An analysis of the environment should seek to identify those aspects of the environment that exert an influence over human behavior and contrast them against those behaviors that are specific to the individual.

5 TRAINING SPECIFICATION

As the systems we expect people to use become increasingly complex, there is a need to pay special attention to the demands this places on providing an effective mechanism for teaching the knowledge and skills necessary to support these interactions.

Training is a necessary overhead to effective system performance. This training must be considered alongside the more traditional cost estimation parameters of purchase and maintenance. Training programs should be designed to ensure that the necessary skills are transferred from the training environment to the operational environment. It is through this demonstration of transfer of training that the training program can be formally evaluated.

The normal approach to demonstrating a transfer of training is to compare the performance of a trained group against an untrained control group to demonstrate a statistically significant difference between the performances of the two groups. Under some circumstances, it is possible for a training program to have a negative transfer. An example might be the training in a flight simulation with a slightly different interface style to the real aircraft. Errors might arise because of the interface differences that have the effect of surprising the operator when they encounter the different real system.

Training systems cannot be solely assessed on their ability to support a transfer of appropriate skills to the real world. While real flight might offer a better transfer of training than the use of flight simulation, the cost of this approach can, in some circumstances, be prohibitive.

Training through simulation has the added advantages of graded, and total, control over the scenario and the ability to automatically gather performance measures with which to set up trainee development.

6 MODELING AND PREDICTION

The complexity of human interaction within the real world reduces our ability to predict outcomes. This leaves the practice of Human Factors with no alternative other than to conduct user testing in representative environments.

The time and logistical costs of running a user experiment is compounded by the time load on the subjects. Any opportunity to achieve the design benefits of user testing through performance prediction and modeling will have obvious savings in costs and timescales.

Human modeling and performance prediction is already used as a tool to support the design and analysis of human systems. There is a range of commercially available models that can be used to predict human performance in a number of ways. Stochastic, that is, based on probability, task models such as MicroSaint™ and The Integrated Performance Modelling Environment™ provide the researcher with the ability to specify task sequences and their associated procedural logic and performance parameters. By defining a concept task in this form, it is possible to make predictions about the likely performance of the task in terms of defined parameters such as completion time. The addition of other parameters such as information flow or physical load can be used to reveal peaks in workload that could have consequences for task performance.

There are several commercially available body modeling tools on the market including JACK™, Safework™, and Sammie™. These tools allow the user to specify the key anthropometric dimensions of virtual mannequins.

Most of these tools allow the user to import virtual Computer Aided Design (CAD) models of concept equipments for evaluation within the virtual environment. To these are added the mannequin with the needed anthropometric data; the two then can be made to interact.

These techniques have demonstrated benefits for the evaluation of issues of fit, reach, and vision. Some include basic modeling of the physiological stresses that might accompany varying posture and loads, although the true complexity for the human musculoskeletal system prevents these models from offering validated predictions of human biodynamics, that is, the study of dynamic forces on the body.

7 PROTOTYPING AND TESTING

The objective of HFE is often to draw conclusions about the merits of concept systems. The difficulty associated with this form of analysis is the fact that these systems do not yet actually exist. Human Factors has developed a wide range of tools and techniques focused on performance measurements that support the comparative evaluation of concept human/systems.

When a system component exists only as a concept, the researcher must be inventive in testing the projected capabilities. The normal approach to this is prototyping, that is, the creation of a model or simulation of a product.

If the availability of a new technology is anticipated within a few years, there may be a requirement to examine the potential issues that may arise in its usage or the implications for the normal approach to associated tasks.

If an early prototype of the technology is available, this can form the basis of product testing to examine these issues. In many instances, the early prototypes of new technologies are extremely limited in their functionality or are unduly bulky. In these cases, there is a danger that the generic capability illustrated by the prototype technology will be missed by the user who becomes distracted by the limitations of the prototype.

In cases in which the prototype technology is too immature for useful user testing, it may be possible to simulate the performance of the system. An example of simulating an immature technology is the use of a researcher to take the place of a proposed artificial intelligence system intended to aid the user in a task. The subject of the evaluation is not made aware of the method used to provide this functionality thus allowing the researchers to examine issues such as modes of interaction and user confidence in the system. This approach allows conclusions to be drawn that will contribute to design decisions that will have to be taken when the prototype technology reaches maturity.

1 COMPARING HUMANS AND MACHINES

This article continues the development of the topic of Human Factors begun in **Article 94, Human Factors Engineering, Volume 2**. There has been an uneasy alliance between people and machines over the course of history. The use of simple tools is cited as one of the first steps in the civilization of the human species.

Subsequent developments of agriculture and weapons are the basis on which civilization in its current forms evolved (Diamond, 1999).

With each technological advance, people have been able to achieve goals in increasingly efficient and effective ways. This is not to say that technology is consistent in delivering advantages. However, the underlying trend is a world in which the traditional labors of the human race have been reduced or replaced by the application of technology by those able to afford to develop and acquire them.

Our understanding of human performance is based on fundamentals revealed through human physiology, for example, Paul Fitts established a law for the speed and accuracy of motor movements, such as, hand control, through laboratory testing (Fitts, 1954).

A wide body of research reveals many parameters of human performance in the areas of speed, strength, and endurance as well as sensitivity to stimulus and the capacity for mental storage, retrieval, and processing.

In most cases, these parameters vary between individuals across the population and with the variations in both the task to be completed and the demands of the environment.

Despite the appeal of a reductionist model of human performance, the ability to accurately predict human performance within a conceptual system remains elusive.

The relationship between man and the engineering design of machines has been discussed in Sydenham (2003).

While the pursuit of this ideal continues, Human Factors (HF) practitioners are left to apply a combination of modeling and human testing within an iterative design cycle to achieve the objectives of true human/system integration.

Fitts contributed further to the toolset of the HF practitioner with his list comparing the performance of humans with machines (Fitts, 1951).

The original Fitts list consists of two columns, comparing the strengths of the person versus strengths of the machine. As technology continues its relentless advance, the ability to establish clear distinctions between the capabilities of people and machines is diminishing.

Opportunities exist to overcome human weaknesses such as physical and mental fatigue with automated solutions capable of quickly and accurately completing repetitive tasks.

Advances in computer technology have allowed machines to outperform people in areas originally considered to be the domain of the human. As a result, the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

original Fitts list serves little purpose beyond illustrating the rapid progress of technology.

That said, the underlying concept holds true. There remains value in considering the allocation of function between the different components of a system, including the person. An example of a modified Fitts list is shown in Table 1.

2 THE INTERFACE

People interface with the world around them by physical actions directed by the nervous system based on sensory inputs. Our ability to sense our posture in relation to the earth's gravitational force and coordinate our muscular response accordingly is the basis by which we are able to stand erect. The rapid feedback loop, from our sense of vision, balance, touch, hearing and so on, allows us to walk, run, and jump in a dynamic environment. The evolution of human capabilities is based on the demands of survival in the natural world. It is against the framework of these capabilities that we must consider and tailor the interfaces of the modern world.

Many of these fundamental parameters of human capability have been well established.

Wavelengths of energy visible to the human eye are defined (400 to 700 nm).

Frequency and intensity of sound waves comfortably heard by the human ear have been established (20 to 20 000 Hz with a sensitivity ratio of 1 : 1 billion).

Resolution of tactile sensation that can be felt over different areas of the human body has been mapped out (2 to 3 mm at the finger).

Across this range of sensory capabilities some modes are better suited to communicating certain information than others, depending on the context of the task and the environment.

Variation in sensory capabilities across a user population places further limits on the method of information presentation.

Table 1. Modified Fitts list.

Human	Machine
Inductive reasoning	Deductive reasoning
Pattern detection	Parallel processing
Improvisation	Processing capacity
Task shedding when overloaded	Accuracy of calculation
Relational memory retrieval	Speed of response
Integration of multiple senses	Absence of fatigue or boredom
Adaptive learning and skill	Supra-human sensory capabilities
Mobility	Data storage and search

Many issues face the interface designer. The task is to clearly and unambiguously present the person with the necessary information without overloading them and to make it as easy as possible for them to implement the actions they decide upon in a timely and error-free manner.

Measuring systems are there to interface the use to the state of selected physical variables; human-factors engineering is therefore part and parcel of measuring instrumentation design.

3 THE VISUAL INTERFACE

Human vision is the primary source of input for most human tasks. The eye shares many similarities with the camera focusing light with a lens on the retina.

The retina is made up of approximately 100 000 low light sensitive rods and 60 000 color sensitive cones that provide daylight vision, which in combination offer a range of light sensitivity from 1 billion to 1.

Photoreceptors are not evenly distributed on the retina. In the region of the fovea, the high concentration of photoreceptors provides a resolving power of 1 min of arc as compared to several minutes of arc in the periphery of the retina. As a consequence of this distribution, visual attention is based on head and eye movement focusing the area of interest on the fovea with the peripheral vision providing an additional cue to visual attention through the detection of movement. Movement of the eye is finely controlled and can range from slow to extremely fast (over 400 degrees per second).

It is important to recognize the capabilities and limitations of the human visual system when designing interfaces to take advantage of this primary sense.

A key factor to recognize in the design of visual interfaces is the singular attention of the human. People can look quickly between different locations but can only focus on one point at any one time.

Efficient design of displays requires a consideration of the task they are supporting and the load the design places on the operator. If there are a number of display elements that need to be monitored at the same time, they should be colocated in a logical fashion to reduce the time taken to search between locations.

A good example is the design of the head up display for fast jet aircraft cockpits. The display places the key information required by the pilot to operate the aircraft and its supporting systems, as an overlay on his view of the world. This allows the pilot to spend more time 'head out', observing the world through which they are flying thus raising the opportunities for developing situational awareness.

Color should be used with care. Although color can help highlight important features of a display, or indicate the

Table 2. Color associations.

Color	Conventions	Other associations
Red	Danger Emergency Failure	Stop Fire Hot
Blue	Mandatory	Water Sky Off Cold
Green	Safe	Safe passage, Exit Continue
Yellow and black	Caution	Ambient Delay Warm

grouping of common elements, its overuse can have the opposite effect, distracting the user instead.

Inappropriate color combination can reduce the contrast between different elements of a display disguising information and reducing the effectiveness. It should be noted that people link colors with particular attributes or task specific associations. In addition, it should be noted that individual variations amongst the population, for example, color-blindness, and changes to the ambient light levels can dramatically alter the perception of a color scene.

Table 2 includes a list of common associations for colors and their combinations.

4 THE AUDITORY INTERFACE

Hearing is the next most important source of information input after vision for most tasks. Hearing and speech is a highly evolved method of communication.

When we talk to another person, we are using an interface in which participants sense and interpret the speech and expressions of the other person, forming a response and then responding through the formation of speech or some other action.

Humans learn to speak through a process of training, trial and error, when growing up. It is a highly effective and adaptable form of communication containing subtle nuances that convey information at a number of levels that are received and recognized in a way that is currently impossible by machines.

When communicating with a person who does not share your language, it is often possible to adapt your technique using gestures and a few shared words to convey meaning, but the speed and quality of the information is degraded.

