting, each ray splits into several components. Consequently, a number of beams of varying path length take part in forming a multiple-beam interference pattern, where high finesse fringes are formed. High precision measurement of thin film thickness, surface contour, and separation of neighboring wavelengths are performed in a multiple-beam interferometer.

9 OPTICAL TRANSFER FUNCTION (OTF)

Various criteria exist to express the performance characteristics of a lens system. Measurement of the individual aberrations gives clues to the designer in respect of its

defects. A standard interferogram depicts the phase error across the pupil. The resolving power test indicates the final resolution limit attainable by the system. However, none of these attributes yields a completely objective assessment of the quality and image-forming capabilities of the optical system under test.

The OTF has been used as a merit function that, to a large extent, serves this need, even though it must be appreciated that this technique also is not the final solution to all lens evaluation problems.

9.1 OTF representation

OTF is basically a resolving power test, but unlike the classical resolution test, it expresses the image contrast at different spatial frequencies of a sinusoidal object. It is, in this respect, similar to the time frequency response tests associated with electrical circuits (Coltman (1954); Schade (1964)).

For elucidation of the OTF concept, consider two bright object points separated by a dark space. Theoretically, the image of this object assembly should be two bright points separated by a dark region. In such a situation, the object is said to be well resolved, and both the object and the image possess unity contrast. However, since any real system is afflicted with aberrations and associated diffraction effects, in actual practice, some light would encroach into the dark space, with consequent reduction in image contrast. As the two object points are brought closer, the contrast decreases until it becomes zero; this is taken as the resolution limit.

According to Fourier mathematics, any periodic function can be expressed in the form of a series containing sinusoidal terms.

Upon combining the above two concepts, the OTF can be taken as a functional representation of the image contrast and location corresponding to various spacings of sinusoidally varying objects.

The OTF and the point spread function are interrelated according to Fourier transformation rules, each being transformable into the other, the point spread function being the representation of intensity variations in the image of a point object. Applying Fourier transform rules, it can further be shown that the OTF is the autocorrelation of the pupil function, where the pupil function is the intensity distribution of the lens system at the exit pupil and autocorrelation is a standard mathematical operation (Francon, 1963; O'Neill, 1963).

Mathematically, the OTF can be expressed in the form

$$O(\xi_x, \eta_y) = M(\xi_x, \eta_y) \ \exp\left[-ik\phi(\xi_x, \eta_y)\right] \qquad (9)$$

where $O(\xi_x, \eta_y)$ is the OTF; ξ_x, η_y are frequency coordinates in the image plane; $M(\xi_x, \eta_y)$ is the modulation transfer function (MTF) and $\phi(\xi_x, \eta_y)$ is the phase transfer function (PTF).

The OTF comprises both the MTF and the PTF. The significance of the phase term is that the image does not remain located at the ideal conjugate point but is displaced by the amount given by the PTF.

The above equation further reveals that for complete evaluation of system performance, both the MTF and PTF are required. However, it has been seen that for a moderate range of object frequencies, the MTF gives sufficient information of practical interest, and is therefore the quantity that is most commonly evaluated.

9.2 OTF evaluation – scanning methods

This method (Murata, 1966) involves scanning the image intensity distribution of a known object, which may be a sinusoidal grating of variable frequency, square-wave grating, single slit, two square-wave gratings rotating in opposite direction (producing Moiré patterns of varying frequency), or of any other arbitrary shape.

The basic experimental setup is given in Figure 8. When the object O is composed of sinusoidally varying intensity gratings of different frequencies, the response of P remains proportional to the corresponding intensity in the image. The image scan therefore directly provides $I_{\max}$ and $I_{\min}$, and hence the contrast. In the case of square-wave gratings, an intermediate electronic subsystem is introduced, which allows only the fundamental of each frequency to be passed, thus indirectly achieving generation of sine-wave targets.

Since, for good performance, the object contrast at all frequencies must be identical, the actual realization of variable frequency sinusoidal or square-wave gratings is in itself a cumbersome task. Furthermore, in both cases, since the object frequency range is limited with regard to generation of higher frequencies, a relay lens located between O and L must be employed. This introduces its own defects into the final result, and hence, it should have much better corrections compared to those of the test lens.

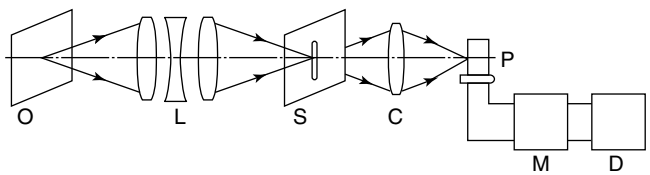

Figure 8. Scanning method of determining OTF: O, object; L, test lens; S, scanning slit; C, condenser; P, photomultiplier tube; M and D, detection and display.

Table 2. Comparison of test objects in OTF evaluation.

Object shape	Advantages	Disadvantages
Sine-wave grating	Direct reading	Difficult to make; limited range of spatial frequencies; intermediate relay lens needed for obtaining higher frequencies
Square-wave grating	Direct reading	Same as in (1). Additional electronic subsystem needed for filtering fundamental of each frequency
Two counter rotating gratings	Rapid direct display	Same as in (2)
Pinhole or single slit	Easy to make; wider range of spatial frequencies	Low light efficiency; computer needed for data conversion; correction factor needed for finite width
Knife-edge	Same as in (4). Also, better light efficiency compared to pinhole or single slit	Computer needed for data conversion; stray light affects the OTF measurement to the largest degree; very low signal to noise ratio at high spatial frequencies

The difficulties are met to the same extent by choosing objects of simple geometry, like a single slit, a pinhole, or a knife-edge, but these have other disadvantages.

Table 2 summarizes the relative advantages and disadvantages of commonly used test objects.

9.3 OTF evaluation – interferometric methods

The desired autocorrelation (or self-convolution) is achieved in lateral shearing interferometers; this provides the basis of an analog technique of OTF measurement (Hopkins, 1955). It is known that if the path difference between the two laterally sheared beams is changed, the total light flux across both of the sheared beams varies sinusoidally. Further, the shear magnitude represents the spatial frequency. Hence, by variation of the shear and measurement of the corresponding contrast, the OTF can be evaluated.

Polarizing type, lateral shear interferometers for OTF measurement have also been developed (Francon, 1966).

9.4 OTF applications

OTF analyzers have been applied with practical advantage in many interesting situations. Examples are as a go/no-go gauge for final checking of optical elements, giving the cumulative effect of residual aberrations, diffraction, and inaccuracies caused during manufacturing processes; providing means of evaluating performance of complex cascaded electro-optical systems; effecting improvement in the quality of optical system at the design stage; and many more.

As an illustration, qualitative representation of MTF curves is made in Figure 9. Curve A is the plot of a diffraction-limited (theoretical best) system; B and C show the effects of adding a central obstruction and of defocusing

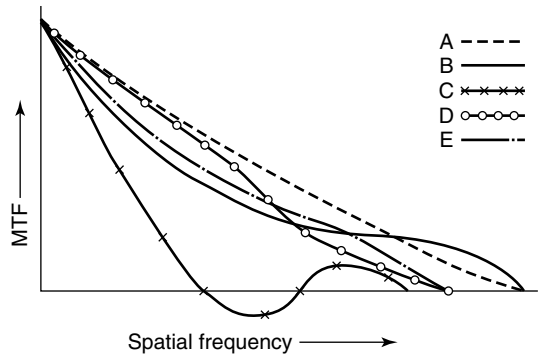

Figure 9. Qualitative representation of MTF curves: A, diffraction-limited system; B, with central obstruction; C, defocusing effect; D, E, different designs of the same optical system.

respectively; and D, E are representations of different practical designs of the same optical system.

It might be noted that while D has better performance at lower spatial frequencies, the quality of E is superior in the high frequency domain. Thus, MTF curves give a reliable quick answer and enable fast selection of a good lens for a particular optical system.

10 HOLOGRAPHY

In the conventional image recording process, the photographic emulsion records the time average square modulus of the complex amplitude function. Hence, the phase information contained in the object wavefront is lost. In 1948, Gabor originated the basic ideas of wavefront reconstruction through which both the phase and amplitude information could be obtained.

It involves two steps. First, a complex interferogram (called a *hologram*), formed by interference between the object and reference wavefronts, is recorded. Second, the hologram is suitably illuminated to reconstruct the original object beam in space.

Holography remained in a dormant stage until the early 1960s when highly coherent (long coherence length) laser sources became available. Considerable improvements in the process were effected. With the laser becoming an integral part of the practice of holography, this subject developed very fast into an active field that has provided new measurement techniques and solutions to a wide range of difficult problems.

10.1 Recording of a hologram

In principle, holography is a kind of lensless photography. The object is illuminated by laser light. The transmitted or scattered object beam is allowed to interfere with a reference beam derived from the same source. A suitably placed photographic plate records the hologram.

Any geometry employed in a comparison-type interferometer, with suitable modification to ensure that the reference beam subtends a certain minimum angle with the object beam at the plane of recording, can be used in making holograms.

The quality of a hologram is influenced by several factors, namely, the various modes present in laser light, diffraction caused by the laser aperture speckles, and stray vibrations. Their effects are minimized to some extent by applying spatial filtering of the incident laser beam using a pinhole placed at the focus of a microscope objective; by properly attenuating the reference wavefront for intensity matching; by mounting the experimental setup on a good vibration isolation table; and by employing high-speed, high-resolution photographic emulsions (nonconventional media are also used) for recording of the hologram.

When the interfering beams fall on the same side of the recording emulsion, a transmission hologram is obtained. To record a reflection hologram, they are introduced from opposite sides of the emulsion, enabling the interference to take place within the depth of the photosensitive layer.

10.2 Wavefront reconstruction

When a transmitting hologram is illuminated by a reference wavefront (spatially filtered as before), the object wavefront and its complex conjugate are reconstructed in space together with two more beams of light travelling near the transparency axis. The latter two beams consist of the directly transmitted reference beam and a beam whose intensity is proportional to the object intensity; these are of little consequence. The object wavefront produces a virtual image of the original object behind the hologram (as seen through it), while the complex conjugate component forms a real image in front. Angular separation between them, and from the axially traveling beams, depends upon the angle between the object and reference beams during recording. The reconstructing beams need not be identical to the recording reference beam. For example, use of a longer wavelength and more divergence give rise to image magnification.

In the case of a reflection hologram, reconstructed wavefronts are obtained on reflection under white light illumination. Holographic images are three dimensional in nature, retaining the parallax effect.

10.3 Applications of holography

The basic concepts of holography were initially introduced to achieve very high magnification in microscopy (Gabor, 1948). Using a shorter wavelength, for example, an electron or X-ray beam, for recording, carrying out reconstruction with a visible radiation wavelength, provides a very high order of magnification in addition to large depth of focus.

Holograms, because of the three-dimensional imaging properties, are used for display and demonstration purposes. Three-dimensional motion and television pictures by holographic principle are potential applications, though yet to be fully developed.

Holographic interferometry utilizes the interference patterns(s) formed by making multiple exposures on the same photographic plate, corresponding to different stages of the object wavefront in a dynamic situation. Vibration analyses have thus been possible by making a continuous exposure of the vibrating object. Instead of photographic plates, the interference patterns can be recorded in a computer, and online monitoring of the vibrating object is now possible. Phase change in the surrounding medium due to the passage of a high velocity missile, thermal gradients of objects, hot spots in electronic integrated circuits, mechanical strain, and particle size distribution are some of the applications of this technique.

The holographic technique has also been applied in the fabrication of diffraction gratings and simulated optical elements and in data storage and information processing.

Standard holographic technique is very sensitive to environmental disturbance, making the measurement difficult. A modified technique called *shearography* (Hung and Durelli, 1979) is robust and free from interference from the surrounding. This technique compares the deformation of one point B in the object with respect to another undeformed point A in the same object (see Figure 10). A coherent optical beam from the light source is split into two beams, one hits the object at B and the other at A. We assume the surface of the object is reflective. The reflected beams

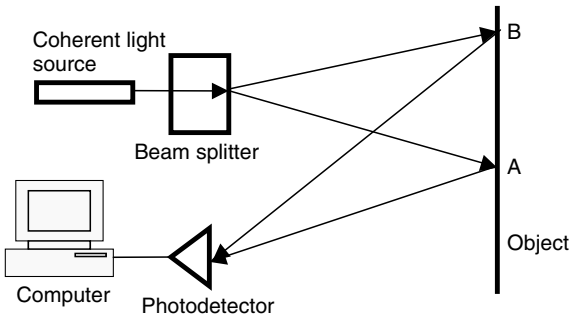

Figure 10. Shearographic setup for monitoring defects.

from A and B fall onto the photodetector, which is a square law detector. Hence, interference fringes are obtained and recorded in the computer. Now, if B undergoes a deformation while A remains unchanged, a new set of interference fringes is obtained and recorded in the computer. The computer then subtracts the two sets of fringes. The result is a set of new fringes due to the deformation at B. Instead of using the computer for signal processing, a photographic film can be used. In this case, the film has to undergo a double exposure before development.

1 LIGHT SOURCES

Light sources may be selected on the basis of several criteria, including:

- power
- spectral range
- wavelength tunability
- duration of emission (continuous, also referred to as CW for *continuous wave* or pulsed)
- coherence
- focusability.

Two groups of light source types have evolved commercially

- low-coherence broad-spectrum sources (incandescent filament lamps, arc lamps, pulsed arc lamps, infrared incandescent sources, light-emitting diodes, i.e. LEDs)
- high-coherence, nearly monochromatic sources (lasers).

Key parameters of light sources are summarized in Table 1. Irradiance spectra of representative light sources are shown in Figure 1.

1.1 Incandescent filament lamps

Incandescent filament lamps generate electromagnetic radiation by resistively heating a filament, made usually of tungsten, to about 3000 K. The filament temperature, and, thus, the maximum of the spectral output (Table 1) depend strongly on the operating voltage, typically in a range of few volts to a few hundred volts. Various configurations of the filament, usually coiled-coil, and the envelope are widely available, including designs featuring integrated ellipsoidal dichroic reflectors, transparent in the infrared (IR), that increase the visible output power.

Spectral output of these lamps (Figure 1) resembles, but is lower than, thermal (blackbody) radiation spectrum with about 90% of the spectral output in the infrared. The spectral output of the filament is modified by the transmission spectrum of the envelope (glass or quartz). Being roughly omnidirectional, extended-area light sources, these lamps make it difficult to collimate or focus light output, for example, launch light into an optical fiber.

Incandescent tungsten lamps are available as vacuum lamps, inert gas filled lamps, and halogen lamps, in the order of the increasing filament temperature. In halogen lamps, a small quantity of iodine or bromine compounds added to the inert gas fill used maintains the lamp output at close to 100% throughout the lamp life, provided the lamps are operated at their nominal voltage to maintain the envelope temperature required for the halogen cycle.

Owing to a relatively large thermal mass of the filament, incandescent lamps are used generally as continuous, steady-output light sources. For high-stability applications, stabilized DC power supplies are required.

Table 1. Key characteristics of electromagnetic radiation sources (CW = continuous output).

Approximate spectral range	Approximate maximum output wavelength	Approximate power range	Approximate pulse length range	Light source type
150 nm–2.5 μm[a,b]	500 nm	1–300 kW 0.1–10 J[g]	1 ns–1 ms	Gas arc lamp[c]
150 nm–20 μm[e]	Varies[h]	0.1 mW–10 kW 1 pJ–20 J[g]	10 fs–10 ms	Laser[d]
250 nm–2.5 μm[b]	0.8–1.2 μm[f]	1–10 kW	–	Incandescent filament lamp[c]
460–950 nm	Varies	0.1–1 mW	1 ns–CW	LED[c]
1–30 μm[a]	Varies	1–100 W	–	Infrared light sources[c]
0.1–100 μm[a]	Varies	0.1–1000 W	–	Blackbody[c]

[a]Broad, thermal spectrum.
[b]Sharp spectral peaks at wavelengths dependent on the fill gas.
[c]Incoherent light source, difficult to focus and collimate.
[d]Coherent light source, easy to focus and collimate.
[e]Nearly monochromatic output at one or more wavelengths within this range.
[f]Depends on the filament temperature and lamp type (halogen, gas filled, or vacuum).
[g]Pulsed output.
[h]May be wavelength-tunable.

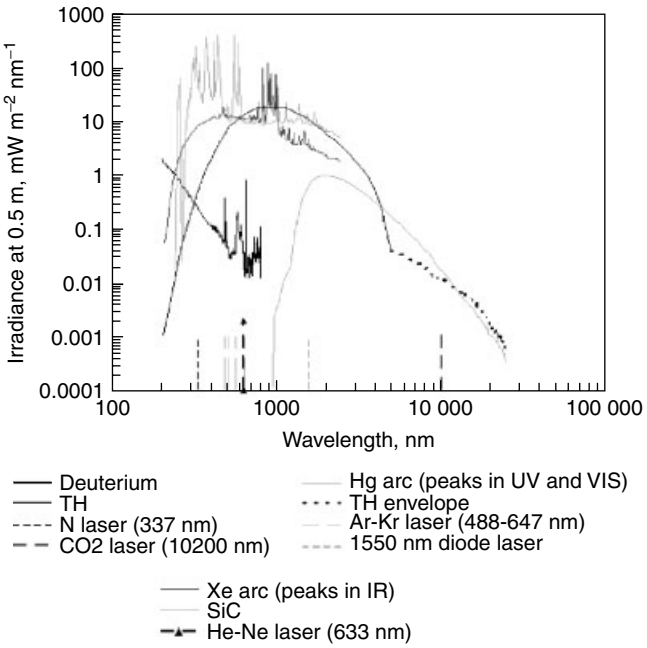

Figure 1. Spectra of representative light sources. Thermal (broadband) light sources spectra are based on the data from a catalog of Oriel Instruments (now Spectra Physics, www.spectra-physics.com): 150-W Xe arc lamp, 200-W Hg arc lamp, 30-W deuterium lamp, 100-W tungsten halogen (TH) lamp (dashed line above about 5000 nm represents the output of the lamp envelope), and 50-W silicon carbide envelope-less infrared element. Wavelength ranges of the lamps' spectra are limited by the envelopes – in the case of a quartz envelope to a range of about 200 to between 2500 and 3500 nm. Spectral lines of few major fixed-wavelength laser types are indicated symbolically with short dashed vertical lines. The vertical range of these lines does not represent the magnitudes of the irradiances that are many orders or magnitude higher than the maximum of the graph scale. For example, a typical 1-mW HeNe laser ($\lambda = 633$ nm, $\Delta\lambda = 0.0002$ nm, beam diameter 1 mm^2) produces irradiance on the order of 5×10^9 mW m^{-2} nm^{-1}.

1.2 Arc lamps

1.2.1 CW arc lamps

In arc lamps, optical radiation is generated by an electric discharge (as an arc) through ionized gas.

The spectral output of an arc lamp (Figure 1) consists of a broad, blackbody-type output and sharp peaks at wavelengths that depend on the gas fill. Gases used in these lamps are typically deuterium, mercury vapor (Hg), xenon (Xe), and a Hg–Xe mixture. The deuterium lamp outputs a smooth spectrum usable from about 160 (envelope limited) to about 400 nm with spectral peaks in an essentially unusable, owing to low spectral power density, visible spectral range. The Hg and Xe lamps (envelope-limited useful range of 250 to 2500 nm) have major peaks at 365.0, 404.6, 434.8, and 546.1 nm (Hg) and between 750 and 1000 nm (Xe). Owing to a high gas pressure in these lamps (of the order of 10 to 100 atm at the operating temperature), the spectral peaks are significantly collision broadened (on the order of several nanometers).

The generally small arc (on the order of 0.1 to 1 mm) allows relatively efficient collimation or focusing of the lamp radiation. Compact Xe arc lamps containing an integrated sealed-in paraboloidal reflector that produces a 'collimated' beam with a moderate divergence are commercially available (CeraLux™, Luxtel, www.luxtel.net). The arc position in an arc lamp varies in time (arc wander) and may cause variations in the output power, especially when this output is collimated or focused.

1.2.2 Xe flash (pulsed) lamps

These arc lamps range from small flashlamps for instruments, to large flashlamps such as those used as pump

sources in lasers. The flash (of the order of microseconds long) is produced by discharging a capacitor. Flash repetition rates are on the order of 100 pulses/s.

1.3 Infrared incandescent sources

The radiating elements of these sources are made of high-temperature-resistant materials such as silicon carbide (Globar), and a sintered mixture of oxides of zirconium, yttrium, thorium, or erbium (Nernst glower). These elements, with sizes on the order of several millimeters, are heated resistively to a temperature on the order of 1000 to 2000 K. The radiating elements are operated in the air with no envelope, limiting the spectral ranges of these sources (Table 1).

Incandescent IR sources have spectral outputs (Figure 1) similar to that of the blackbody, but their wavelength-dependent emissivity is less than unity, typically on the order of 0.9. Blackbody sources operable at temperatures ranging from 400 to 3000 K are brighter (emissivity >0.99), but an order of magnitude more expensive alternatives to these IR emitters.

2 LIGHT-EMITTING DIODES (LEDs)

The light-emitting diodes are relatively narrowband (20–50 nm), low-voltage (2 V), and low-power sources (Table 1) available in a wide spectral range spanning the visible and near IR. White-light LEDs that use a phosphor to convert the base emission wavelength range into a broad range perceived as white light are also available. LEDs convert electric current ($\sim$20 mA) to light by recombining charge carriers in semiconductors. The semiconductors used include SiC, GaN, ZnSe, GaInN (blue), GaP (green), GaP:N (yellow), and AlInGaP, GaAsP (red).

LEDs are available in a wide range of packages, ranging from plastic encapsulation to TO-type metal transistor cans with flat or lensed windows. The emitting area is on the order of a fraction of 1 mm in size. Plastic and glass lensed packages provide rough collimation of the output, but a better result in collimating or focusing a LED output can frequently be obtained with flat-window packages that generally provide a nearly Lambertian spatial radiation pattern.

3 LASERS

The laser (for example, Hecht, 1992) consists of an optical resonator cavity, created by two opposing, high-reflectance mirror surfaces (generally slightly concave), and gain medium inside that cavity. The cavity supports a set of optical radiation modes (resonances) each embodying a discrete wavelength and irradiance pattern in a plane perpendicular to the optical axis of the cavity. The gain medium is selected so that its absorption band overlaps with the wavelength of at least one of the cavity modes and that the radiative energy transition is the most probable transition corresponding to that absorption band. In lasers that employ gain media with wide spectra, prisms or gratings are used to select a subrange of the gain medium spectrum.

By 'pumping' the gain medium with an electric discharge, current, or light, one excites electrons of that medium to an energy state. Electrons falling (initially spontaneously) from that state to a lower one emit light of various radiation modes. Competition, via stimulated emission, of modes supported by the cavity for energy supplied to the gain medium quickly leaves a few dominant modes inside the cavity. The simplest and commonly provided mode, TEM_{00}, has an axially symmetric Gaussian irradiance profile that is frequently associated with the laser beam in general. The process of generation of light by a laser is more akin to that used in an electronic frequency generator than to optical noise generation characteristic of a thermal light source.

The cavity is deliberately made slightly leaky ($<1\%$ loss) in order to let laser radiation out. In pulsed lasers that use Q-switching technique for generation of high-power moderately short pulses (on the order of nanoseconds long), the cavity quality (Q-factor) is spoiled for a sufficient time to build a significant population of electrons in an excited state and then it is temporarily restored to generate a short pulse of radiation. Trains of much shorter pulses (several femtoseconds) can be obtained by mode locking, that is, introducing a fixed phase relationship between the cavity modes. The pulse train is a result of interference between the locked modes.

The cooperation of the resonant cavity properties, gain medium absorption profile, and the stimulated emission gives the laser beam its directionality, high monochromaticity, and coherence. Stabilized frequency lasers have line widths $<1 \times 10^{-11}$ nm (3 MHz), and coherence lengths on the order of 1 km. Key characteristics of representative laser types are summarized in Table 2. Wavelengths of major laser types are shown in Figure 1.

3.1 Gas lasers

These lasers span a wide wavelength range from UV (excimer, for example, XeF, XeCl; nitrogen), through visible (argon, argon/krypton, copper vapor, helium–neon, helium–cadmium) to far IR (CO_2). The gain medium is gas excited by an electric discharge. The gas lasers provide good-quality low-divergence beams with the diameters on the order of 1 mm.

Table 2. Basic data on major laser types listed according to the increasing first wavelength of the spectral range. CW denotes continuous output. This table is mainly based on the *Laser FocusWorld* 2003 Buyer's Guide. Additional data obtained from specifications of selected manufacturers have been also used. Users of this table should exercise caution when applying the data given.