At a lower sound level, the introduction of noise may mask some of the information leading to misinterpretation. In these circumstances, we tend to use visual cues such as the movement of the other person's mouth as well as an anticipation of what might be said, based on the subject of the discussion, to fill in gaps in the information masked by the noise.

Hearing can be a useful alternative to vision for the communication of information, particularly when we do not wish to be distracted from a visual task. For example, it is possible to conduct a simple visual search task while maintaining a conversation.

It can also be a useful medium when the display of visual information would be difficult for example, at night. Auditory warnings are used extensively to attract our attention away from a visual task. The characteristics of the sound can be tailored to convey the importance of the message thus increasing the amount of information a relatively simple warning sound conveys.

5 THE OTHER SENSES

While vision and hearing are the main sources of information to the human user of a system, we are sensitive to many other attributes of our environment.

Walking along the street draws on visual input to judge where to place our foot when taking the next step. Auditory information warns us if there is traffic approaching from behind. Our vestibular system continually updates our orientation without which balance would be impossible. Proprioceptors in our feet tell us when our feet are in contact with the ground. Our linked senses of smell and taste might play a part in directing our destination in search of somewhere to have lunch.

The ability of the human to filter and integrate the vast amounts of information continually received from our broad range of sensory capabilities and our ability to adapt our processing of this information in a changing environment sets us apart from machines.

6 CONTROL DEVICES

The human ability to sense our environment is just one part of the story when considering the human, or the Man Machine Interface (MMI).

As mentioned above, the information we receive is processed at several levels in our central nervous system from reflex responses up through lower brain control to higher cortical control. Having decided on a response to the information gathered by our senses and their relation to other memory and cognitive processes we are able to influence our environment. Our methods for influencing the environment are based on bodily control through the

movement of our limbs and our ability to communicate using speech.

From the most basic tools, such as a rock used to open a nutshell, through to a pilot's yoke linked to a sophisticated fly-by-wire jet aircraft, we convert physical movement, through gripping objects, into a desired outcome. Our ability to tailor these tools to our requirements is central to our ever-advancing technologies.

The shaping of the earliest flint tools to the hand size of its intended user illustrates our early skills in tailoring to our requirements. In the case of aircraft controls, the need to tailor the design to the capabilities of potential pilots continues to hold true with the need to avoid the exclusion of users on the grounds of hand size or grip strength, and so on.

The usability of controls extends beyond the person's ability to physically grip or manipulate the control device. Our ability to use controls is based on an expectation of their function. We are able to use a hammer because we have past experience of hammers and their use. The hammer itself provides us with cues to its function with an obvious area to grip and a flattened metal area for hitting the nail.

More advanced tools/machines rely on the same components of knowledge and cueing to convey their function to the human operator. For complex systems such as an aircraft flight deck, this places a requirement for consistency in design and operation without which pilots experienced in flying planes with different controls will require retraining and, even once trained, may make errors owing to a tendency to revert to the operational expectations of other systems.

This expectation of how something operates can be seen on a wider scale with the existence of population stereotypes such as association with twisting a tap head clockwise to turn it off. When designing a system that may be used by a multinational population, these stereotypes may change with a consequent risk of error.

Where clear conventions exist, such as turning a wheel clockwise to move a vehicle to the right, they should be adopted.

Where there is some doubt over the natural physical relationship between the cause and effect, for example, using a horizontally mounted joystick to move a cursor up or down a screen, the stereotype of the population should be explored.

As the design of interfaces shifts from physical design toward one of human computer interaction design, this tailoring of the controls has developed a new emphasis on information flow and the associated mental workload. The basic objective of ensuring that the capabilities and limitations of the potential user population are respected continues to hold true across this range of technologies from the very simplest through to future technologies yet to be conceived.

This article has provided an introduction to the Man Machine Interface. The topic is extended by explaining the six human factor domains in **Article 96, The Domains of Human Factors Integration, Volume 2**; and **Article 97, Design Methodology, Volume 2** covering how to go about designing for Human Factors.

1 HUMAN FACTORS INTEGRATION AND MANPRINT

Large-scale acquisition, for example, military procurement, is normally approached at a high level with the aim of achieving a general capability. The lower level objectives and the functionality required from any system designed to fulfill this capability are often unclear at the outset.

Procurement programs generally set out a vision of the capability and then set about establishing, in ever-increasing detail, the system design solutions necessary to achieve the vision – *see* **Article 63, Outline of Systems Thinking, Volume 2** and other articles within the section *Engineering a Measuring System.*

Commonly adopted procurement processes share similarities in their approach, stepping through defined sequences of specification, design, refinement, acceptance, delivery, through life support, and finally disposal.

The process is normally interspersed with milestones by which the progress of the program is assessed and approval to continue is attained – *see* **Article 66, Phases of System Life Cycle, Volume 2** and **Article 69, Requirements Allocation, Volume 2**.

This process is well suited to the specification and testing of tightly defined engineering solutions designed to meet a clear functional requirement – *see* **Article 69, Requirements Allocation, Volume 2**.

However, where human performance contributes to total system effectiveness, the users' capabilities and limitations must be taken into account. At the same time, the added complexity of human involvement reduces the predictability of design alternatives taken within the development process, thus limiting the degree to which the requirements can be tightly specified or met.

Despite these difficulties, accounting for the human component must not be overlooked. To the contrary, the need was recognized for a more effective way of inserting Human Factors Analysis into the defence procurement lifecycle. From this requirement, emerged the Manpower Integration (MANPRINT) program, developed by the US Air Force in support of their system acquisition program, MANPRINT (2003).

MANPRINT sets out the necessary Human Factors inputs to the procurement process in the form of prescribed analysis and reporting for each stage of a system's procurement. Further guidance was provided through its positive direction to design teams to consider defined areas of Human Factors assessment, called *domains*. These are considered here.

UKMOD adapted the MANPRINT framework to map onto their own updated procurement process (UK MOD 2000). The UK's Human Factors Integration (HFI) program defines the Human Factors specific roles and responsibilities of the Capability Working Groups and Integrated Project

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Teams prescribed by the overall procurement process thus giving HF a formal place in the development cycle.

Central to the HFI process is the activity of Early Human Factors Analysis, in which concepts are reviewed within the domains of HFI. This is started at the earliest opportunity to avoid where possible costly changes to the final design due to the discovery of incompatibilities with the human user. The specified activity of Early Human Factors Analysis compiles a log of the issues identified within each domain, the plan for each issue's resolution, and the process toward an acceptable design.

As defense equipment includes numerous measuring systems that have to perform in demanding conditions, MANPRINT methodology will be found useful for measuring systems design of all kinds.

2 MANPOWER

The Manpower domain of HFI is concerned with the number of people required to operate and maintain a system.

This consideration goes beyond the issue of the person sitting at the controls of a piece of machinery, extending to the people required to train that person, maintain the system, relieve that person when they become fatigued, and so on.

When considering large system structures involving many people, such as the manning of a ship, the logistical issues of manpower can become critical to the sustainability of the system. For example, the total cost of a naval ship owes far more to the manning and sustainment cost than it does to the hardware purchase costs.

This situation is commonly met in many of today's systems. A design or operational approach that efficiently uses the capabilities of the people to reduce the total number of people required to operate a large system can represent a significant financial saving.

Reducing the number of people available for operating a system is likely to raise the responsibilities and associated workload placed on those remaining. The sustainability of this approach must be considered across a range of scenarios. For example, it may be possible to conduct the normal operations of the ship under a peaceful scenario with a given staffing level. If, however, a wartime scenario places raised demands on the crew and their ability to consistently perform at the required level cannot be sustained, this situation must be accounted for.

Important implications can arise if the design demands a higher entry requirement for the people chosen to operate the ship than those currently employed in similar roles. If this is the case, then the availability of these people in the workforce and the ability to motivate them into working on the future ship will be important assumptions that must be planned for in the full life considerations of setting up and maintaining a capability. Similarly so with complex measuring systems such as are found in aircraft, transport systems, industrial plants, and medical health systems.

Where a system relies on a particular set of skills at different levels within the system, its design should consider the program's phasing demands to supply the right people with the right level of skills at the right time along with a sustainable succession plan over the lifetime of the system.

3 PERSONNEL

The Personnel domain of HFI is concerned with the characteristics of the people in relation to the requirements of the total system, in pursuit of the optimal system performance.

People's characteristics vary considerably; it is necessary to recognize their capabilities and limitations in the context of the system's demands on the person. It is also important from the point of selection and training and their associated costs to recognize when and where, in which subsystem, a system design is likely to demand particular aptitudes or knowledge.

In some cases, for instance in aircraft and race car cockpits, the system places physical constraints on the individual such as body size, physical strength, or a resistance to motion sickness.

Whilst training and experience can help develop candidates to meet a system's requirements in terms of physical strength, endurance, and motor skills, some attributes such as anthropometry are fixed.

Some trades require certain physical criteria for selection designed to ensure that the people selected are capable of meeting the requirements of the systems they support. For example, selection into the army demands a level of physical fitness that allows the designer of supporting systems to make certain assumptions about the target population's physical abilities.

The mental aptitude of the user group can greatly decide their ability to develop the cognitive skills necessary for contributing to the performance of a system. For example, market traders must demonstrate a capacity for extracting relevant information from a multitude of market information sources and apply this information, along with relevant knowledge and experience, to make informed decisions on the purchase and sale of assets. The personal attributes necessary to be successful in this occupation are not common across the whole population.

The design of any system should clearly establish the assumptions about the personnel it is making with regard

to the skills, limitations, and expectations of its intended user population; this will help ensure a significant mismatch does not arise. For large-scale system acquisitions, this is normally captured in a document called a *Target Audience Description* (TAD).

4 HUMAN FACTORS ENGINEERING

The Human Factors Engineering (HFE) domain of HFI is concerned with the physical and operational integration of the user with a system's process and associated technologies. These considerations extend to all aspects of human/system design and include guidance documentation, and a range of tools and techniques designed to ensure the full integration of the system's characteristics with the capabilities and limitations of the human operator, the demands of the task, and the attributes of the environment.

HFE within the HFI process is normally concerned with the specification of mandatory criteria such as are given in Def Stan 00–25 (A UK MOD Defence Standard) and Mil Std 1472F (A US DOD Standard) against which designs will be judged. These not only prescribe documents but also offer guidance for specifying both the known user specific–design constraints and the appropriate methodologies for ensuring that user requirements are established and accounted for throughout the design process.

An increasing concern of HFE is in the area of Human Computer Interaction (HCI). An analysis of the underlying task is frequently the starting point from which concept designs are created and iterated on the basis of subjective user feedback, workload assessments, and objective measures of human performance.

The traditional area of ergonomics also begins with the need to understand the task and the characteristics of the user to ensure an appropriate fit. Human body modeling, prototype development, and user-based testing and evaluation, all contribute to the activity of ensuring the fit between the human and the system. The knowledge, experience, and skills, both physical and cognitive, must also be determined to inform the design process. All of these processes have a large supporting literature – Chapanis (1996), Jacko and Sears (2002), Sanders and McCormick (1993), Tilley (2001), Wickens, Gordon and Liu (1997).