Wavelengths (nm)[m]	Laser type	Power (W) or pulse energy (J)	Pulse repetition rate ($1\,s^{-1}$)[l]	Pulse width (s)	Beam size[a] (mm)	Beam divergence (mrad)
154–532[f], (1064), 2950	Nd:YAG[c] (pulsed)	0.001–180 J	$1–50 \times 10^3$	$20 \times 10^{-12}–10 \times 10^{-3}$	1–14	0.5–130
157, 193, 248, 308, 351	Excimer[b] (pulsed)	0.001–0.2 W	$20–2 \times 10^3$	$0.01–30 \times 10^{-9}$	2.5×22	0.3–4
190–18000[h,k]	Tunable solid state (pulsed)	$0.1 \times 10^{-9}–100$ J	$0–90 \times 10^6$	$17 \times 10^{-15}–100 \times 10^{-9}$	3–10[g]	0.5–1.5[g]
197–4500[h]	Tunable dye (pulsed)[g]	$30 \times 10^{-6}–0.2$ J	$1–10 \times 10^3$	$5 \times 10^{-12}–20 \times 10^{-9}$	$1–3 \times 6$	5
202–1090[i] (514)	Argon[b] (CW)	$2 \times 10^{-3}–25$ W	–	–	0.6–3.5	0.05–3
266–532[f] (1064), 1320	Nd:YAG[c] (CW)	$0.01–5.4 \times 10^3$ W	–	–	0.7–6	1–200
(337)	Nitrogen[b,g] (pulsed)	$0.1 \times 10^{-3}–0.5 \times 10^{-3}$ J	1–100	$\sim 1 \times 10^{-9}$	1×2	2×3
375–760[h]	Alexandrite[c,g] (CW)	0.01–0.15 W	–	–	1	0.1
375–2900[h] (500–1550)[h]	Semiconductor diode (CW)	$0.1 \times 10^{-3}–4 \times 10^{3}$[e] W	–	–	–	$1–17 \times 1–17$[j,d], 87×870[d]
380–1935[h] (600–1550)[h]	Semiconductor diode (pulsed)	$5 \times 10^{-12}–10^{2}$[e] J	$100–100 \times 10^6$	$15 \times 10^{-12}–0.8 \times 10^{-3}$	–	0.3[j], 87×785[d]
543, (632.8), 1152, 3392	HeNe[b]	$0.1 \times 10^{-3}–35 \times 10^{-3}$ W	–	–	0.5–2.7	0.7–4.5

9000–11 400 (10 600)	CO_2[b] (pulsed)	0.5–60 J	$0–130 \times 10^3$	0.3 to over 10^{-3}	$1.8–30 \times 30$	1–10

[a] If one value is given, it is the TEM_{00} (Gaussian) beam diameter.
[b] Gas laser.
[c] Solid-state laser.
[d] In two perpendicular dimensions.
[e] The upper end of the range refers to the output of laser stacks.
[f] Through harmonic frequency conversion.
[g] Few data.
[h] Continuously tunable, may be tunable in a subrange of the stated range.
[i] Line selection.
[j] Diode lasers equipped with collimating optics.
[k] Line widths from several GHz down to 1 kHz.
[l] A repetition rate of 0 denotes a single-shot mode.
[m] Dominant wavelengths in parentheses.

3.2 Semiconductor (diode) lasers

These lasers (for example, Camparo, 1985) are similar to LEDs in that they use a recombination of charges in semiconductors to generate emission of light. Owing to a very small emitting area of unequal sizes (on the order of 10 μm) in two perpendicular directions, these lasers typically emit a divergent astigmatic light beam and require complicated optical systems to either collimate or focus it. In fiber-optics applications, the small emitting area can be simply butt-coupled to a fiber.

Semiconductor diode lasers are also available in vertical emitting cavity (VCSEL) configuration that emit low-divergence, circular beams. Although these lasers are more difficult structures to grow on a semiconductor wafer, they do not need to be cleaved to produce the resonant cavity and, thus, can be fabricated solely by using standard semiconductor processing techniques (for example, Lang, 2002).

3.3 Dye lasers

Dye lasers use as their gain media various dyes (including coumarin, fluorescein, and rhodamine) covering a wavelength range from about 190 to 4500 nm. These lasers are pumped with either flashlamps or other lasers, for example, nitrogen lasers. The wide absorption bands of the dyes, as compared, for example, to narrow absorption spectra of gases, support the generation of very short light pulses (several femtoseconds long).

3.4 Solid-state lasers

3.4.1 Fixed-wavelength lasers

Solid-state lasers (SSLs) utilize a solid gain medium, permitting high-quality beams, and various pumping mechanisms. The first solid-state laser used the ruby crystal as the gain medium and a flashlamp as the pump. SSLs are also pumped by other lasers and by semiconductor diode lasers (diode-pumped solid-state lasers – DPSSL). In addition to ruby, the gain media include neodymium-doped (Nd:YAG, Nd:YLF, Nd:YVO_4) and holmium-doped (Ho:YAG, Ho:YLF) crystals and glasses, alexandrite and titanium-doped sapphire (Ti:sapphire). As in dye lasers, the wide absorption bands of the solid gain media support the generation of extremely short light pulses.

These lasers emit in the red and near IR range. Radiation in the near-UV and blue/green region of the visible spectrum can be generated by the harmonic up-conversion (for example, 532 nm in an ND:YAG laser).

3.4.2 Tunable lasers

Tunable solid-state lasers, available mainly as pulsed lasers, operate by using principles similar to those employed in dye lasers except that the gain medium is solid state. In particular, a tunable titanium-doped-sapphire (Ti:sapphire – the broadest range of any tunable laser: 660–1180 nm) laser has become a widely used replacement for tunable dye lasers. However, the Ti:sapphire laser has the noise lower by a factor of 10 as compared to the dye laser and also has a much narrower line width (down to 1 kHz). As with other SSLs, up-conversion is used to provide tunable light in the UV and visible range.

4 DETECTORS

Developments in electro-optical detector technology (for example, Donati, 2000) combined with advantages of direct electronic signal processing have long displaced the human eye and photographic film as detectors of light in all but marginal applications. Two basic groups of electro-optical detectors are discussed here: thermal and photon detectors.

An electro-optical detector of light is selected on the basis of one or more of the characteristics listed in Table 3. Some detector types may have additional selection criteria, for example, after-pulsing for photomultipliers.

The sensitivity is frequently the dominant selection criterion. Hence, the ranges of light power that can be measured with the various detector types are listed in Table 4 and shown in Figure 2 for major detector types.

5 THERMAL DETECTORS

In a thermal detector, the active element is heated via absorption of light. This heating induces electrically sensed changes in that element's properties. Thermal detectors have a flat spectral response in a broad spectral range, determined by the absorption spectrum of the sensing element material or its absorptive coating that converts the energy of the incident radiation to heat. The detector spectral range is limited/modified by the detector window/filter. A weak thermal link to a heat sink allows the detector to correctly respond to the incident radiation power. Thermal detectors are generally less expensive than photon detectors, and do not require cooling when operated in the infrared. However, thermal detectors are typically slower and have a lower sensitivity than photon detectors.

The basic types of thermal detectors are:

- thermocouples
- thermopiles

Table 3. Key characteristics of radiation detectors.

Name and typical symbol	Typical units	Definition
Responsivity, R	A/W, V/W, V/J[a]	Ratio of the detector output to the incident light power dose
Quantum efficiency, QE[b]	Nondimensional	Number of electrons generated by the detector in response to an input of one photon of radiation
Dark current, I_D, or dark voltage, V_D	A, V	The baseline output of the detector in the absence of incident light
Response time, t_R	s	Time interval required for a detector to generate an output commensurate with the input light power (dose) when that detector is illuminated by a step increase in the light power (rise time) or when the illumination ceases abruptly (fall time)
Linearity range	W	A range of the input light power within which the detector output is linearly proportional to the input power
Noise equivalent power, NEP	W, W/$\sqrt{\text{Hz}}$	Light power that generates a detector output equal to the RMS detector noise[c]

[a]For detectors sensitive to the radiation dose.
[b]Applicable to photon detectors only.
[c]With the detector noise being a function of the measurement (electrical) frequency bandwidth, NEP is usually given at a frequency of 1 kHz and for a 1-Hz bandwidth. An amplifier, if needed, may significantly increase the NEP of a complete detection system.

Table 4. The first order of magnitude incident radiation power ranges that can be measured by the various detector types. The minimum power is the detector noise equivalent power at the wavelength of the maximum responsivity. PMT = photomultiplier, APD = avalanche (semiconductor) photodiode.

Approximate power range[h], W		Detector type	Approximate spectral range[b]
Minimum	Maximum		
10^{-19} [a]	10^{-12}	PMT: photon counting[e]	100–900 nm
10^{-19} [a]	10^{-12}	APD: photon counting[e]	200–2500 nm
10^{-15}	10^{-9} [c]	PMT: analog detection[e]	100–900 nm
10^{-13}	10^{-6}	APD: analog detection[e]	200–2200 nm
10^{-12}	10^{-1}	Semiconductor photodiode[e]	0.1 nm–5 μm
10^{-12}	1	Semiconductor photoconductor[e]	400 nm–150 μm
10^{-9}	10^{-3}	Thermopiles[f]	200 nm–200 μm
10^{-9}	10^{-3}	Pyroelectric[f]	200 nm–1 mm
10^{-8} [d]	1	Bolometer[f]	0.1 nm[g]–5 mm

[a]This power corresponds to ~1 photon/s in the visible and near infrared.
[b]Various detectors of the stated type (except thermal detectors) may have their maximum sensitivity located at different wavelengths in this range and be sensitive each in a subrange of this range.
[c]A much higher maximum power (about 7 mW) was measured with short (~1 μs) light pulses (Lasher and Redhead, 1963) at the cost of high mortality of the PMTs.
[d]down to 10^{-17} in the far infrared at a temperature close to 0 K.
[e]Photon detector.
[f]Thermal detector.
[g]Can be used as a photon counter/spectrometer for X rays.
[h]The dynamic range of a detector may be smaller than the min–max range.

- pyroelectric detectors
- bolometers.

Golay cells (pneumatic detectors) were the mainstay thermal detectors in the past but have been all but displaced by other thermal detector types.

5.1 Thermocouples and thermopiles

Thermocouples and thermopiles (a series of thermocouples) utilize the temperature dependence of voltage generated by a junction of dissimilar metals, usually bismuth and antimony. The thermocouple consists of two such junctions connected in series in reverse in order to cancel the effect of the ambient temperature – *see* **Article 196, Thermocouple Temperature Sensors, Volume 3**. One of these junctions is coated with a thin light-absorbing layer. The other is shielded from the incident light, that is, remains at the ambient temperature. The voltage generated by a thermocouple is low (in the mV range); therefore, several thermocouples are typically connected in series (thermopiles).

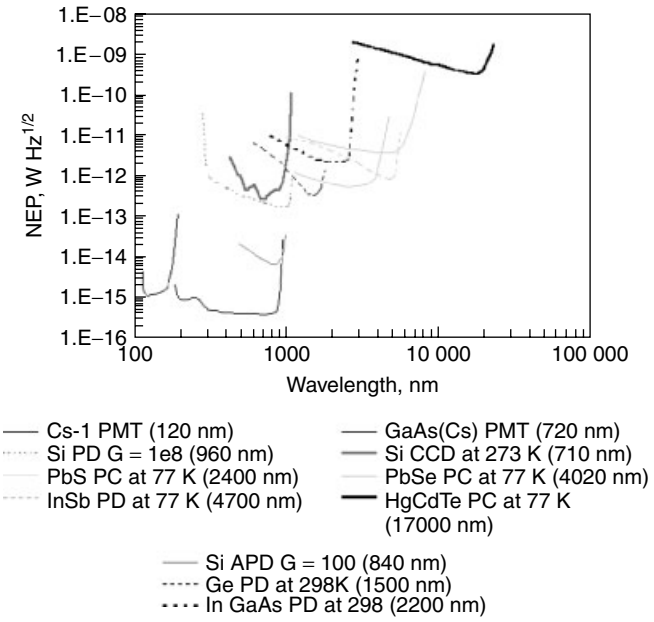

Figure 2. Sample spectra of the noise equivalent power (NEP) for major types of photon detectors (the wavelength of the minimum NEP is given in parentheses in the curve label). They indicate approximately the minimum power that can be measured by a given detector type at a signal-to-noise ratio of 1. The NEP of a specific detector of that type may vary, depending on the detector area and temperature. Abbreviations: APD = avalanche photodiode, LAAPD = large-area avalanche photodiode, G = gain, PC = photoconductor, PD = photodiode, PMT = photomultiplier. PC and PD detectors require external signal amplifiers that typically significantly increase the total NEP of the detection system. Long-term signal integration (on the order of seconds) may reduce the total NEP in such a case. The field of view of the far IR detectors is limited to 60°. The NEP is generally specified at a modulation frequency of the optical input of about 1 kHz, with a bandwidth of 1 Hz. However, an external amplifier with a high gain required for the PDs may significantly limit the maximum modulation frequency. Detector areas are on the order of 0.01 cm^2, except those of the PMTs (~0.5 cm^2) and the LAAPD (~0.1 cm^2). Pyroelectric, thermopile, and bolometer detectors (not included) have a flat spectral response with NEP ~10^{-9} to 10^{-11} (at several Hz) typically from UV to far IR. This spectral range is limited/modified by the window/filter transmission range. The graph is based on the data of the following manufacturers: Si PD and the PMTs – Hamamatsu (1994), www.hamamatsu.com, Si APD – Perkin Elmer, www.perkinelmer.com, Si LAAPD – Advanced Photonics, www.advancedphotonix.com, PbS and PbSe PC – New England Photoconductor, www.nepcorp.com, Ge, InGaAs, InSb PDs, and HgCdTe PC – Judson Technologies, www.judtech.com.