Human Factors analysis techniques must be sensitive to variations in the user population and the different contexts of operations. Designs must take into account different task demands dictated by possible scenarios, in which the system might be required to function.

The impact of different environments on the user population's ability to use the system in the intended manner needs consideration to allow appropriate changes to be made to the design or the intended operational procedure.

5 TRAINING

The Training Domain of HFI is concerned with the knowledge and skills required for operating and maintaining the system. The importance of training increases with the complexity of a system and with the negative consequences of system failure. Some instrument systems are easy to learn to operate but some require specific training to be used correctly. For example, using a simple digital voltmeter should not tax any competent technical person but setting up an automated test equipment console is another matter.

Consideration of the training requirements of a system should produce recommendations regarding what should be taught and the method that should be adopted for teaching.

There exist many approaches to training and many different scales of training appropriate to the system under consideration. Training for a simple system such as a common consumer product, for example, a television set, might simply take the form of a reference leaflet. People with experience of similar systems might not require the leaflet to access the regular features of the television, using it only to explain unfamiliar features.

Complex systems, for example, large software applications, such as setting up an exhaustive in-flight test plan for a new car, railway, or aircraft, are often accompanied by a training course that leads potential users through the available functionality and provides worked examples to ensure an understanding of the concepts on which the software's functionality is based.

Techniques, such as computer-based training and self-instructional packages, have increased in popularity given their ability to support training at a pace determined by the trainee without the overheads of a human trainer.

Computer-based training tool development should be based on a careful analysis of the knowledge and skills required by the trainees, and so are not suited to all training demands for a given system.

The use of simulation as a training tool has expanded the range of tasks that can be trained for using a computer. A current limitation to computer-based training is that it is only able to provide limited feedback. Humans still remain the most effective trainers across a wide range of contexts, offering insights based on a deep base of knowledge and experience combined with the power of inductive reasoning and wisdom to appropriately guide the trainees.

The normal form of training analysis and reporting applied to large-scale procurements is called the *training needs analysis* (TNA). Development of a TNA is conducted early in the design and development process setting out anticipated training system requirements such as the required facilities, the necessary fidelity, the time requirement for trainees, and so on.

6 SAFETY

An important responsibility of the system designer is to safeguard the well being of people using or coming into contact with the system. The System Safety domain of HFI is concerned with the risks to human health that might arise from system failure or use in an unintended manner.

Consideration of system safety is in reality an analysis of risk. This requires consideration of all aspects of system design and operation, in which the demands of the task place the operator, or bystanders, under a risk of injury.

This analysis must include opportunities for error in the operation of the system.

In each case, a standard risk assessment is normally undertaken, in which the likelihood of the risk occurring and the consequence for human safety are rated.

Issues revealed by this process can have additional implications for system performance that may not represent a significant risk to user safety, but may still result in the failure of a system to meet its objectives.

The output of a safety assessment and its risk analysis is usually a hazard log that characterizes the risk and draws on relevant expertise to establish measures that should be taken to mitigate the risk, for example, the mitigation of the risk of sailors falling from their yachts in high seas is usually a combination of harnessing, lifejackets, and location beacons.

In some cases, a conflict will arise between the proposed safety measure and the performance of the system. On rare occasions, users may be faced with a potential compromise between the risk of injury against the performance of the system.

When failure of the system has significant implications for the welfare of the individual, for example, in some military systems, there may be circumstances in which the individual may elect to bypass a safeguard in the interest of system performance. In such cases, it is important for designs and procedures to be developed that ensure safe use under normal circumstance and a reasonable balance of risks in life-threatening situations. Within the guides of relevant legislation, the design should allow the user to make these decisions when necessary. Safety in systems is also covered in **Article 99, Safety Organization, Volume 2**; **Article 100, Safety Analysis Methods, Volume 2**; and **Article 101, Assessing and Demonstrating Safety, Volume 2**.

7 HAZARDS

Whereas the Safety domain was concerned with risks related to the use and abuse of a system, Health Hazards domain of HFI is concerned with the conditions of operation inherent in the system and their impact on the health and safety of the human operator.

At the heart of hazard analysis is the consideration of the system's operational characteristics and the environment in which it operates.

Factors such as noise and vibration can have health implications for its operators and those around them.

Noise dose limits are set in legislation on the basis of dose limits worked out as a combination of intensity and frequency range. Vibration levels can have significant implications for the health of the individual with the link between prolonged doses of mid to high frequency vibrations to back pain arising from musculoskeletal injury. The combination of vibration, repetition, and wrist deflection when using power tools, has been linked to high incidence of repetitive strain injuries (RSI) such as vibration white finger and carpal tunnel syndrome.

Many mechanical systems include an inherent risk to the operator. Many systems contain toxic substances or produce toxic fumes from which the operator must be protected.

Similarly, moving parts present a risk to the operator with opportunities for cutting, trapping, and crushing limbs and digits. Well-established methods of guarding the operation of mechanical systems should be in place and should be tested against a range of potential operational scenarios including the risk of circumvention by the operators themselves.

Inherent risk to the vision of the operator can arise. Activities that require long periods of visual attention should be broken up into shorter periods to reduce fatigue. Some systems such as the use of high-magnification optics require safeguards ranging from training and procedures through to reactive optical filters that prevent operator blindness caused by pointing the device at a high luminance source such as the sun or a laser.

Extremes in temperature are a hazard to the operator whether they are a result of the external environment given the scenario or because of the heating or cooling of a component.

Where a risk is identified, consideration should be given to guarding against the risk, including an assessment of whether the system's operational procedure raises or lowers the individual's exposure to the risk.

1 THE OBJECTIVE OF DESIGN

The underlying objective of the design process is to provide a new or enhanced capability. Design can be either evolutionary or revolutionary in nature.

An evolutionary design takes discrete steps forward from an existing design's form and functionality.

The alternative is a revolutionary design in the capability that is normally associated with the availability of a new technological development that will support a new capability or an ability to do something in a new and improved way.

One difficulty associated with evolutionary design is that the expectations of the user are firmly aligned to the current product. This can have the effect of coloring their opinion of prototype systems that operate in a slightly different way.

Revolutionary design faces a different problem in that with no model to relate to, the potential users of a revolutionary system may have difficulty in grasping the role and function of the new system sufficiently to provide useful feedback for the system's design and evaluation.

In either case, the role of the user, as the foremost expert in their requirements, is vital in guiding the design process. The challenge facing the human factors practitioner is to ensure that users are provided with appropriate levels of information and experience of emerging concepts, and that any bias within the population are recognized and balanced where appropriate.

When designing a system, many attributes must be considered on the way to meeting its associated capability. Designs are a trade-off of attributes such as functionality, ease of use, cost, maintainability, training demands, and so on. For example, if you are designing a consumer product such as a kettle, the product's overriding objective is to appeal to the consumer market and thus achieve sales. The attributes necessary to achieve this go beyond the technology required for boiling water – to the cost of production, ease of use, and aesthetics of the design. Other issues such as brand styling and reputation may place additional demands on a design team.

Any design can be judged on the basis of its comparative achievement in providing a defined capability, that is, it must be fit for the purpose. It must not only provide the necessary functionality but also take account of the users' capabilities, the demands of the task and the restrictions of the environment.

As a consequence, designs should be considered in the broad context of their operating environment. Setting up the boundary limits of a project are covered in **Article 68, Setting the System Boundaries, Volume 2**. If a design does not account for the user's requirements, it will at best be inefficient and at worst be rejected outright by its intended user. Phases of the life cycle of a development are covered in **Article 66, Phases of System Life Cycle, Volume 2**. More on requirements generation

is found in **Article 69, Requirements Allocation, Volume 2**.

2 REQUIREMENTS SPECIFICATION

Specification of large-scale systems is frequently conducted as a two-stage process starting with a capability focused user requirement that is then refined to become a more detailed, functionality focused, systems requirement.

This is essentially driven by engineering-based, quality control processes. Guidance for the input of Human Factors into this process has been developed in the form of the UK's Human Factors Integration (HFI) Process and the US's MANPRINT program. In these programs, human analyses and their deliverables are mapped onto a defined acquisition process, in which the various customer and supplier responsibilities are prescribed, and the milestones for acceptance, delivery, and payment are set out within the framework of the design and development process.

The user requirements document normally sets out the characteristics of the current capability, its users and the procedures for use whilst describing the enhanced concept, its associated functions, and the context of operation.

Also defined is an initial assessment of the constraints, such as user recruitment, that might be placed on the future system and the measures of effectiveness, (MoE) by which a system could be evaluated. MoEs should be sensitive to all aspects of the concept capability and are particularly important for the evaluation of design options. Example measures include subjective measures such as user acceptance and objective measures expressed in terms of system performance and usage errors.

For large scale systems, the user specific information should include an overview of the likely capabilities of the target population, available numbers, existing training demands, career, retention issues, and so on.

The system requirement document (SRD) is normally a more tightly defined description of the required system and its components. It is derived through a process of user based–concept refinement using prototypes developed in response to the user requirements document (URD). This document sets out clearly defined functions and their associated performance criteria.

Human specific performance criteria should relate to issues of safety, operability, reliability, maintainability, training, and so on, and might include such performance standards and metrics as completion times, error rates, lifting limits, workload limits, and so on.

It will specify the necessary standards to adopt and should include appropriate Human Factors standards for design such as the UK's Def Stan 00-25 or the US's Mil Std 1472F.

3 THE DESIGN LIFE CYCLE

The design life cycle is a process of concept refinement to the point of production of a solution that can be implemented. The design of a new car or a new training program each start with a concept that brings together particular attributes perceived to present the intended product with a niche in the marketplace.

The design life cycle should extract and question the assumptions surrounding these perceived qualities whilst seeking to embody them in the final design.

The scale of the design process should be tailored to an appropriate level given the available resources and the consequence of design failure.

Safety critical systems rely on stringent safeguards that prolong the design cycle whilst some low cost commercial products can afford to fail in the market place as long as lessons are learned that improve the chances of success for subsequent products.

Design should be considered to be a competitive process. There are costs associated with the design process in time and money as well as disruption to the intended user of the new design, particularly when it is intended to replace an established system. The value of the proposed design enhancement should always be compared to a baseline taken from what has gone before. Where available, a comparison should be made with alternative designs.

If the life cycle process of a design raises the costs beyond the resources of the potential purchaser, or delays the delivery to a point that it becomes obsolete before delivery, the life cycle process will have failed.

There has been increasing pressure to reduce the time and costs associated with the design life cycle. This, in parallel with recognition of a user's inability to completely specify their requirements in the early stages of the design process, has led to a shift toward a process of concept prototyping and design evolution through user testing and virtual prototyping.

Within this process, there remains a need to establish clearly defined criteria for acceptance with which to evaluate the progress of a design and to manage the contractual obligations between the customer and the supplier.

At the same time, there has been recognition of the risk of failure associated with design and the need for a closer partnership between the user/specifier and the supplier/designer in moving toward a product that achieves the best balance between the inevitable compromises of design.