5.2 Pyroelectric detectors

Pyroelectric detectors use materials, typically lithium tantalate, that maintain electrical polarization even when no voltage is applied to the detector. When an active element of a pyroelectric detector is heated via absorption of light, it expands. This changes the polarization of this element and causes current to flow in a circuit connected to it. Pyroelectric detectors thus respond to changes in the incident light power, that is, to chopped or otherwise modulated radiation power.

5.3 Bolometers

Bolometers utilize changes in the conductivity of a resistor to sense its temperature that is affected by absorption of radiation. Room-temperature bolometer arrays allow inexpensive imaging of IR radiation, as compared to other IR imaging arrays.

When operated at room temperature, these devices are relatively poor detectors. Chopping, or modulating the incident radiation power, can be used to reduce the effect of slow-changing ambient temperature. Room-temperature bolometer detectors may also utilize two identical bolometers (one exposed to the incident radiation, the other shielded from it) in two arms of an electrical bridge. This arrangement cancels the effect of the ambient temperature on the detector output. However, the full potential of these devices is realized by operating them at temperatures close to absolute zero, which reduces their inherent thermal noise. Cryogenically cooled bolometers operating in the far IR are by several orders of magnitude more sensitive than other detectors of electromagnetic radiation in that spectral range.

6 PHOTON DETECTORS

Photon detectors convert the energy of incident light photons to electricity directly. These detectors work in relatively narrow spectral ranges, with a distinct long-wavelength cutoff, but can be extremely sensitive, up to the detection of single photons. Biological detectors of light are nearly as sensitive. The human eye can detect a burst of several photons and the rat eye can reliably detect single photons (Hagins, Penn and Yoshikami, 1970).

6.1 Photoemissive detectors

Photomultipliers (PMTs; BI, 1980; Hamamatsu, 1994) are by far the most commonly used detectors in this class, followed by image intensifiers.

6.1.1 Photomultipliers

A classical photomultiplier is a vacuum tube with a photosensitive cathode (Table 5) and on the order of 10 dynodes

Table 5. Basic characteristics of typical photocathodes.

Photocathode type	Photosensitive material	Spectral range (nm)	Wavelength of maximum responsivity (nm)	Responsivity (mA/W)	Maximum quantum efficiency
S-1	Ag–O–Cs	400–1100	350–800	3.5	0.012
S-4	Cs–Sb	160–550	300	50	0.21
S-11	Cs–Sb	290–600	450	55	0.15
S-20	Na–K–Cs–Sb	160–720	400	50	0.15
–	GaAs (Cs)	160–850	400	37	0.22

that collect and multiply the photocurrent generated at the cathode. A high voltage of the order of 1000 V is distributed between the electrodes of a PMT by a voltage divider network. A photon striking the photocathode ejects an electron with the quantum efficiency (QE) of less than one-fourth. That electron is accelerated by the potential differences between the cathode and the following electrode and – upon impacting that electrode – ejects several next-generation electrons. This electron-multiplication process continues for each following dynode until the anode, where electrons are collected, and results in a total electron gain on the order of 10^6 to 10^8. A high gain and a low dark current on the order of 1 photoelectron/s (and less when cooled) enable the detection of single photons of the incident light. Classical PMTs are available generally in two forms:

- side-on (with a reflective photocathode)
- end-on (with a semitransparent photocathode).

The side-on form is typically a faster detector (rise time on the order of a fraction of 1 ns), due to a more compact electron multiplier design. Supercompact multianode PMTs that enable a low-resolution imaging of the incident irradiance distribution ($\sim 10 \times 10$ 'pixels') are also available. The sensitivity spectra of PMTs span the near-UV to near-IR wavelength range (Figure 2).

A radical variance of the vacuum-tube design is a multichannel-plate PMT (MCP PMT), where the multiplier section is a glass plate, about 0.5-mm thick, with closely packed narrow (on the order of 10 μm) cylindrical channels, each acting as a set of dynodes. The MCP offers the most compact PMT design allowing rise times on the order of 100 ps.

6.1.2 Image intensifiers

Image intensifiers (IMIs) use various forms of imaging electron multipliers, typically the MCP, to map the distribution of photoelectrons exiting the photocathode to that at the anode (for example, Johnson and Owen, 1993). The anode is a phosphor screen (metallized to conduct electric current) that emits visible light when impacted by electrons with energy sufficient to penetrate the screen metallization. With the MCP multiplier, the imaging of the input electron irradiance distribution is ensured by restricting each electron cascade to its own microchannel and by placing the photocathode, MPC, and the anode-phosphor screen close to each other (<1 mm). This creates compact devices with imaging resolutions of the order of 50 line pairs per mm. Photon gains up to the order of 10^9 are possible with devices that employ stacks of two or three MCPs.

The IMI is by itself an optical-to-optical converter and requires an array detector such as a CCD (discussed in Section 6.2) to convert an optical image to electronically processable image. Phosphor-less versions of an image-intensified CCD are also available. In these imaging detectors, the phosphor screen is replaced with a CCD embedded inside the vacuum tube.

6.2 Solid-state detectors

The sensitivity spectra of solid-state detectors span a wide wavelength range from the soft X rays to far IR. Spectra of major types of solid-state detectors are shown in Figure 2.

6.2.1 Photovoltaic detectors and detector arrays

In a photovoltaic semiconductor detector, the semiconductor junction separates charge carriers generated by absorption of photons of the incident light and produces current in an electric circuit connected to the detector. Photovoltaic detectors can be used in the low-speed short-circuit photovoltaic mode (no dark current and the related noise) and in the high-speed photoconductive mode with moderate bias current and resulting higher noise. A wide variety of semiconductor photovoltaic detectors are available commercially, including position-sensitive detectors and imaging (array) detectors. These detectors are typically made of Si, GaAs, Ge, InGaAs, InAs, and InSb semiconductors that absorb light in subranges of a wide range between X rays and far IR (Table 6). Detectors specialized for either low-noise, low-speed operation or high-speed operation (>100 GHz) are available. Semiconductor detectors have QE on the order of unity, much higher than that of PMTs,

Table 6. Basic characteristics of typical photovoltaic semiconductor detectors at room temperature, unless indicated otherwise.

Photosensitive material	Spectral range (μm)	Wavelength(s) of maximum responsivity (μm)	Maximum responsivity, A/W	Maximum quantum efficiency
Si	0.2–1.2	0.8–0.95	0.7	0.9
GaAs	0.3–0.75	0.6–0.72	0.4	0.7
Ge	0.8–1.8	1.55	0.9	0.7
InGaAs	0.7–1.7	1.6	1	0.8
	0.7–2.6	2.3[a]	1.1	0.6
InAs	1–3.1	3[b]	2	0.8
InSb	1–5.5	5.2[b]	2	0.5

[a] At 253 K.
[b] At 77 K (liquid nitrogen).

that is relatively insensitive to temperature changes, except near the long-wavelength cutoff (Figure 2).

Photovoltaic detectors are available both as:

- unity gain devices (photodiodes, photodiode arrays, CCDs, CMOS arrays)
- detectors with internal amplification: avalanche photodiodes (APDs) and APD arrays.

In the latter detectors, the cascade multiplication of photoelectrons is induced by applying a high voltage on the order of several hundred to several thousand volts. In the lower part of the high-voltage range, the number of electrons produced is proportional to the applied voltage, as it is in the PMT. In the high part of the voltage range, the cascade multiplication becomes free running. This latter mode of operation (Geiger mode), is used for single-photon counting. In that mode, the electron cascade is quenched to enable photon counting at a rate on the order of up to 10^6 photons/s (active quenching) limited by dead time and APD heating (for example, Dravins, Faria and Nilsson, 2000).

Semiconductor array detectors are the mainstream of imaging detectors. Arrays with pixel sizes on the order of $10 \times 10\,\mu m$ are available in the photodiode array, CCD, and CMOS formats. The photodiode arrays have individually addressable elements and offer high quantum efficiency but suffer from a substantial read-out noise (for example, Johnson, Edwards and Mendenhall, 1994). CCD arrays have a much lower readout noise but also a lower quantum efficiency. In a CCD array, the photogenerated charges, instead of being in real time removed from the sensitive volume as it is done in the photodiode, are stored in a potential well until they are transported out with an extremely high efficiency, along a column or row of pixels that perform the role of an analog shift register.

Charge integration and transfer are achieved at the rate of an external clock signal by varying potentials of an array of electrodes and semiconductor gates located at the CCD chip surface. It is these surface structures that reduce the quantum efficiency of the CCD array as compared to that of the photodiodes.

Back-illuminated operation of the CCDs compensates somewhat for this reduction. CCDs tend to suffer from 'blooming' caused by spilling charge from an overfilled pixel to the surrounding pixels (Janesick *et al*., 1987).

Recently, electron-multiplying CCDs (EMCCDs) have been commercialized (e2v technologies, www.e2v.com). These CCDs utilize, in the readout section, an electron-multiplication technique implemented in the APDs. This allows high gain (single-photon counting) with the low-noise characteristic of the CCDs.

The CMOS imaging arrays utilize silicon as photosensitive material and have a similar spectral response to that of silicon CCDs. However, the CMOS arrays use a different approach to sensing the incident light power and also different manufacturing techniques. In a pixel of a CMOS array, a photodiode typically discharges a storage capacitor, thus preventing blooming. The capacitor charge can be directly read out via an integrated amplifier.

This allows addressing selected sections of the array and enables a high-speed readout. The CMOS arrays employ technology used for microprocessors. This permits integration of preprocessing electronics, such as an analog-to-digital converter, on the array chip. However, additional semiconductor/metal structures implementing these functions take up a significant portion of the area available for light collection. Complexity of these structures also increases the manufacturing defect rate. Such disadvantages have generally limited applications of CMOS arrays to low-cost and low-quality consumer applications (Taylor, 1998).

6.2.2 Photoconductive devices

Photogeneration of charges in semiconductors significantly affects its conductivity. This is utilized in junctionless semiconductor detectors, photoconductors, for the detection of electromagnetic radiation. Typical semiconductors used

Table 7. Basic characteristics of typical photoconductive semiconductor detectors at room temperature, unless indicated otherwise.

Photosensitive material	Spectral range (max sensitivity) (μm)	Maximum responsivity (V/W)
CdS	0.4–0.75 (0.56)	– [b]
CdSe	0.6–0.9 (0.71)	– [b]
PbS	1–2.7 (2.2)	6×10^5
	1–4.2 (3.1)[a]	9×10^5 [a]
PbSe	1–5 (4)	7500
	1–6 (5)[a]	55 000[a]
HgCdTe	1–4[a] – 24[a]	10^5 [a]–200[a]

[a]At 77 K (liquid nitrogen).
[b]These detectors are used mainly as light switches, because of the sensitivity of their response to their light-exposure history.

in these photoconductors are CdS and CdSe (visible), PbS and PbSe (near IR), and HgCdTe (IR) (Table 7). Note that the semiconductor conductivity is also a significant function of temperature, so that the detector temperature must be stabilized.

The literature on optical engineering usually covers sources and detectors. A useful general book is OSA (1993). A useful reference work on infrared engineering is Hudson, 1969.

1 REFRACTOMETERS

This article shows how the building blocks of optical systems – materials, **Article 89, Optical Materials, Volume 2**; elements, **Article 90, Optical Elements, Volume 2**; and sources and detectors, **Article 91, Light Sources and Detectors, Volume 2** – are assembled to form whole optical systems. Testing of optical systems is found in **Article 93, Testing Optical and Other Radiation Systems, Volume 2**.

Refractometers are employed for refractive index and Abbe value measurement. Depending upon the precision needed, several instruments are available commercially.

Abbe and Pulfrich refractometers are the most commonly used instruments for precise measurement. The design of both these instruments is based upon the total internal reflection principle.

An Abbe refractometer consists of two $90^\circ - 60^\circ - 30^\circ$ prisms, a pair of Amici prisms, and a telescope. One right-angled prism is used for illumination, while the other serves as the test specimen holder, which is placed over it with a liquid of high refractive index at the contact area. The Amici prisms are rotated in opposite directions to compensate for the dispersion introduced by the test specimen and stage prism. The telescope can be swiveled along an arc to pick up the total internally reflected light and its position is read on a scale directly calibrated in terms of refractive index. The instrument also incorporates the provision for measuring the refractive index of liquid samples.

In the Pulfrich refractometer, the emergent angle I' of the grazing incident rays, as measured by the telescope, is used for the determination of the refractive index N of the test samples, according to the equation $N = (n^2 - \sin^2 I')^{1/2}$, where n is the refractive index of the supporting glass block.

2 CURVATURE MEASUREMENT

Measurement of radius of curvature r of optical surfaces is conventionally made employing mechanical or optical spherometers.

In mechanical spherometers, the sag of the test surface is obtained by locating the correct contact point with the help of a plunger. This quantity in conjunction with other known parameters enables calculation of r.

The optical spherometer is based on the autocollimation principle. The instrument is first focused on the test surface and then at its center of curvature. The distance between the two image positions determines r.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

The well-known Foucault knife-edge test method is usually employed for testing long radius of curvature, concave surfaces, and assessing sphericity errors at different zones.

3 AUTOCOLLIMATORS

Parallelism of a glass plate, prism and wedge angles, and surface flatness can be efficiently tested using an autocollimator. It is also frequently used for alignment purposes.

When the surface under test is not exactly normal to the incident rays, the reflected image is transversely displaced. This image displacement is measured (manually and photoelectrically) precisely, yielding test surface inclination.

In the angle Dekkor method, the test specimen is placed horizontally upon a flat base, while the autocollimator can be swung in a vertical plane. A precision goniometer is essentially a spectrometer with an in-built autocollimating telescope.

4 FOCOMETERS

The two standard techniques conventionally used for focal length measurement of an optical system are the focal collimator and nodal slide methods. For better precision, an autocollimating microscope can be used.

A wide variety of optical instruments are available for various measurements in the industry. Brief details of some common types of instruments are now discussed.

5 MICROSCOPES

A microscope consists essentially of a condenser lens to illuminate the object, an objective lens for image formation, and an eyepiece optical system for viewing. Opaque objects are illuminated from the top, either by a beam splitter placed below the objective or by fixing miniature lamps by the side of the objective. An industrial version of a stereozoom microscope is shown in Figure 1.

A tool-room microscope eyepiece can be fitted with a special graticule pattern. Microthreads, tool shape, and the like are checked by matching their images with respect to a corresponding ideal pattern contained in the graticule.

Dimension-measuring traveling microscopes are mounted on a high-precision translating rail. The travel distance is read from a scale using an optical vernier.

In the case of metallurgical specimens (where it is important to study fine scratches in polished surfaces, faults, and inclusions, which, due to glare, are usually not visible under normal illumination), a special objective, carrying a beam splitter at its back, is used.

Figure 1. Stereozoom microscope. (Copyright © Bausch & Lomb.)

When the object has only variation in phase or refractive index and no differential absorption, a phase-contrast microscope is used. With the help of a phase-shifting device, the variations in the object are converted into intensity variations in the image. On phase retardation, a denser medium appears brighter and vice versa in the case of phase advancement.

In fluorescence microscopy, the specimen (usually biological) is dyed with an appropriate dye and observed, using filters, under ultraviolet light.

Study of the crystals is done on a polarizing microscope. Plane polarized light, after passing through the specimen, changes its state of polarization and the output beam is studied by an analyzer.

Interference objectives are basically Twyman–Green types of microinterferometers, which are coupled with a microscope to measure the microsurface structure of polished reflecting surfaces.

6 TELESCOPES

Basically, a telescope has an objective and an eyepiece. Astronomical telescopes of the reflecting type contain at least a large primary mirror and a small secondary mirror. Terrestrial telescopes are often of the refracting type fitted with additional inverting optics for image erection.

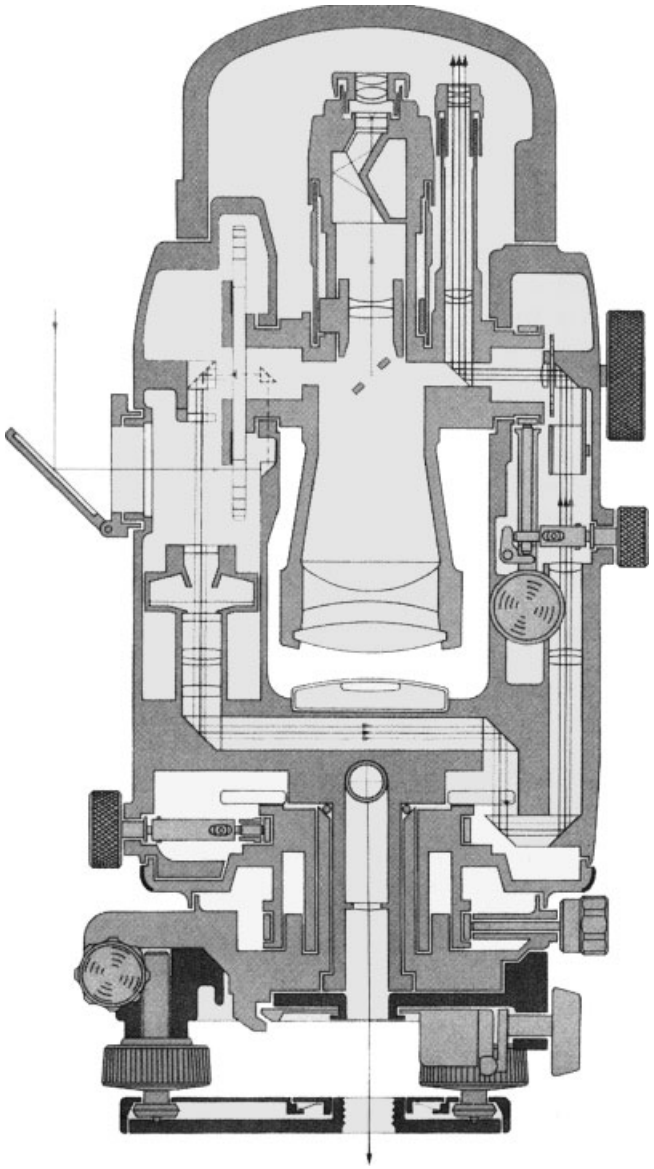

Figure 2. Micrometer theodolite. (Copyright © Wild Heerbrugg Ltd.)

The precision theodolite and sighting level are another important class of telescopic instrument. They are extensively used in land surveying, geodesy, and tacheometry. Figures 2 and 3 illustrate, as examples, the optical configurations of standard versions of the micrometer theodolite and universal automatic level.

As an example of an optical system, consider the technical data of a Wild micrometer theodolite shown in Figure 2. Telescope magnification with a standard eyepiece is 30×. The field of view at 1000 m is 27 m with a shortest focusing distance of 1.7 m. Bubble sensitivity per 2 mm run, for the circular level is 8 min of arc and for the plate level 30 s of arc. Liquid compensator setting accuracy is ±1 s of arc,

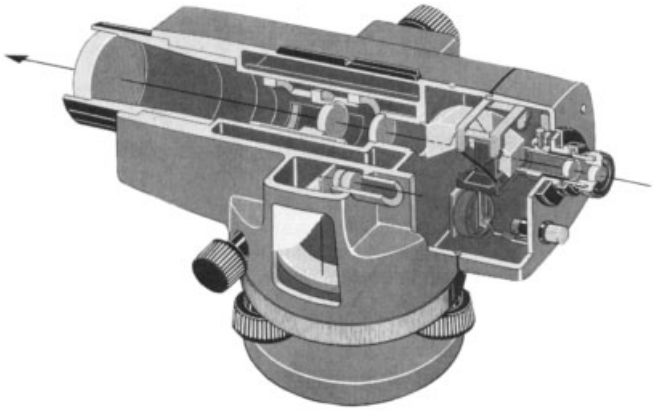

Figure 3. Universal automatic level. (Copyright © Wild Heerbrugg Ltd.)

and the working range is ±2 min of arc. Graduation intervals of the horizontal and vertical glass circles is 1° of arc with direct reading on the micrometer to 6 s of arc and by estimation, 3 s of arc.

In the case of the Wild universal automatic level shown in Figure 3, the compensator setting accuracy is enhanced to ±0.3 s of arc and working range to ±15 min of arc. For precise leveling, a parallel-plate micrometer, reading at 0.1 mm direct and 0.01 mm by estimation, is attached to the basic instrument.

Endoscopes are often employed in industry for observations inside high-temperature enclosures or other inaccessible areas. Figure 4 shows a commercial model of a portable endoscope for photographic and visual examination of the inside walls of operating furnaces and boilers. Photo-visual endoscopes suitable for use in very high pressure (25 kg cm^{-2}) chambers with corrosive atmospheres are

Figure 4. Portable endoscope. (Copyright © S.R. Clave.)

also available. A wide range of forms for medical use is covered in Section 9.

7 PROJECTORS

Projection equipment consists essentially of a high-power lamp, a suitably designed condenser lens system and a well-corrected projection objective lens. The condenser fully illuminates the entrance pupil of the objective, which forms a magnified image on a distant screen. The diascope is used for the projection of transparencies (the overhead projector) and the episcope for opaque objects.

Profile projectors are made epidiascopic in design so that both opaque and transparent objects may be imaged. A set of projection objectives, of different magnifications, is mounted on a revolving turret. The test specimen is mounted on a glass platform provided with X–Y translational motion. The image is received on the rear of a ground glass screen. Reflecting mirrors are used to fold the optical path to make the instrument more compact.

Optical micrometric readers are incorporated on several machine tools; these help in accurate positioning of the workpiece. An optical dividing head is used for precise angular and displacement measurements.

8 SPECTROPHOTOMETERS

Spectrophotometers are used for a variety of applications in industry, including routine batch composition analyses and pollution control.

The principal component of the instrument is the monochromator, an optical source, which provides a selectable continuous range of wavelengths in the specified spectral region.

A commercial model of the instrument together with the schematic layout of the optical system of the monochromator used is given in Figure 5(a) and (b). The specifications, as given by the manufacturer, are wavelength range 0.35 to 0.80 μm; source, a tungsten lamp; dispersing element, a holographic concave grating with 1200 grooves/mm; and wavelength separation accuracy better than 0.02 μm. The detector is a silicon photodiode.

A colorimeter basically employs optical filters instead of the dispersing element.

A large number of other instruments based on optical principles are used for quality control and other purposes in industry. A selection of examples, which have not been dealt with already, includes the infrared-based instruments such as the IR (infrared) spectrophotometer, IR gas analyzers, and noncontact-type online IR moisture analyzer, which are based upon the principle that depending upon its composition, each substance has its own characteristic IR absorption band(s), which serves as a fingerprint for its identification and quantitative evaluation.