4 ACCOUNTING FOR USER VARIATION

Human variation must be recognized when designing for a heterogeneous population. Each person is an individual

in the whole population and it is important to recognize and design for the range of capabilities in a targeted user population.

Variation in size, weight, strength, sight, hearing, memory, experience, skills, and so on, can each influence our ability to use an interface or play a part as a component of a wider system.

From the perspective of design, there are four main approaches for accounting for human variation. These are product tailoring, self-adjustment, multiple versions, and one size fits all.

The tailoring of a suit to our body shape has similarities with bespoke software and product design offering confidence in a product's fitness for purpose, at a price.

The approach of allowing self-adjustment is highly suitable for many products. Car and office chairs must accommodate a wide range of the population and must therefore include the capability for adjustment, without which large proportions of the community would find the product unusable. Many of the mainstream software applications allow a degree of user adjustment to suit their working practices. It should be noted that too much adjustment capability can bring with it costs in adjustment time or even weaknesses in the structural integrity of a product.

The approach of producing multiple versions is familiar to us all through the purchase of off-the-shelf clothing. This term off-the-shelf has been adopted more widely to describe products that have already been developed and marketed. The two usages bear similarities in their associated cost savings.

The final approach of one-size fits all is appropriate for a subset of products depending on their intended purpose. The term is frequently applied to T-shirts that will look like a tent on some people and stretch to fit others. This design compromise frequently offers considerable savings at the cost of poor fits for proportions of the potential user population.

5 DESIGN STANDARDS AND GUIDELINES

The normal repository for the knowledge gathered through research on human attributes is the published literature and teaching textbooks; it is widely dispersed. The broad application of human sciences findings to system design and their implications for system success has led to the need for design standards and guidelines that are accessible to the design community.

These documents often have the dual role of offering advice to a designer as they seek to develop a product that integrates with the human, and at the same time setting out the expectations of the procurer by defining acceptable levels of performance of a system.

This is particularly important for areas such as human health and safety, in which design standards play an essential role in safeguarding future users of a system.

Several organizations develop standards for engineering design, including the International Standards Organization (ISO), the UK's Defence Standardization Organization (Dstan) and the US Department of Defence (USDOD).

Key Human Factors standards from these organizations include ISO 9241, Def Stan 00-25 and Mil Std 1472F. Whilst some are created for defense application, they are also useful to all human factors uses. Standards from the government military and some standards organizations are freely available on their Web sites. The ISO standards are available in some libraries, or can be purchased on-line.

Standards such as the UK's Def Stand 00-25 cover a broad range of human, task, and environmental attributes and their design implications.

Def Stan 00-25 assists the designer by defining known parameters of the military user population it serves providing the designer with reference tables for operator size, strength, sensory capabilities, and so on. It also provides guidance on appropriate strategies for design and testing to ensure that the government's requirements for integration of the human users are met.

6 CONCEPT MODELING

It can be quite difficult to tightly define specifications for a concept early in the design cycle. Without a product or system on which to base their assessment, users and designers alike encounter problems in specifying and refining their concepts.

A common approach to making these concepts more concrete as a tool for evaluation or design refinement is through modeling.

A model of a system can take many forms. The form chosen should reflect the purpose of the intended model. A simple paper-based prototype of a series of screen interface designs can be a low cost, quick to develop, and flexible tool for communicating a concept and seeking user feedback. High-end prototyping applications can be used to simulate the design and intended functionality of a proposed system. This might be a logical progression from the use of paper-based prototypes to refine a concept. The degree to which these methods are used depends on the complexity of the system being designed and the consequences of inappropriate design features remaining in the final design.

Given the costs associated with altering physical designs, there is an obvious emphasis on prototyping to reveal

design issues prior to the final production run. Physical prototypes can take many forms from cardboard mock-ups through to machined pieces. Computers are playing an increasing role in the modeling process with computer aided design techniques used to refine design concepts and to provide visualizations. Human body modeling tools offer the designer the ability to examine issues of population fit and reach at the very earliest stages of concept formulation, helping them to weigh up alternative design strategies and avoid the cost of large changes that would have been associated with discovering these problems further along the design path. More recently, the use of stereo lithography has increased to provide physical outputs to computer designs providing further realism to the process of evaluation.

7 PRODUCT EVALUATION

The evaluation of designs can be conducted at several levels. Evaluations might be an assessment of the design's fitness for an intended purpose or it might seek to compare two existing designs to determine which is the best, or the least bad, design for the intended purpose.

In the process of either evaluation, it is possible to reveal attributes of a design that are particularly suitable or unsuitable thus providing a third option by which desirable components of competing systems are brought together, or unsuitable components are enhanced in the process of developing a new and improved system.

It should be recognized when evaluating a design's fitness for a purpose, that it may be that the design was developed to meet a slightly different requirement of an alternative user group.

Variations in user, task, or environmental context can have important implications for the success of a design. Whilst there is much that can be done to assess the attributes of a potential system through basic analysis, the findings cannot assure one that it will provide absolute assurance of suitability.

Prior to final acceptance a design should be tested in its context, or perhaps within a close representation of that context, to reveal issues of suitability.

For example, the down selection between a number of new cars might be made on the basis of their promotional literature but the final selection before purchase normally involves a test drive of the remaining options. If you were buying a fleet of cars, there may be value in arranging for a longer term loan of a vehicle to consider other issues of suitability within your context of intended operation.

The process of comparative evaluation is similar with the availability of many tests possible for comparing competing products against a priority list of desirable features and negative attributes to be avoided.

There exist a number of tools and techniques that can be used to help in the development of a priority list of attributes in situations in which different users can be expected to hold different opinions. Approaches include workshops, ballots, and a tool called the *repertory grid*, in which attributes are compared individually and analyzed to produce a ranked list.

With all approaches, there is a need to ensure that users are given sufficient access to the designs under consideration of representative circumstances. Where required, training should be provided and the implications of skill development with training over time accounted for in the analysis and the interpretation of the user's subjective responses to a system.

1 CONCEPTS OF RELIABILITY AND MAINTAINABILITY

1.1 Reliability

Reliability is the ability of an item or system to keep operating, or to be available for operation, over a period of time without failing. Reliability can be defined as a mathematical probability of not failing or of being available for use.

Durability is the ability of an item to withstand wear out mechanisms such as fatigue, wear, and so on. Durability is usually expressed as a minimum time before the occurrence of wear out failures.

Reliability is also expressed as the mean time to failure (MTTF) (for an item that can only fail once, like a light bulb, microprocessor or interplanetary spacecraft), or the mean time between failures (MTBF), for an item that can fail and be repaired a number of times, like a car or an electronic assembly.

The MTBF measure implies that the rate at which failures occur is, on average, constant over the time considered, and then MTBF is equal to the inverse of the failure rate.

In the case of components that can only fail once, the expression *hazard rate* is used. It is often expressed as failures per million hours (fpmh). Failure rate and hazard rate are conventionally denoted as λ.

In the case of a constant failure/hazard rate, the reliability (R = probability of no failures over a time interval t) is

$$R = (1 - \text{probability of failure}) = \text{EXP}[-\lambda t] \qquad (1)$$

If the hazard/failure rate is not constant, other relationships apply. The reliability formula most often used is the Weibull distribution:

$$R = \text{EXP}\left[-\frac{(t-\gamma)}{\eta}\right]^{\beta} \qquad (2)$$

where γ is the failure-free life (durability), η is the location parameter, and β is the shape (or slope) parameter.

If $\beta = 1$, then the constant hazard/failure rate is represented, and η is the MTTF/MTBF. If $\beta > 1$, it represents a hazard/failure rate that is increasing over time (wear out).

If $\beta < 1$, it represents a hazard/failure rate that is decreasing over time (infant mortality).

Figure 1 shows the three basic patterns of failure that typically occur. This is often called the *bathtub curve*. As shown, it applies best for electronic systems but not so well for mixed ones with mechanical components.

Reliability statistics and methods are fully described in O'Connor (2002).

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

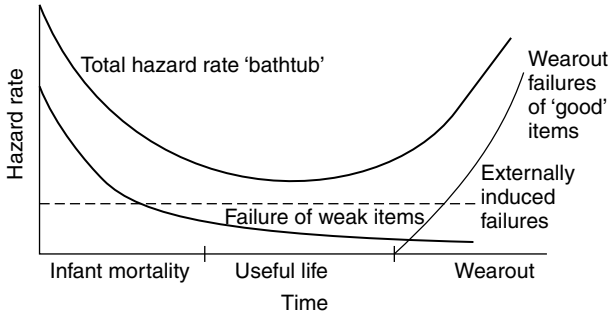

Figure 1. Patterns of failure: the bathtub curve.

1.2 Maintainability and availability

Maintainability is the property of an item to be returned to a working condition after failure (corrective maintenance, CM), or to be kept in a working condition by performing preventive (or planned) maintenance (PM). CM is expressed as the mean time to repair (MTTR). PM can be expressed as total time (e.g. man-hours) over a period.

Availability is the probability that an item or system will be available for use at a particular time, or the ratio of available time to total time. In the steady state, assuming a constant hazard/failure rate and no PM:

$$\text{Availability(A)} = \frac{\text{MTBF}}{(\text{MTBF} + \text{MTTR})} \qquad (3)$$

2 CAUSES OF FAILURE

There are many reasons and causes why a product might fail. The main causes of failures are the following:

1. The design might be inherently incapable. The list of possible reasons is endless, and every design problem presents the potential for errors, omissions, and oversights. The more complex the design or difficult the problems to be overcome, the greater is this potential.
2. The item might be overstressed in some way. If the stress applied exceeds the strength, then failure will occur.
3. Failures might be caused by variation. The actual strength values of any population of components will vary: there will be some that are relatively strong, others that are relatively weak, but most will be of nearly average strength. Also, the stresses applied will be variable. Figure 2 shows this general stress–strength situation. Failure will not occur if the applied stress does not exceed the strength. However, if there is an overlap (interference) between the distributions of stress and strength, and a stress value in the high tail of the stress distribution is applied to an item in the weak tail of the strength distribution so that there is overlap, then failure will occur. Obviously, it becomes more difficult to design against failure, or to predict reliability, in this kind of situation. We can no longer rely on simple, deterministic, values of load and strength. We now need to know how these values vary, particularly in the high tail of the stress distribution and in the low tail of the strength distribution. Values near the average, or in the opposite tails, are of little interest to engineers when considering this kind of failure, during design and test.
4. Failures can be caused by wear out. Figure 3 shows how time-dependent strength variation affects reliability. The level of uncertainty in predicting reliability increases considerably over time.
5. Failures can be caused by other time-dependent mechanisms. Battery run-down, material creep, and progressive drift of electronic component parameter values are examples of such mechanisms.