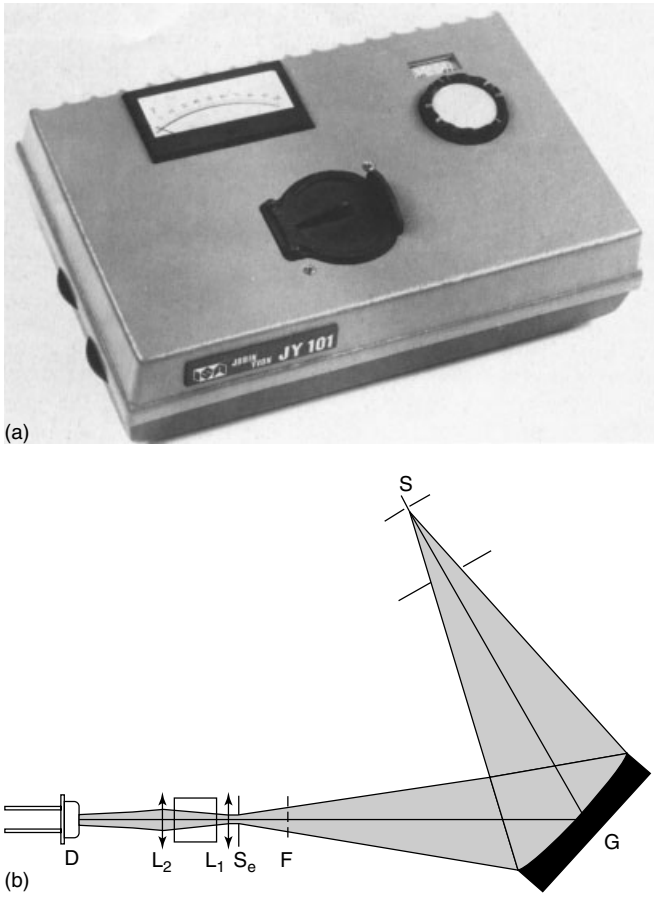

Figure 5. (a) Spectrophotometer; (b) schematic layout of monochromator comprising: S, source; G, holographic grating; F, removable filters; S_e, exit slit; L_1, L_2, lens; and D, detector. (Copyright © Jobin Yvon.)

Optical pyrometers are used for the temperature measurement of industrial furnaces wherein the flame luminosity is compared with that of an incandescent filament under varying electric power input conditions until complete photometrical matching is obtained.

The saccharimeter is used to determine sucrose concentration in the sugar industry: in these the property of optical rotation is used.

Photometers are used for determining the light output of various sources and illumination measurements.

Moiré fringe methods use two sets of ruled lines overlaid at a slight angle to form fringes that move transversely to the relative motion of the grating and its index. Movement of a fringe at a fixed location is counted with a detector driving a high-speed digital electronic counter. They are used extensively by the machine-tool industry for precise determination and control of linear and radial movements,

and in many aspects of gauge-room inspection. Lastly, in these examples, liquid and gas chromatographs are used for rapid estimation of sample purity and for conducting chemical analyses.

9 OPTO-MEDICAL INSTRUMENTS

For diagnostic purposes, observation of different places inside the human body is made by the endoscopic class of optical instruments. The cystoscope, laparoscope, arthroscope, bronchoscope, gastroscope, colonoscope, auriscope are some of the instruments belonging to this family. These vary mainly in their length, diameter, and other configuration parameters, to suit the particular application.

An endoscope is essentially a tele-microscopic system with a large number of intermediate image transfer relay lenses or coherent optical fiber bundles. Usually a low-wattage miniature lamp, fitted at the viewing side, provides illumination. Use of a higher-wattage light source, photography, and electro-optical sensor arrays is feasible with optical fiber–based endoscopes.

Ophthalmic instruments are designed to examine and measure various parameters of the human eye. Retinal observation is done by an ophthalmoscope. It has a miniature low-wattage light source, which is focused by a condenser onto a tiny mirror and the light reflected from the mirror illuminates the retina. During observation, any of the number of small lenses of different dioptric power, mounted on a rotatable disc, can be brought into the return light path. A lens introduced in the correct focus position gives the refraction error of the eye. A retinoscope measures the retinal curvature and is based on the Foucault knife-edge test principle.

Retinal photography is taken by a fundus camera. It focuses the filament of a lamp onto the pupil, while the eye, to be examined, looks at a small steel ball placed suitably in the light path. The same objective, used for illumination, focuses the image of the retina onto a photographic plate. After initial adjustment is made, a photograph or photo array image is taken under electronic flash illumination.

A cold light source, which is basically a noncoherent fiber bundle transmitting only visible light (IR content is filtered out by thin film device) is often used in retinal surgery.

An ophthalmometer is used to measure corneal curvature; the size of the reflected image from the cornea is measured by a variable image-doubling technique.

An Hbmeter (Figure 6) determines the hemoglobin concentration in blood. The instrument compares the absorption of light by hemoglobin in a carefully defined depth of hemolyzed blood with a standard glass wedge of similar absorption characteristics.

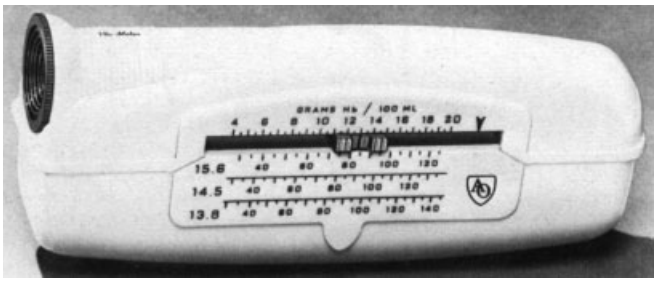

Figure 6. Hemoglobinometer. (Copyright © American Optical.)

Other opto-medical instruments not covered above are the ear microscope, slit lamp, trial sets and refractors, optometer, keratoscope, projection perimeter, Nagel anomaloscope, photocoagulators, focimeter, noncontact tonometer, IR body temperature ear probe, and colony counters.

10 LASER-BASED INSTRUMENTS AND SYSTEMS

The highly coherent, high-power, well-collimated beams obtainable from lasers have rendered them extremely useful in different sophisticated instruments. Both accuracy and range of many conventional systems are enhanced using the laser radiation source. Shop floor, as well as field, alignment problems from micrometers to kilometers can easily be accomplished precisely with a laser beam.

As an example, the schematic diagram of an early military tank, laser-based, range-finder system is shown in Figure 7. The laser transmitter–receiver system and optical sight are housed in the tank. The line of sight in elevation is aligned to the axis of the gun by means of a precision parallel linkage and in azimuth by coincident turret mounting. Bore sighting is achieved using controls on the unit with either a muzzle boresight or muzzle reference system. Gunlaying is achieved through a ballistic graticule.

A laser speckle interferometer is used to measure small displacement, vibration, deformation, turbulence, contour generation of three-dimensional objects, and for thermal mapping; it is analogous to holographic interferometry. It is based on the principle that scattered laser light from a grainy surface (grain size larger than the wavelength of light employed) gives rise to an interference pattern (called *speckle*). Overlapping of two speckle patterns produces Moiré fringes.

Using a laser source and flexible optical fiber as a probe, it has been found possible to measure vibrations inside a closed chamber or of other places where normal optical techniques may not be suitable. The fiber bundle carries the object beam forming one arm of a

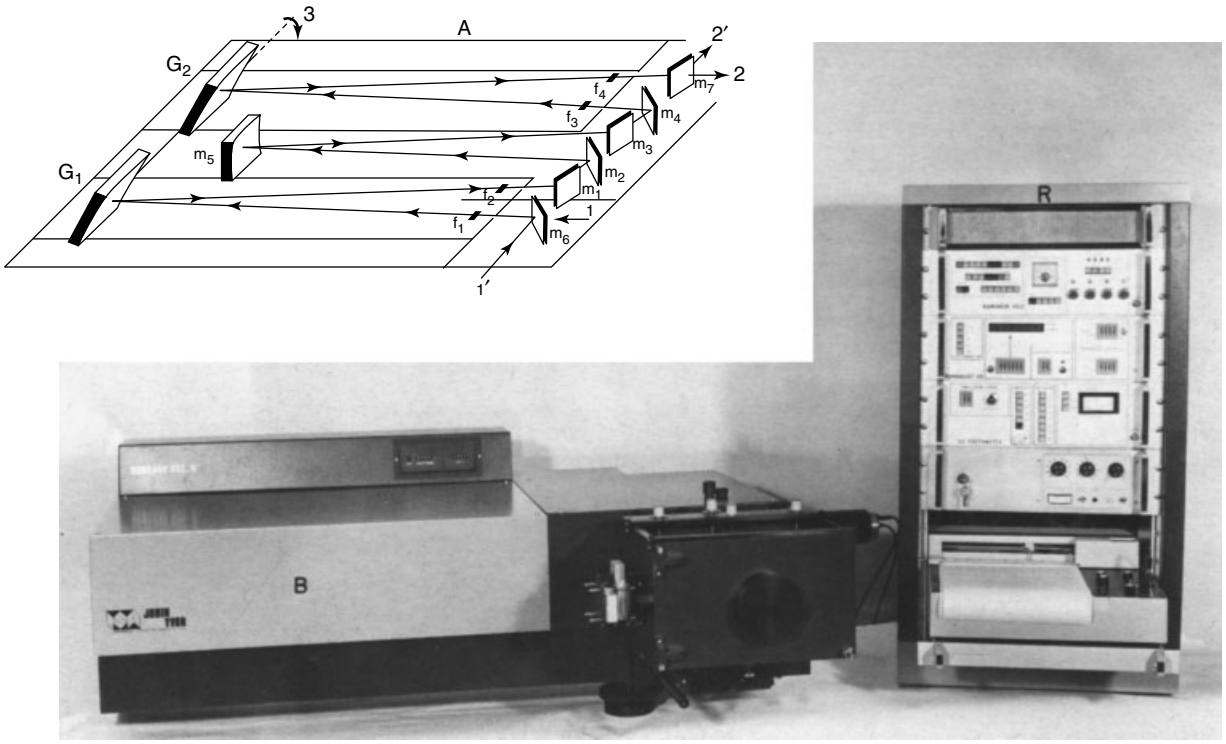

Figure 8. Laser Raman spectrophotometer: A, optical diagram; B, basic unit; R, detection system; 1, entrance beam path; 1′, alternate entrance beam path when m_6 is present; f_1, f_2, f_3, and f_4, stepping-motor controlled slits; m_6, kinematically mounted plane mirror, which permits use of 1′ as entrance path; 2′, alternate exit beam path when m_7 is present; 3, grating holders and shaft; G_1, G_2, holographic gratings; m_1, m_2, m_3, m_4, m_5, plane mirrors, and concave mirror for imaging exit slit of first monochromator f_2 on entrance slit f_3 of second monochromator; and m_7, kinematically mounted plane mirror to permit use of 2′ as exit path. (Copyright © Jobin Yvon.)

Twyman–Green-type interferometric setup. The laser interferometer has also been used in the measurement of refractive index variation, plasma density, and fluid velocity with the laser velocimeter.

A laser Raman spectrophotometer is based on the principle that a change in radiation frequency occurs due to molecular scattering. This has become a very powerful tool for studying vibrational and rotational energy levels of a

test sample. A commercial model of a laser Raman spectrophotometer, together with its optical diagram, is shown in Figure 8. The instrument employs two concave, aberration-corrected, holographic gratings with 2000 grooves/mm and offers a resolution better than $0.5\,\mathrm{cm}^{-1}$ at $0.5145\,\mu\mathrm{m}$.

1 BASIC PARAMETERS OF OPTICAL INSTRUMENTATION

In general, optical instrumentation may be classified as either imaging (e.g. camera lens) or afocal (e.g. telescope), where the term 'optical' strictly implies operation within the visible band (∼400 nm to ∼700 nm) although the ultraviolet and infrared spectral bands are also included here.

There are a large number of basic design parameters associated with an optical instrument, such as focal length, numerical aperture, magnification, and distortion; however, here we consider more specifically wavefront and image quality.

1.1 Wavefront quality

Imaging systems: Light from an object point, emerging from the exit pupil of an imaging optical system, will ideally be in the form of a spherical wavefront capable of focusing to an image point the size of which is limited only by diffraction effects. When this spot size is achieved, the system is said to be diffraction limited. Real optical systems generally have aberrations that degrade the wavefront leading to larger spot sizes and lowered resolution.

Afocal systems: For an afocal system (not image point forming), a plane output wavefront is implied. In the case of visual systems, however, a departure from this condition may be used to correct refractive error for the users.

1.2 Overall image quality

In addition to wavefront quality, this depends upon factors such as system transmission losses, chromatic aberration, image distortion, and the effects of stray light. Wavefront vignetting due to internal aperture sizes and positions will also affect final image quality (by modifying the numerical aperture) as will the method of detecting the image. In visual systems, the eye may limit image quality; with conventional camera systems, film grain size and the processing method may be the limiting factor. For digital cameras using CCDs (Charge Coupled Devices), resolution is limited by the pixel size.