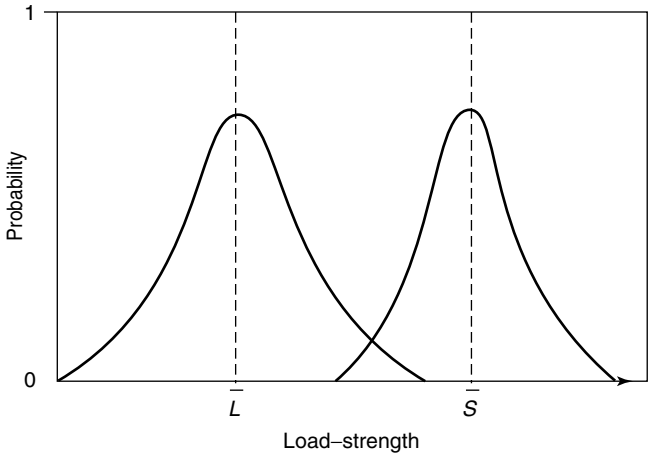

Figure 2. Stress and strength variation.

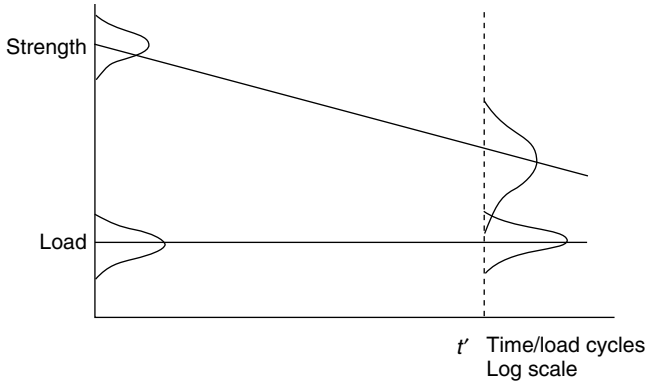

Figure 3. Time-dependent strength variation.

6. There are many other potential causes of failure. Gears might be noisy, oil seals might leak, display screens might flicker, operating instructions might be wrong or ambiguous, electronic systems might suffer from electromagnetic interference, and so on.

The important point to appreciate is that failures are by no means always clear cut and unambiguous. They are often open to interpretation and argument. They also differ in terms of importance (cost, safety, other effects). Therefore, we must be careful not to apply conventional scientific, deterministic thinking to the interpretation of failure data and the estimation of reliability.

For example, a mere count of total reported failures of a product is seldom useful or revealing. It tells us nothing about causes or consequences, and therefore nothing about how to improve the situation. This contrasts with a statement of a physical attribute such as weight or power consumption, which is usually unambiguous and complete.

3 DESIGN FOR R&M

Manual and computer-driven analyses are usually cheaper than testing, and testing also adds to project timescales. Therefore, designs should be analyzed as far as is practicable, (*see* **Article 71, Modeling Methodology, Volume 2**) to obviate or to reduce the need for testing.

Analysis can also show up which aspects of the design might need to be further investigated or confirmed by testing, by highlighting aspects that present risks or uncertainty.

Reliability, durability, and performance aspects that can be affected by variation are difficult to analyze effectively, so further testing is nearly always necessary to confirm these aspects.

Designs can be analyzed manually, with mathematics software, or with computer aided engineering (CAE) software. These include computer aided design (CAD), finite element analysis (FEA), electronic design automation (EDA), electromagnetics (EM) analysis, system simulation, and other tools.

The tools enable engineers to create and analyze complex and difficult designs quickly and economically. However, it is not safe to rely on the software to replace the need for testing. All CAE methods involve assumptions and simplifications that can, to varying degrees, generate erroneous or misleading results. No design analysis software can deal with the whole range of possible operating stresses, environments, variations, and degradation mechanisms that can cause failures.

Some methods are used specifically for R&M analysis of new designs. The methods most often used are the following:

Reliability prediction: The expected reliability of the new design is estimated, using data and assumptions regarding application environments, and so on. Reliability data is published for many component types, most notably the US Military Handbook 217 MIL-HDBK-217 (Reliability Prediction for Electronic Systems). However, this approach is nearly always misleading, on several grounds. The most notable are the following:

- Engineering components have no intrinsic, quantifiable property of failure rate.
- The mathematical models used to represent the effects of application conditions (temperature, etc.) on failure rate are not always consistent with the physical and other causes of failure.
- The data provided in such sources is nearly always of dubious quality and several years out of date in relation to the technology and capability, thus giving pessimistic/conservative predictions in comparison with what can actually be achieved with adequate engineering effort being applied.
- Failures do not generally occur at constant average rates over time. They can be time-dependent, cyclic-stress dependent, and so on.
- Component failures do not necessarily cause system failures, and system failures are not always the result of component failures.

Failure modes and effects (and criticality) analysis: Failure modes and effects analysis (FMEA) or failure modes and effects (and criticality) analysis (FME(C)A) is a method for tabulating all of the components (or functions) within a design, and asking the following questions of each one:

1. How can it fail in the application? (failure mode).
2. How likely is each failure mode? (failure probability or failure rate).
3. What would be the effect of each failure mode? (failure effect).
4. How critical is the effect? (failure effect criticality).
5. What should or could be done about it?

FME(C)A is widely used in many industries, particularly in those for which failures can have serious consequences, such as military, aerospace, transport, medical equipment, and so on.

Some industries have established standardized approaches (the US Military Handbook is MIL-HDBK-1629, and the US Society of Automotive Engineers (SAE) has also produced a guidance document).

Variation analysis: Variations (tolerances, environmental conditions, interactions, etc.) should be analyzed to ensure that they can be controlled and their effects are minimized,

see **Article 55, Uncertainty Determination, Volume 1**; **Article 52, Error Models, Error Budgets and their Calculation, Volume 1**.

Maintainability analysis: Maintenance tasks that might be necessary (failure diagnosis and repair, and PM tasks such as lubrication, cleaning, replenishment, calibration, etc.), must all be analyzed to estimate the effort involved and to ensure that they can be performed correctly by the people likely to be involved.

Conclusions: Since the analytical methods indicate the aspects of designs that are critical or might present risks, they provide an excellent basis for optimizing development and manufacturing tests. Therefore, the results of the analyses should be used to help plan and prioritize the tests, and the engineers involved should be part of the test team.

R&M design analysis methods are described in O'Connor (2002). Information on the most popular software for design analysis, with Internet contact information, is provided on the homepage of O'Connor (2002) *see also* http://www.pat-oconnor.co.uk/practicalreliability.htm.

4 TESTING FOR R&M

4.1 Reliability testing

Generally, functional and compliance testing of a new design needs to be performed only once, or maybe a small number of times or on a small number of items.

However, reliability/durability/variability testing usually involves multiple tests and test items, because of the wider uncertainty associated with these aspects. Another important difference is that we do not deliberately plan to cause failures in the first category, but we should do so in the second, using the methods of accelerated testing, as explained in **Article 214, Accelerated Testing, Volume 3**.

4.2 Statistical design of experiments DOE

In a statistically designed experiment, a range of tests is performed in which every variable is set at its expected high and low values (and possibly also at intermediate values), and the effects are recorded for each set of values. The results are analyzed using the technique of analysis of variance (ANOVA), which determines the magnitude of the effect of each variable, and of the interactions between variables.

Taguchi developed a framework for statistical DOE adapted to the particular requirements of engineering design, with the objective of making the design robust in relation to expected variations. The design process is explicitly considered to include the design of the production methods and their control.

Statistical experimental methods of optimization in engineering design can be effective and economic. They can provide higher levels of optimization and better understanding of the effects of variables than is possible with purely deterministic approaches, when the effects are difficult to calculate or are caused by interactions.

Table 1. Accelerated test/DoE selection.

Important variables, effects, etc.	DoE/Accel. test
Parameters: electrical, dimensions, etc.	DoE
Effects on measured performance parameters, yields	DoE
Stress: temperature, vibration, etc.	Accel. test
Effects on reliability/durability	Accel. test
Several uncertain variables	DoE
Not enough items available for DoE	Accel. test
Not enough time available for DoE	Accel. test

Note: These are by no means clear-cut criteria, and there will often be shades of gray between them. We must decide on the most appropriate method or combination of methods in relation to all of the factors: risks, knowledge, costs, and time.

4.3 Accelerated test or DoE?

Accelerated test and DOE are complementary approaches in development testing for reliability. Table 1 (from O'Connor (2002)) gives some guidance on which approach to select for particular situations.

4.4 Maintainability test

Testing for maintainability involves the timed performance of specified tasks. The maintainability parameters can be estimated using weighted averages, based upon the expected rates of occurrence of the tasks. See O'Connor (2002).

5 RELIABILITY DATA ANALYSIS

5.1 Reliability demonstration

Reliability demonstration testing (RDT) is based upon the method of probability ratio sequential testing (PRST).

The equipment being evaluated is operated for a period of time expressed as multiples of the specified MTBF, and as failures occur they are plotted against the operating time. Testing is continued until the staircase plot of failures versus time crosses a decision line. The decision lines are

constructed from the test criteria that have been decided beforehand. These are as follows:

- The upper test MTBF, θ_0, the level considered to be acceptable.
- The lower test MTBF, θ_1, the agreed minimum value to be demonstrated.
- The design ratio, $d = \theta_0/\theta_1$.
- The decision risks, expressed as percentages. The producer's risk, α, is the probability that equipment with an actual MTBF that is higher than required to pass, will by chance fail. The supplier's risk, β, is the opposite.

The tests are required to be performed using operating and environmental conditions that represent expected in-service conditions.

The method is the basis for US MIL-HDBK-781 and other standards, as described in O'Connor (2002). Figure 4 shows an example of a PRST plot.

Care should be exercised when considering its use. It should not be used during development testing for the following reasons:

- It implies that all failures are of equal importance, so that simple summation can provide the main criterion.
- It implies that all failures occur at constant average rates in time, in particular, that there are no significant wear out failure modes which could cause increasing numbers of failures later.
- It ignores action taken to correct causes of failures that have occurred.
- It ignores failures that have NOT occurred, but that might occur in future.
- By being based upon simulated instead of accelerated stress conditions, it does not effectively or economically stimulate failures to identify opportunities for improvement, as described in **Article 214, Accelerated Testing, Volume 3**.
- It generates an attitude that discourages the occurrence of failures, since the objective is to pass the test, rather than to generate improvement opportunities. The parties concerned argue about aspects such as whether or not particular failures should be counted and statistical interpretations, instead of concentrating on the engineering.

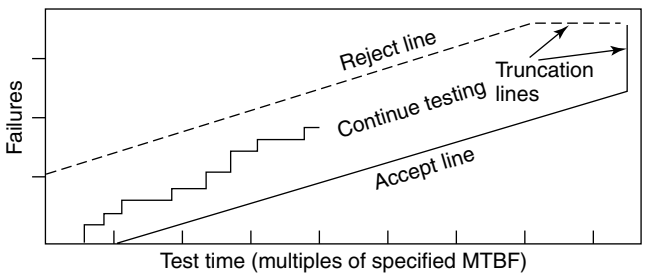

Figure 4. Probability ratio sequential test (PRST).

5.2 Reliability growth monitoring, RGM

Reliability growth monitoring (RGM) is the term used to cover a range of statistical methods that have been developed for comparing the MTBF measured during tests or in service with targets or requirements. The best known is the Duane method. The cumulative MTBF, measured at intervals, is plotted and compared with the target or required value, using logarithmic scales. The slope gives an indication of the rate of MTBF growth, and extrapolations indicate when the target or requirement might be achieved. Figure 5 shows an example.

These methods are subject to most of the same criticisms that apply to reliability demonstration tests. RGM should never be used for monitoring reliability growth during development testing, since the objective in this phase should be to generate failures as quickly as possible so that real reliability growth can be achieved by identifying and implementing improvements. It can be used as part of an in-service monitoring process, provided that it is supplemented by other methods that can help to identify failure causes and priorities.

5.3 Trend analysis

Times to failure of items on test or in service can be analyzed using a range of methods, to determine the underlying trends. The most useful of these are

- probability plots and hazard plots,
- time series analysis,

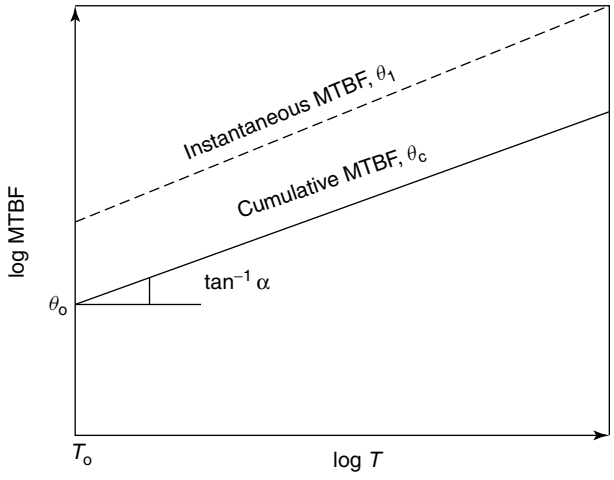

Figure 5. Duane reliability growth plot.

- proportional hazards analysis,
- M(t) method.

These methods are described in more detail in O'Connor (2002). Computer software is available for performing the analysis methods described. Software is listed in the book's homepage – http://www.pat-oconnor.co.uk/practicalreliability.htm.

6 RELATED CONCEPTS

6.1 Manufacturing quality

Manufacturing quality is just as important a driver of reliability as is design. Therefore, the reliability effort must include this aspect, see O'Connor (2002).

6.2 Safety

Safety and reliability are closely linked. The analysis and test methods used are mostly the same. Therefore safety and reliability effort and management should be integrated. *See* **Article 99, Safety Organization, Volume 2**; **Article 100, Safety Analysis Methods, Volume 2**; **Article 101, Assessing and Demonstrating Safety, Volume 2** and O'Connor (2002).

1 DEFINITIONS OF SAFETY

Safety is simply defined as 'Freedom from acceptable risk' (Railtrack, 2000).

This is a high level intention that needs elaboration.

What the concept means to an organization that designs and/or operates a system is better understood from a typical Health, Safety, and Environment Policy statement, the one chosen here being that of Rolls-Royce (2003), the designer and maker of aircraft engines, nuclear reactors, and other highly sophisticated engineering equipment that need the highest levels of safety in their manufacture and operation:

> 'The Rolls-Royce Group will make proper provision for the health, safety and welfare of its people, visitors and contractors and those in the community who may be affected by its activities. It will care for the environment through a commitment to good environmental practices. Continual improvement will be achieved by implementing the Group's HS&E Management System and related standards, which will include the setting of objectives and targets. As a minimum, the standards will meet relevant legal, industrial, and other requirements. ... etc.'

The statement continues, over a page, to address key aspects including how it will do this, who is responsible, the role of employees, its internal audit and reporting, training commitment, and, at the end explains how each person involved is responsible for implementing HS&E.

Safety statements cannot be formally precise in their expression; the concept of safety is necessarily subjective.

Greater appreciation is seen by considering the consequences of failure of a system that leads to death, injury to persons, and damage to property.

Safety cannot be designed into a system by dictating specific solutions but has to be developed by effective risk estimation and consequent risk reduction through good design.

Of the many risk factors that can be attributed to a system, it is those that cause catastrophic failure that are most closely associated with getting the safety aspects right.

The design and operation of measuring systems need safety consideration just as much as the larger systems aspects do.

Issues affecting safety are not proportionate to the cost or size of a component or subsystem. A critical element of any size and cost, such as a small hole in a test valve, could be the cause of a catastrophic failure, as it was for an early submarine that sank on its maiden voyage losing all those aboard her when the hole, being filled solidly with paint, did not show that the torpedo tube was open to the sea when the test valve was opened.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Measuring systems are too often seen as a minor part of the larger systems in which they are placed. They are, however, as critical as other subsystems in themselves, but further, they can be part of a critical safety assessment system such as a smoke alarm in an aircraft engine compartment.

First, to state it as it is. Safety could only be totally assured if absolutely every aspect and future circumstance were known and fully understood in advance. The practical reality is that even the best design effort might still miss making a critical assumption. The safest designs are those that have their safety and operation systematically addressed by very experienced persons, within a continuous improvement regime that learns and upgrades the system as an ongoing process.

2 CONCEPTS OF SAFETY AND ITS APPLICATION TO MEASUREMENT SYSTEMS

The issues involved in safe systems are many. Here are a few of the salient ones:

Possibly the first question to be resolved is where does safety start in a design? Can it be added at some later date when the system and its use are better understood? At what stage of the system development life cycle should it be addressed?

The answer here is categorically as soon as development commences.

It will only be fulfilled well enough if seen as a 'whole of life cycle' issue. It is a matter for all to take most seriously. It cannot all be left to the person designated to take responsibility for setting it in place. The whole organization must take it seriously and develop a culture that makes designers constantly conscious of the need to assure they create safe systems.

Key issues of system safety are

- the definition of safety,
- safety acceptance levels,
- hazards, accidents, and causal factors,
- organizational fundamentals,
- management considerations,
- standards of safety and safety assessment,
- safety planning.

Safety as a concept has many interpretations (Mugridge, 2002) such as

- totally zero rate of dangerous defects (a nice idea, but impractical),
- absence of all danger ('cotton wool' mentality),
- acceptably unsafe (this is the usual principle applied). Benefits outweigh the risks is a criterion; different groups of people have different views on what this is. It is usually enshrined in the law of the country involved. For example, the UK law is the Health and Safety at Work (H&SW) Act 1974.)

A large systems development organization will certainly have its own policies and practices in place for safety aspects of systems under its development. Smaller organizations may not have their own safety policy and may have to rely on national laws for guidance.

What is acceptable depends on whom you ask:

In the United Kingdom, the ALARP (As Low As Reasonably Practicable) principle is often applied. In France, the GAMAB (Globalement Au Moins Aussi Bon) principle based on '... a level of risk globally at least as good as the one offered by any equivalent existing system' is applied.

In Germany, they use the Minimum Endogenous Mortality (MEM) principle in which '... hazards introduced by the system should not significantly increase the mortality rate, due to technological facts, above the MEM'.

In the United States, numerous safety principles statements exist. For example, the Threshold Level Value (TLV) used by the US Government Conference of Hygienists as the 'safe' level states it is the

> '... airborne concentration of a material to which nearly all persons can be exposed day after day without adverse effects'.

Note that all of these statements are subjective – it is not possible to define safety in a strictly formal way.

The public has very strong views on safety risk, but again with much subjectivity being apparent. The public perception of safety risk must be taken into account to suit the area of application of the measuring system.

For example, in rail travel, the general public will tolerate many single fatality accidents much more readily than a single multiple fatality incident. The level of safety acceptable for road travel is way below that for air travel.

A sensor system built to protect a small electric hand tool from overheating can use a more relaxed approach to safety design than a sensor used to detect overheating of an aircraft engine.

It also depends on whose safety is threatened; some groups are more tolerant than others:

- *Armed forces*: becoming more safety conscious for its friendly users but a hard area to make safe under all conditions.
- *Workers in industry*: now much more safety conscious than at prior times.

- *Civilians, for example, commuters*: often seen as secondary to the system they use but are equally in need of safety as are those who build or run it.
- *Children*: sentimental views easily come to the fore more than for the above classes.

It also depends on what type of system application the company design work is directed toward. If it is for electronic games equipment, then it will not need the same level of attention as it does for sensors to be placed to monitor a nuclear reactor vessel.

More detail on safety is provided in Brauer (1994), Hammer (1993), McPartland and McPartland (2002), Roland and Moriarty (1990) and Roughton and Mercurio (2002). Web sites exist where safety information and group activities are available, Safety US (2003).

A useful guide to the issue of safety engineering is Railtrack (2000). Although compiled for the UK railway industry, it is written as a general guide and in a language that is easily understood.

When preparing a measuring system design, however, it is at the least necessary to adhere to the safety standards in force for the project.

With so many variations being in use, it is necessary to adhere to those defined as being needed by the system development in which the measuring systems are placed.

It is also not usually feasible to cater to all standards at once, so the measuring system design built for one application may not be deemed satisfactory for another.

3 THE SAFETY CONSCIOUS CULTURE

'Safety' then, is much more than making sure a design is safe in the engineering sense and that it will be used safely.

Engineering Safety Management (ESM) is a systemic (all encompassing) and systematic (follows rules) process and a state of awareness that collectively leads to a system being sufficiently safe in its design and in its likely applications.

For the safety culture to develop, several important aspects need attention. These are

- understanding of the nature and language of safety;
- clear expression of safety responsibilities;
- existence of a sound safety culture;
- competence in safety issues by staff and users;
- maintaining that culture with all concerned including contractors and users;
- tight management of system changes to ensure safety levels are not compromised as systems are repaired and upgraded (there was the instance of an explosion-proof instrumentation enclosure being left open after some maintenance was done!);
- effective communication and coordination of safety related issues to all who should know;
- ability by those who need to know of how to develop a safety case for a system in terms of requirements, purposes, and detailed engineering;
- understanding and application of relevant standards;
- ability to plan safety into a system.

4 RESPONSIBILITY FOR A SAFE DESIGN

Even though the law will point to one, or a few, persons as being finally responsible, safety is not one person's responsibility alone. To reach good safety levels in the development of a project requires the operation of an effective safety organization. Different types of responsibility exist. They need to be defined, recorded, and formally accepted by signed agreements. Delegation of safety duties can be made – but not the responsibility.

A key organizational need is for some form of authority such as a Board of Safety Management (BSM). This group needs to have excellent communication with all necessary parts of the organization, its contractors, and its system users. After a tragedy occurs is not when such a board should be set up – as is seen in the press so often – but it should be set up as soon as the project begins. If it does not have one, it should immediately be formed.

Responsibilities suggested in Railtrack (2000) are

- setting, maintaining, and monitoring a safety policy;
- ensuring that the ESM is effectively implemented and maintained;
- agreeing to safety classifications for projects;
- endorsing key safety documentation;
- monitoring ESM performed on each project;
- appointing a system of auditors and assessors.

Allocation of safety responsibility is a serious task. It should be done in a clearly traceable manner, which usually implies a top-down military type line-management structure.