2 PRINCIPLES USED IN TESTING OF OPTICAL INSTRUMENTATION

2.1 Interference

Wavefront amplitude and phase: Optical radiation propagates in the form of a wave. A converging wavefront must

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

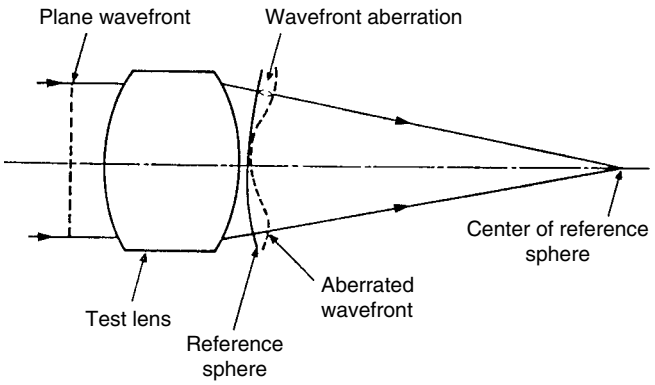

Figure 1. Wavefront aberration related to the reference sphere. (*Source*: Reproduced by permission of Sira and IoP Publishing.)

be perfectly spherical if the minimum focal spot size is to be achieved. By comparing a real wavefront with a perfect reference wavefront, we can specify the wavefront error, Figure 1.

Two-beam interference: If both reference and test wavefronts are 'coherent', then interference fringes will occur. Maximum fringe intensity occurs where the local phase difference in radians is given by,

$$\Delta\phi = n2\pi \text{ radians}(n = 0, 1, 2\ldots) \quad (1)$$

2.2 Diffraction

The diffraction effect: When a beam of light touches an aperture boundary, the beam is spread slightly (diffracted). For a circular aperture, this spreading causes the beam diameter to increase. The amount of spreading is related inversely to the wavelength of light used.

Airy disc and point spread function (PSF): In the case in which diffraction effects were absent, a perfect spherical wavefront could produce an infinitely small focal spot. Diffraction effects, however, limit the minimum possible spot diameter to the Airy disc (a fact made use of in Knife-edge and Star Tests). This diameter increases when optical aberrations are present. The distribution of intensity in the image plane is represented by the PSF.

Line spread function (LSF) and edge spread function (ESF): By scanning a narrow slit across the PSF we obtain the LSF. For practical purposes, the LSF is usually obtained by scanning a slit aperture across the image of a slit source (or alternatively by imaging the slit source onto a 2D array detector). This function is useful when we wish to assess image quality using an OTF Optical Transfer Function bench. An associated function, the ESF, can also be used to determine OTF. This function is derived by recording the energy passed by an edge boundary moved across the image plane (Williams, 1999).

2.3 Optical transfer function

We can consider image quality measurement in terms of both 'spatial' (e.g. millimeters) and 'spatial frequency' (e.g. cycles per mm) units. These two domains are related through a Fourier Transform. By performing a Fourier Transform of the (spatial) image, LSF, we obtain the OTF having both amplitude modulation (MTF or Modulation Transfer Function) and phase (PTF or Phase Transfer Function) terms. MTF is of particular significance, giving information on image contrast (Williams, 1999).

3 EQUIPMENT USED IN TESTING OF OPTICAL INSTRUMENTATION

3.1 Radiation test sources

Incandescent sources: One of the most useful is the quartz tungsten halogen lamp where a tungsten filament is enclosed in a quartz envelope (*see also* **Article 91, Light Sources and Detectors, Volume 2**). The halogen gas and quartz envelope allow the lamp to be run at high temperatures, thus shifting the continuous spectral curve to shorter wavelengths (down to ∼350 nm).

Gas discharge sources: At low pressures, gases such as Na and Ne, and Hg vapor, will radiate just at fixed resonant wavelengths. Such spectral line lamps are useful for wavelength calibration purposes. As pressure is increased, so will light intensity; however, the lines will gradually broaden and be superimposed on a spectral continuum. Mercury lamps are widely used, with the 546.1 nm spectral line being a common optical standard.

Arc lamps: Two closely spaced electrodes located within a quartz envelope filled typically with high-pressure xenon gas or mercury vapor. Very bright concentrated sources are produced with resonant lines superimposed on a thermal radiation continuum. Compared with tungsten halogen sources they produce more ultraviolet light and much higher brightness in the visible band.

Lasers and Light emitting diodes (LEDs): A laser source has the special property of 'coherence', which is

put to good use in the interferometer. Laser sources also have intrinsically very high brightness and narrow bandwidths. For optical testing purposes, the He–Ne (633 nm) laser is frequently used; others are available such as the CO_2 laser for testing in the infrared (10.6 μm). The LED is similar to the laser except that it does not have an optical cavity; consequently, the spectral bandwidth is broader and the coherence lower.

Blackbody infrared source: An ideal blackbody source completely absorbs all radiant energy striking it and, therefore, appears perfectly black at all wavelengths. A perfect blackbody source emits radiation with an emissivity of 1 (see Burnay, Williams and Jones, 1988). Real sources, using controlled high temperature cavities, can emit wavelengths between 1 μm and >25 μm. The shorter wavelengths require higher temperatures. When used with a pyroelectric detector, the radiation source must be used with an optical chopper.

3.2 Test targets

USAF 1951 target: A significant number of targets formed from opaque line patterns deposited on substrates such as fused silica are available. These are used to assess resolution limit directly. One of the most common is the USAF 1951 target, shown in Figure 2. Use of this and other similar targets is considered in the Military Standardization Handbook (MIL-HDBK-141, 1962).

Slit and bar targets: Formed either by deposition techniques, or machined into a solid opaque substrate. In the latter case, substrate transmission is not an issue. These targets are frequently used to produce an LSF from which the system OTF can be calculated. Bar targets are generally multiple, wide slits with equal mark-space ratio.

3.3 Integrating sphere

Used to produce an output beam that is insensitive to any spatial, angular, or polarization changes occurring in the input beam. They do this by collecting input light through one aperture, which, after multiple reflections and scattering at a high reflectivity surface, eventually emerges through a second aperture at right angles to the first (see Figure 3). Integrating spheres are used to overcome problems such as spatial and angular response variations exhibited by many detectors and the effects of input beam position and profile changes.

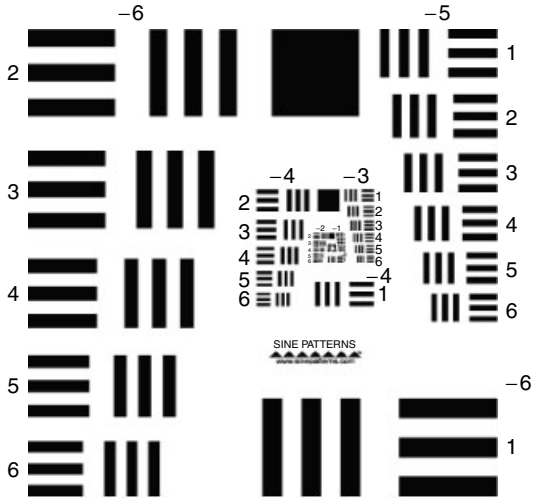

Figure 2. USAF 1951 target. Public domain. (*Source*: Copyright Sine Patterns LLC.)

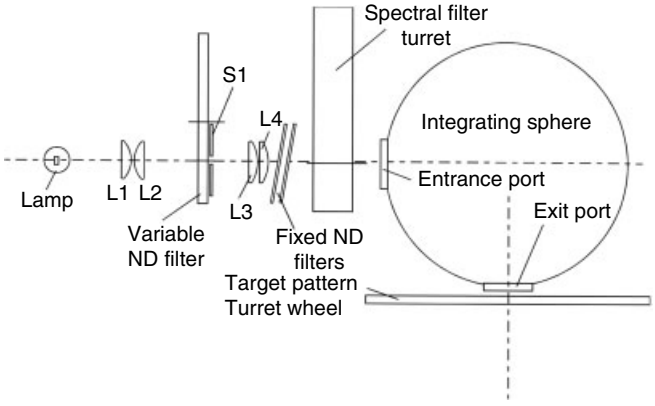

Figure 3. The integrating sphere as part of Sira's helmet mounted display test facility. (*Source*: Reproduced by permission of Sira and IoP Publishing.)

3.4 Knife-edge and star tests

Knife-edge or Foucault test: As shown in Figure 4, a sharp edge is positioned close to a beam focus, produced by a lens or mirror, with the eye immediately behind and focused at the exit pupil position. By moving the edge across the beam, sections of the exit pupil are seen to go dark in correspondence with the blocked rays. From the pupil patterns seen, experienced observers can deduce the aberrations present (Malacara, 1978).

Star test: For this test, the optical system is used with a point object (similar to a star) to produce a geometrical image that is smaller than the Airy disc. By using an eyepiece to examine the image, the experienced observer can

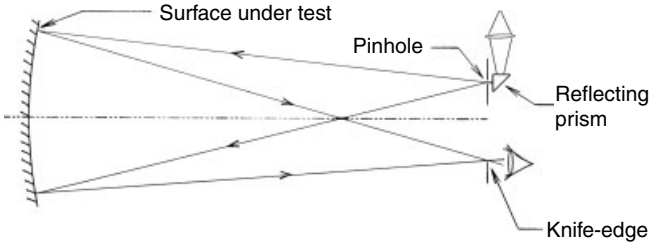

Figure 4. Knife-edge test configuration. (*Source*: Reproduced by permission of Sira and IoP Publishing.)

again learn a great deal about the aberrations present that affect the shape of the diffraction pattern (Malacara, 1978).

3.5 Interferometer

A number of different types of interferometer exist; however, in each case, coherent beams derived from the same source are made to interfere in the optical domain.

Perhaps the most common type is the He–Ne Fizeau. The laser beam passes into an air gap formed between two surfaces one of which is a plane (flat) reference surface. The other surface is the plane test surface. An interference fringe pattern is produced, which maps the errors on the test surface. Spherical test surfaces may also be examined when the interferometer is fitted with a special lens called a *transmission sphere* (see Figure 5). In this case, the last concave surface acts as the reference surface.

Because two-beam interference effects repeat for every 2π phase difference, the interferogram will be ambiguous outside this range. Phase shifting of the reference beam is commonly used to overcome this problem (Zygo Corp, 1998).

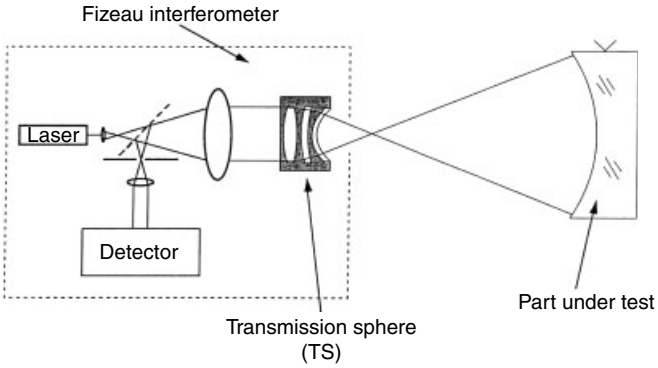

Figure 5. Fizeau interferometer test configuration using a transmission sphere. (*Source*: Reproduced by permission of Sira and IoP Publishing.)

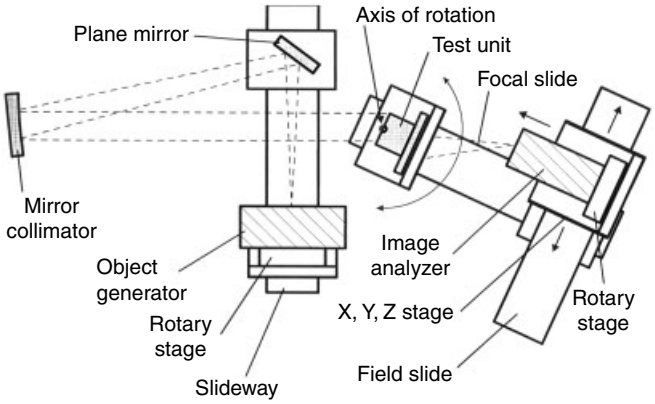

Figure 6. Typical OTF test bench configuration. (*Source*: Reproduced by permission of Sira and IoP Publishing.)

3.6 Camera/OTF bench

The camera bench is an important piece of basic test equipment and is used in the measurement of fundamental system parameters, such as focal length, magnification, and distortion. When used with a single element detector behind a slit aperture and a (scanned) slit source, an OTF bench is formed, Figure 6. Because the detector axis direction usually remains fixed, test limitations can occur at larger field angles in cases in which the image slit cannot be placed close to the detector surface. This is due to the signal falling outside the detector boundary. OTF benches often use an area array detector in place of the originally used image slit, which overcomes this problem (Williams, 1999).

4 LIMITATIONS TO TESTING OF OPTICAL INSTRUMENTATION

Limitations are broadly related to

1. accuracy of the measurement equipment,
2. suitability of the measurement configuration, and
3. environmental effects.