Everyone should have access to that structural information in order to know who is responsible for what.

Delegating safety responsibility to outside organizations and individuals can be fraught with weakness if not firmly handled. As people get removed from the safety structure set up, the messages about being safety conscious attenuate with regard to the whole, but can enhance for the individual concerned.

When commissioning systems, all the necessary documentation and data on safety needs to be passed into a sound depository and a clearly capable safety organization must exist for that system.

More detail is to be found in Railtrack (2000) and for the various safety standards – *see* **Article 100, Safety Analysis Methods, Volume 2**.

5 PLANNING FOR SAFETY

Some of the task of planning will already be apparent. As the Systems Engineering life cycle is traversed – *see* **Article 66, Phases of System Life Cycle, Volume 2**, a safety system must be running alongside as a whole life activity.

It is rarely possible to economically bootstrap a project with safety systems, that option getting increasingly harder as the life cycle stages move on to production. At the production stage, the cost of redesign and rework just gets too great to bear.

Figure 1 shows a suggested framework of plans and their timings (Railtrack, 2000).

For a new development, or to upgrade, the final Safety Plan usually has to pass through a Preliminary Safety Plan stage for, at the Concept Stage, **Article 67, Principle of Concept of Operations (ConOps), Volume 2**, things are still far too fluid to start to dictate issues of detail. However, the major parts of the safety plan are formed as the project gets better defined. Safety issues can have a great impact on engineering design.

It is recommended that once the Preliminary Safety Plan is ready, it should be submitted to the safety authority that would have been set up by this time.

The next major activity is to create a Hazard Log. This log records details of expected hazards on the basis of relevant past experience for a newly started development and as they arise in an ongoing one. Not only is this a source design data but it is also an important part of the necessary burden of proof that will invariably be needed to defend any legal actions that may result.

With this log in place, it is possible to conduct various forms of safety analysis – *see* **Article 100, Safety Analysis Methods, Volume 2** and **Article 101, Assessing and Demonstrating Safety, Volume 2**. This stage is often called the *Hazard Identification and Analysis* (HIA) stage; it permits the all-important Risk Analysis to be done.

Risk analysis allows Safety Requirements to be prepared as part of the overall system requirements engineering task.

The required full Safety Plan can then be prepared and authorized to be placed alongside the System Engineering Plan, and the Test and Evaluation Plan.

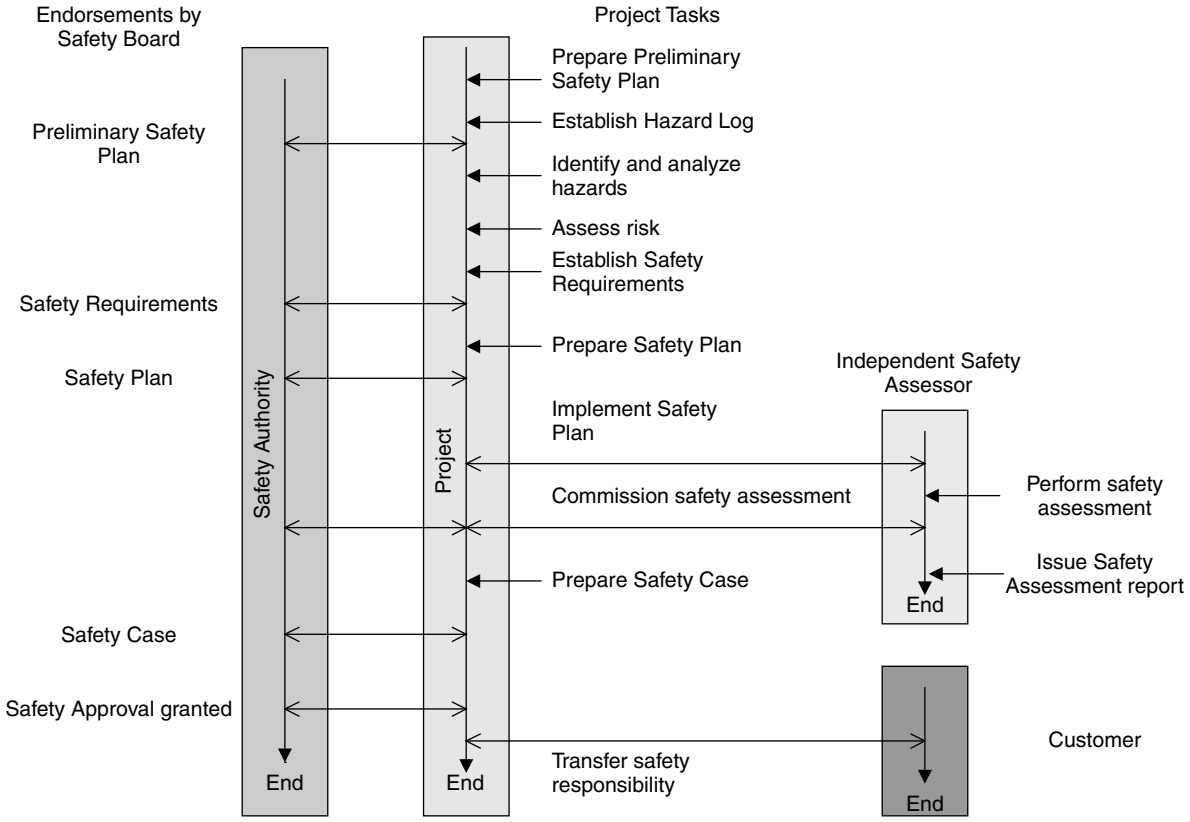

Figure 1. Suggested framework of safety activities. (Reproduced from Railtrack (2000) *Yellow Book – 3*, Railtrack PLC, Euston Square, London, distributed by Praxis Critical Systems Ltd, 20 Manvers Street, Bath BA1 1PX, UK, pp. 1–4, Fig 1-1 of *Yellow Book*.)

Once all this has been done, it provides the substance needed for a Safety Case to be prepared, which, after receiving endorsement, allows Safety Approval to be granted.

This may seem to be a large overhead on a project. Its extent is tailored to suit the type and size of project. The driving force for doing it well – and beyond just professional responsibility – is the fear of legal repercussions. A catastrophic failure can lead to very large legal settlements and perhaps to imprisonment. Even a low level breach of safety could lead to product recall for a simple modification, a process that has the potential to bankrupt a company due to the cost of the recall and fixes, without the cost of legal action.

6 MANAGEMENT OF SAFETY IN A CHANGE ENVIRONMENT

Safety is not an issue to be addressed at the start of a development and then ignored.

Each time a design change is made, its impact on safety needs to be investigated to see if the level of safety reached has been compromised. This is not always easy to establish.

Each engineering change has to be assessed via the change management process adopted for the development. That adding safety features will change the level of safety is obvious; but so also can removing them.

A Change Management Committee, or the like, is needed. They review proposals for change that is put to them. No change is permitted without correct approval.

All changes are accounted for within the configuration management process; each has to have its impact on safety assessed. This process needs to record

- identification of versions,
- history and status of versions,
- parts forming items,
- relationships between items.

Figure 2 is a change proposal management process suggested in Sage and Rouse (1999). The Engineering Change Proposal (ECP) is created and subsequently put to the Change Control Board (CCB) for approval before it can be put to use.

Software tools are available to assist the task of configuration management, but its use will need safety approval in safety critical systems developments.

Lack of sufficient safety is an insidious parameter for it is usually not one event in isolation that leads to failure but a complex chain of repercussions that lead, often unexpectedly, to failure. Reasons become blatantly obvious only after the event!

Somewhere, in one or more places in a chain, unpredicted events arise. Once they have been seen – usually too late at the first occurrence – they can be avoided. Not knowing about them leaves the situation waiting for that particular

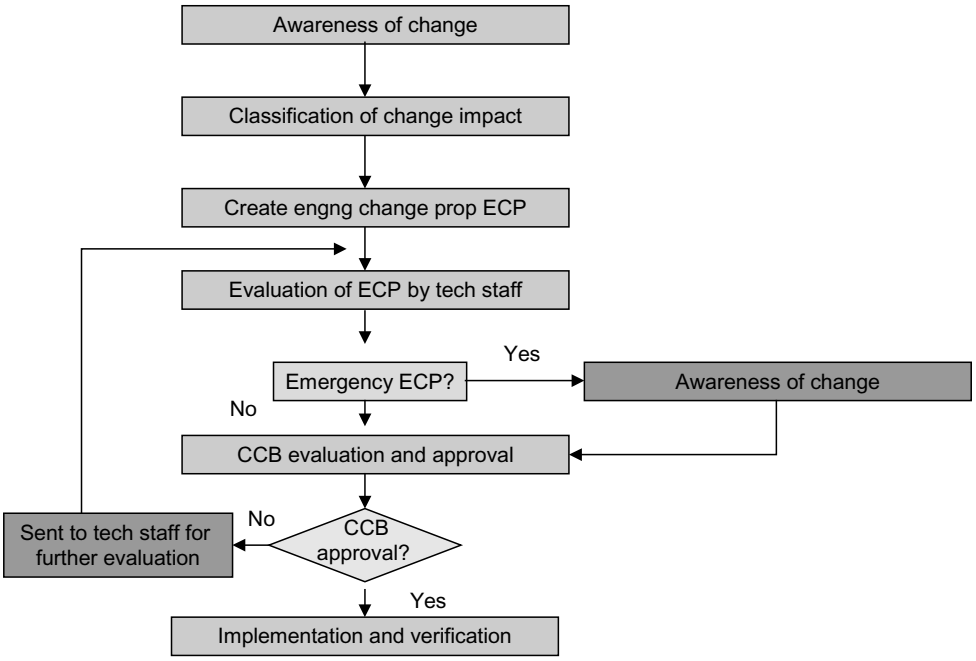

Figure 2. Change proposal management process. (Reproduced from *Handbook of Systems Engineering and Management*, Sage and Rouse, Copyright © (1999), Reprinted with permission of John Wiley & Sons, Inc.)

set of circumstances to arise. Because something has never happened before, does not demonstrate it never will.

The software component of safety critical systems is particularly risky and has to have far more effort expended on its development than do run-of-the-mill applications. In these cases, even the tools used to check the software have to be understood to the point at which their standard of operation will not compromise safety levels by, for instance, not finding potential faults. For this reason, safety critical system developers will often build their own safety examination tools.

The safest system could well be the one that is not used! It is not possible to build a useful system that is perfectly safe. The cost to provide it would not be practical. Such a system would be so overburdened with safety features as to be not workable. Safety then is a gradually improved facet of a systems development.

Swapping of safety cases and data is recommended as that increases the pool of event situations; but organizations are not always willing to do this because of legal and media ramifications of things they may wish to keep low key.

7 COMMUNICATING AND COORDINATING SAFETY ISSUES

Given that a project development often involves many people who would normally never meet for discussion of common problems, it is necessary to ensure that issues that arise, no matter what the source, are communicated to whoever needs to know.

This can be a difficult issue to address, as people are often loath to be critical of the work of others, or to offer too much about aspects of their own work that could be construed as a weakness on their part. Good, effective communication is essential between all involved.