In some cases, the limitation may be absolute, in other cases the limitation may be reduced by careful recalibration of measurement equipment or changing the measurement configuration. Any tests made must take into account the instrument's intended mode of use. This is particularly true in the case of visual instrumentation where the users perception of image quality is a key factor (Haig and Burton, 1987).

In the case of an imaging system, such as a film camera, a common test would be to photograph a resolution test chart;

however, the results are generally subjective. It is therefore usually necessary to test the lens objectively. When performing OTF tests, measured image quality is limited through aberrations introduced by the optical components used to provide the input beam (although it is usually easy to make them insignificant). Wherever possible, additional components should not be used to relay the test image to the detector. Where this is necessary (for example, when testing afocal systems), the relay optics should be diffraction limited.

The use of interferometers, in conjunction with phase-shifting techniques, has the potential for high measurement accuracy. However, poor agreement between different instruments and operators has been a source of concern (Briers, 1999). Special techniques are also required when using high aperture (e.g. NA 0.5) transmission spheres (Selberg, 1990).

For visual system tests, it is usual to perform photometric measurements where an observer's response is standardized through a combination of detector and matching filters. While the overall detector spectral response achieved may appear close to the ideal form, small localized variations can result in significant measurement errors (Ohno and Thompson, 1998). These errors may be increased through effects such as detector ageing and filter degradation, uncorrected thermal dependence, and stray light. Periodic recalibration of such detection equipment is crucial if the highest measurement accuracy is to be achieved.

Testing of thermal (or heat) imaging systems operating in the mid- and longwave infrared presents additional problems. In particular, the optical elements and support structures are themselves a source of radiation that can lead to reduced image contrast. A common practice is to chop the infrared source, which can then be separated electronically from the DC background – *see* **Article 184, Photon Counting, Volume 3**. This technique is effective when performing OTF measurements; however, limitations will occur when accurate radiometric measurements are required, unless the temperature and emissivity of the chopper blades are known. The limitation may be reduced by using a chopper with mirror blades, which allow a calibrated blackbody to be imaged during the obscuration period.

Precise knowledge of target and background plate temperature and emissivity is also required when undertaking other forms of differential temperature imagery (e.g. Minimum Detectable Temperature Difference, or MDTD, and Minimum Resolvable Temperature Difference or MRTD) as thermal imagers respond to radiance and not temperature differences. Further consideration is given to this aspect in (Burnay, Williams and Jones, 1988)).

In the above text, we have seen that thermal and stray light effects can act to limit the accuracy of test measurements. Other environmental effects, such as vibration, shock, and humidity, can similarly limit performance. Vibration, for example, can affect significantly the accuracy of interferometric measurements. This is particularly the case when using phase-shifting hardware.

A very wide range of optical instrumentation exists, from complete imaging systems to instruments that are themselves used in the testing of other optical instruments. As a consequence, a wide range of test requirements will also arise. By understanding the physical limitations involved and adopting environmental control procedures and regular equipment recalibration, an acceptable result can usually be achieved.

5 LIST OF GLOBAL OPTICAL CALIBRATION FACILITIES

The foremost optical metrology laboratory in the United Kingdom is the National Physical Laboratory (NPL):

National Physical Laboratory (NPL)
Queens Road
Teddington, Middlesex TW 11 OLW
Phone: (44 181) 977 3222
Fax: (44 181) 943 6458
E-mail: enquiry@npl.co.uk

1 ERGONOMICS AND HUMAN FACTORS ENGINEERING

Translated literally from the Greek words *ergon* (work) and *nomos* (science/laws), Ergonomics means the 'Science of work'.

The study of work has been traced back to a publication in 1713 by Bernardino Ramazinni on work related injuries.

Before World War II, the focus on workplace studies was on efficiency and productivity through time and motion studies by Taylor (1911) and Gilbreth (1911). Concentration on the design of military systems prompted a shift in focus to human performance, behavior, and safety.

The term *Ergonomics* was proposed by Prof. Hugh Murrell in 1949 and first applied to this field through the naming of the UK's human research focused Ergonomics society that year. It is this broader description of the field for which the term Ergonomics has been adopted. As the study of the human in the context of their working environment expanded so other terms such as the more general Human Factors (HF) and the more design specific Human Factors Engineering (HFE) have increased in use – for more on HFE *see* **Article 97, Design Methodology, Volume 2**.

Despite hot debate about the appropriate use of terminology, the terms Ergonomics and Human Factors Engineering are frequently used interchangeably. There are numerous definitions that seek to encapsulate all aspects of the discipline, each serving a purpose in setting out the scope for the discipline. In trying to cover this range, they tend to be relatively long and wordy. An alternative method of communicating the scope and purpose of this area is to convey the underlying philosophy of the discipline. This is put succinctly in the statement that Ergonomics is about 'equipping the man, *not* manning the equipment'.

This conveys the idea that in order to get the most from the total system, designs should be tailored to the capabilities of the human rather than relying on people to adapt to unsuited designs.

The practice of Ergonomics/HFE draws on a number of broad activities that combine to improve our understanding of human/system performance and ensure that this knowledge is available to positively influence system design in the goal of achieving more efficient and safer systems.

Ergonomics is underpinned by a knowledge base informed by research. Fundamental research in areas such as vision, memory, and motor skills provides data that can often be generalized across a wide range of contexts.

At a higher level of human function where basic functions, such as the senses and cognition, combine, for example, human behavior, the influence of functional combinations and context increases.

The consequence is a reduction in our ability to apply the findings of generic research for the purpose of prediction.

Given the limitations on prediction, final confirmation of design suitability is normally based on testing

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

within a close representation of the system's intended context.

To effectively influence design, it is important to package the accumulation of research knowledge and experience in a way that is accessible to multidisciplinary human factors and engineering design communities.

As with all areas of science, the published research literature is the main repository for knowledge. The level of domain knowledge required to retrieve, review, and apply this knowledge limits its widespread applicability. Countering this problem, a large number of documents have been developed to bring together principles of design, guides to best practice and agreed standards. Key documents in this area include Def Stan 00–25, UKMOD (2000); Mil Std 1472F, USDOD (1999); and ISO 9241, ISO (1993).

In the absence of an all-encompassing deterministic predictive model of human/system performance, it is necessary to study the human/system in context.

A wide range of tools and techniques has emerged from the human factors community over the years to support this activity. These tools include techniques for measurement, analysis, and for influencing the design cycle. Tools such as task analysis, that is, the systematic decomposition of an activity to support understanding and redesign, are a fundamental activity for most ergonomists seeking to understand the goals and associated activities carried out in pursuit of a system objective.

Human/system performance measurements, using a range of objective and subjective measurement tools and techniques within designs sensitive to the human/system variable, are a vital part of design testing.

At the top-level process, methods such as the Human Factors Integration (HFI) Program (UKMOD, 2000; UKMOD, 2002) – see other documents on http://www.ams.mod.uk/ams/content/docs/hfiweb/hfihome.htm, and the US Manpower Integration (MANPRINT) Program (see documentation on http://www.manprint.army.mil/manprint/guides/mpref-guidebook.asp), are followed to ensure consistency of analysis and to provide an audit trail of the human science support to the design process.

2 TASK CAPTURE AND DESIGN

Ergonomics at its most fundamental remains the science of work. It is not the study of the human in isolation, nor is it the study of the world around the person, although it draws on each of these disciplines. At its core, ergonomics is concerned with the activities of people, the design of the systems that define these activities, and an understanding of how the capabilities of the human and the demands of the environment impact on the way people interact with the world around them.

Given the central role of the activity of the human to the practice of Human Factors, it is not surprising that the documentation and analysis of these activities lies at the heart of many human factors studies.

The process of task description is often one of the starting points of any human factors analysis. The capture of a baseline description of a person's activities within the context of a system's function is an essential part of assessing opportunities for, and the achievement of, progress through design and development. It is not possible to demonstrate that a design change has improved a situation without establishing what went before.

Task description of an existing process can be a useful baselining diagnostic tool for revealing parts of an activity that are inefficient or error prone. At this point, there is a blurring between the terms *task description* and *task analysis*.

The widespread application of task analysis within the fields of ergonomics and HFE became popular in the 1950s. It has since been modified and tailored to a variety of objectives.

Task analysis has a key role in process and product design. This concept is akin to a ConOps – *see* **Article 67, Principle of Concept of Operations (ConOps), Volume 2**. It can be used to aid the allocation of function, product testing, and for the evaluation of workload. Accidents and assessments of the risk of accidents can benefit from the use of task analysis. A more complete description of task analysis techniques is available in Kirwan and Ainsworth (1992).

Task analysis methods are often distinguished by their method of subtask separation and organization. A widely applied approach to task analysis is called hierarchical task analysis (HTA). It starts with a high-level objective oriented description of the activity and proceeds to decompose the activity into goal focused tasks and subtasks.

The approach to HTA descriptions can be freely adapted to capture specific information relevant to the objective of the analysis such as information flows, or associated technologies. Frequently, the sequence and logic underlying the conduct of a task sequence is represented within the HTA box diagram.

A baseline task description of an existing process, when analyzed systematically, can reveal opportunities to rationalize the number, or order, of steps to gain time savings or reduce errors.

The form and content of the task description should be based on the objectives of the method. If the issue of concern is the mental workload placed on the operator, the task description should capture and represent the information flows over time.

This information, when applied to user walk throughs using representative scenarios designed to test the limits of the system, can provide a means of assessing operator loading and the associated potential for failure.

An alternative form of task description and analysis is the operational sequence diagram (OSD). A representation of the task sequences and the logical links between tasks can be a useful tool for examining the implications of changes to a system on its performance. This approach to modeling forms the basis of computer-based task-modeling tools such MicroSaint and the Integrated Performance Modeling Environment (IPME).

Occasionally, it can be useful to consider the linkages between subcomponents of a system. An example might be the analysis of communications between different people within a control room. A diagrammatic representation of the control room overlaid with lines depicting the distribution of communications amongst people within the control room can be a useful tool for examining the location of workstations and the information necessary to meet the control room's operational role. This method of system description is called *link analysis*.

3 CHARACTERIZING THE USER POPULATION

If a design is to take account of the characteristics of its intended user population, the key characteristics relevant to a system's emerging concept must be captured as a reference for the designers and decision makers.

If assumptions made about the intended population, such as the ability to recruit and retain highly skilled engineers as users, are unfounded, then the procuring organization could be left with an expensive system that cannot be operated due to insufficient numbers of capable operators. Within the UK's military procurement process the tool for characterizing the user is called the Target Audience Description (TAD).

The TAD is a document that is created early in the design concept phase of a procurement program. The TAD has become a standard tool whose structure prompts the gathering of information likely to be relevant to the procurement program.

The document starts with a general description of the current group who would be intended to use a system. A reasonable assumption for the manning of a system is that the future users will have the same level of skills and capabilities as the existing population.

There is a danger in specifying a highly technologically sophisticated replacement for an existing low tech system when the new system would require a range of skills, knowledge, and experience considered to be beyond the reasonable training expectations of the current population.

If the requirement for skills and training is noted at an early stage, the parallel processes of training and recruitment can be put in place over the timescale for system procurement.

It should, however, be recognized that in an increasingly technological world, the number of trades that will be competing for the pool of highly skilled individuals could also be expected to increase.

For the purposes of ergonomic design, the parameters of the population, including anthropometric, that is, body size, dimensions, should be captured.

The population ranges normally captured in databases and tables and formulae include stature, weight, strength, functional reach, leg length, sitting height, and hip breadth.

A wider list of anthropometric measures should be provided when the design has a large human/equipment integration component.

System designs are normally required to safely and comfortably accommodate potential users within the 5th to 95th percentile, that is, the percentage of the target population that can fit, reach, and operate the system.

In addition, cognitive attributes of the target population have become increasingly relevant for systems designers. This may be specified by selection tests applied to people within the target group. Selection criteria may provide an additional source of information regarding the group's normal spread of knowledge, experience, and skills as relevant to the design under consideration.

The TAD is simply a method of formalizing and reporting the capture and consideration of user attributes. Small-scale design programs may not justify the development of a full TAD. However, the process of capturing and considering these attributes at an appropriate level of detail has a place in all human system procurement and development activities.

4 ESTABLISHING CONTEXT

The study of human centered systems is inextricably linked with the context in which they are placed. It is on this premise that the ecological approach to human factors research is based. The ecological approach starts from the position that there is a reciprocal coupling between the person and their environment. It takes the view that the environment is both an opportunity for human action (or affordance) and a constraint. For example, a maze affords a path for progress while at the same time constraining the path's direction. From this perspective, it is clearly of particular importance to analyze it.