Usually, the project will operate under many mandatory issues. If so, one will assuredly be that all persons have the obligation to report safety matters to a central place for action. All parties involved, including contractors, are subject to this ruling. An example is found in the UK Engineering Council 'Code of Professional Practice on Risk Issues'. In essence, it states the following:

- Communicate up and down the chain of responsibility.
- Seek to raise awareness of potential hazards and risks with colleagues.
- Make clear limitations and implications of risks.
- Discuss near misses and incidents with peers and take action on findings.

Commence communication verbally and look for a sound, simple solution. Many issues would have been resolved by this stage. Use all forms of communication, especially those with formal records once the issue is seen to need more central action. Formal records – the auditable paper trail – tend to be heeded more than discussion does.

It is to be expected that organizations will naturally set up liaison groups between their respective safety boards.

As safety issues are risks, the use of the risk control register should be the database and control mechanism for safety.

Formal committee type units usually have associated with them long delays in getting issues resolved. As with any committee of importance, there needs to be an executive group who can act rapidly when safety issues need urgent attention.

1 SOME TERMS AND DEFINITIONS COMMONLY USED IN SAFETY DESIGN AND EVALUATION

Many terms will be encountered in the safety aspects of designing and operating a system. No single definitive set is used; several exist. Where a safety standard is used for a project, the terms used there should be adhered to. Table 1 provides a composite set for use where they are not defined elsewhere for a project.

2 STANDARDS AND OTHER INFORMATION ON SAFETY

It is essential that terms, methods, and reporting be done consistently throughout a project. Consistency can be established by the use of a suitable safety standard that is appropriate for the project.

Some key safety standards are

- DEFSTAN 00-56
- IEC 61508
- CENELEC EN50126

All of the above are useful, but can be a little difficult to come to grips with. For overall guidance, each has its own kind of explanations. The defense safety standards are written in a directive tone with numerous updates and revisions to be taken into account as they are used; these are not always easy to read and maybe difficult to appreciate.

Several texts on safety are available – see Brauer (1994), Railtrack (2000), Roland and Moriarty (1990) and Roughton and Mercurio (2002).

Information given in texts should not be applied to the letter where definite standards are clearly defined to be used in a development. The texts should be viewed as useful reference works and are essential for building up one's personal safety attitude and design experience. The difficulty is that whereas they might maintain adherence to one standard, they, more often than not, pick up terms and ideas from several sources and can also use the author's own terminology from time to time.

One useful, Web accessed, general introduction and guide that was compiled recently for use by a very wide range of civilian users – as are found in a large railway system, is Railtrack (2003) – known as the '*Yellow Book*'. Its features are as follows:

- Prepared only as a guide to concepts and methods.
- Developed for use within the breadth of activities of the railway sector.
- Principles are applicable to all sectors.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Table 1. Composite set of terms and definitions used in safety.

Term or acronym	Meaning
Accident	Unintended event that results in harm
Accident trigger	Event that causes a hazard leading to an accident
ALARP	As Low As Reasonably Practicable
BSM	Board of Safety Management
Causal factor	State of system that is systematic, for which a cause is clearly defined – once established
CCB	Change Control Board
CENELEC EN50126	Electrical Industry Standard on safety
CMC	Change Management Committee
DEFSTAN 00–56	UK Ministry of Defence. Standard on safety
ECM	Engineering Change Proposal
ESM	Engineering Safety Management
ETA	Event Tree Analysis
Failure	Deviation from intended performance, usually in a catastrophic manner
FTA	Fault Tree Analysis
FMEA	Failure Mode and Effects Analysis
FMECA	Failure Mode and Effects and Criticality Analysis
GAMAB	Globalement Au Moins Aussi Bon
H&SW	Health and Safety at Work Act of UK
Hazard log	Record of hazards and potential accidents identified from analysis of safety
HAZOP	Hazard and Operability Analysis
HIA	Hazard Identification and Analysis
HS&E	Health, Safety, and Environment
IEC 61508	International Electrotechnical Commission safety standard
Incident	Event that could have safety significance
Individual risk	Risk experienced by the individual. Usually expressed as probability of fatality per unit time
Intolerable risk	Risk that is totally unacceptable
MEM	Minimum Endogenous Mortality
MIL-STD-882C/D	US Defense Department Standard on safety
PSP	Preliminary Safety Plan
Risk analysis	Analysis of system risk, by various methods
Safety	Freedom from unacceptable risk
Safety Approval	Process through which the Safety Board grants approval to make changes
Safety Audit	Activity to verify that project is following the Safety Plan and maybe the veracity of that plan
Safety Case	Formal presentation aiming to provide assurance system will be safe and fit for purpose
Safety certificate	Formal statement authorizing the system for use
Safety integrity level	SIL. Discrete level, usually from 5, for specifying safety integrity zero being the lowest level where safety is not relied upon
Safety Plan	Documented plan that details how the system will be made sufficiently safe
Safety Requirements	Requirements needed to make a system safe under the definitions that apply
TLV	Threshold Level Value
Value of Preventing a Fatality	VPF. Defined monetary figure used to indicate reasonable expenditure for preventing a single fatality
WSA	Work Safety Assessment

- Developed by a committee of Railtrack® employees and supported by the committee as versions with updates provided on the Web site, Railtrack (2003).

It is important to recognize that it is all too easy to spread unsafe practices by sloppy use of terms due to the semantic nature of the necessarily subjective statements and varied use of terms.

3 OVERVIEW OF SAFETY ASSESSMENT METHODS

Failure of a system can cause death, injury, and property damage to a product or system. Examples are loss to an individual and the more geared-up situations where, say, a ship and its passengers are affected. It can also cause destruction of facilities and the environment.

Safety standards are essential as they contribute to safety management by providing generic means to design safe systems: they do not specify design solutions.

Methods deployed must be acceptable to all involved and cannot be imposed without user ownership across the system.

To prevent or minimize impact of human error, make use of key mechanisms like

- adoption of fail safe, or not fail at all, operations, activities, and events;
- redundant system units;
- fault-tolerant (error tolerant) design of hardware and computing;
- preventing unsafe actions by the way the system is designed and operated;
- providing assistance with making key decisions on a safe basis;
- using comprehensive integration and testing procedures.

Some key characteristics of failures are

- failure of individual small components and subassemblies are relatively easily controlled with low risk – that is, high confidence, by allocation of more resource;
- many disastrous failures have been the result of a series of apparently unimportant events that line up to create a pathway through the whole system, which adds up to major failure – like it did in the Challenger disaster and some Mars explorer missions;
- Reason's 'Swiss cheese' model points out that the 'holes in the cheese need to line up for both good and bad actions to result'.

Sources of safety requirements can be from a Regulatory Authority or be derived from assessment and analysis.

Types of safety requirement are many such as

- failure probability target – random or systematic;
- hazard removal requirement;
- functional safety requirement;
- process requirement.

Safety requirements must be

- auditable
- testable
- reasonable
- unambiguous
- uniquely identified.

Safety can be regarded as fitting into two groups of interest – safe technical behavior and safe human operation.

Several well-developed and documented methods exist for establishing safety risk. All are similar in their methodology. Whichever method is adopted, it must be used under advice to prevent shortcomings arising from differences in use of terms, process steps, and documentation.

There is a particularly strong need for a tightly specified, hardware and software codesign: the simplest of changes to software can negate prior safety analyses so regression for safety assessment can be very expensive to carry out.

Several methods of safety analysis are now introduced to set the scene. For application, these short overviews will need expansion using the appropriate standards in force for a project and the texts referred to above.

4 WORK SAFETY ASSESSMENT (WSA)

Work Safety Analysis (WSA) is a simple means for systematically identifying hazards and potential corrective measures, Sage and Rouse (1999). It is used mainly for physical operational work by people, but its relatively basic methodology has a place in safety assessments where deep detail is not required.

This is a hierarchical task analysis in which the hazards for each step are identified; once these are established, their likely causal effects are identified.

It is predominantly based on the judgment of an expert(s), plus considerable relevant data from past studies. It is often found that a lay person, one unfamiliar with the system, can often 'see' additional hazards that experts do not!

Likely issues are best handled using a checklist to ensure things already known from prior histories are not overlooked. Checklists for use by safety assessors, auditors, and designers are provided in Railtrack (2000, 2003).

Once established, each hazard is classified in terms of its relative likelihood of occurrence on a 0 (hazard eliminated) to 5 (very serious) scale and its severity of consequence.

Relative risk is then calculated as the product of probability and consequence.

Once the risk table has been reduced by calculation it will become clear where corrective measures can be taken to reduce the salient hazards to acceptable levels.

WSA is extended in different ways, as follows.

5 FAILURE MODE AND EFFECTS ANALYSIS (FMEA)

Failure Mode and Effects Analysis (FMEA) is another commonly used method. It has the same basic steps as WSA but is made more objective by use of the methods of reliability analysis. It too is used to establish potential systems failures that are then analyzed to establish the safety regime and make improvements.

This method was developed from hardware reliability engineering and thus there exist many similarities between safety and reliability analysis; this is to be expected for both are for investigating the risk of failure.

It tabulates the percentages of failures by the mode of failure and then categorizes these as critical or noncritical. It leads to *event trees*.

As with most safety assessment methods, it is most effective if used early in a development to flush out likely failures at the time when they can be avoided at lesser cost by design or operational correction.

An FMEA study is also of value to setting up the logistics of through life maintenance as it determines what needs to be, or not to be, done when servicing the system.

Carrying out an FMEA study can be done on either hardware, or a functional basis. The hardware approach is only practical once sufficient design drawings and analyses have become available – that is, in the later development life cycle stages. It can be carried out with various levels of system subassembly.

In the functional approach, the system is studied using the system functional decomposition breakdown levels. It starts studies of likely failure at the top level, working down to the level of detail needed. It is used to precede a hardware study.

It is suggested, extending the list given in Sage and Rouse (1990), that an FMEA be carried out with the following steps:

- Use the functional or hardware approach according to the stages of development available.
- Define the blocks using a clear numbering system such as that commonly used in functional flow diagrams (FFD) used in system functional decomposition.
- Locate the system requirements documents.
- Define and record failure modes and mechanisms using a checklist that defines them along with the relevant environmental parameters to be applied.
- Work on all potential failures found suggesting corrective actions that avoid them or sufficiently attenuate them
- List any special conditions of use that are essential for safe operation.

Traceability is essential for all of the above process documentation for any open link may leave issues unaddressed or see rekeyed starts using different semantic appreciations.

6 FAILURE MODE AND EFFECTS AND CRITICALITY ANALYSIS (FMECA)

Failure Mode, Effects, and Criticality Analysis (FMECA) is a similar process to the FMEA in that it is for identifying and investigating the safety and failure spots of potential systems designs.

The impact of unsafe situations will vary from low to extreme. FMECA extends FMEA to take in the criticality factors.

It is mainly applicable in the concept and preliminary design stages of the development life cycle for preventing unsafe events but it can also be used to study the safety of existing designs.

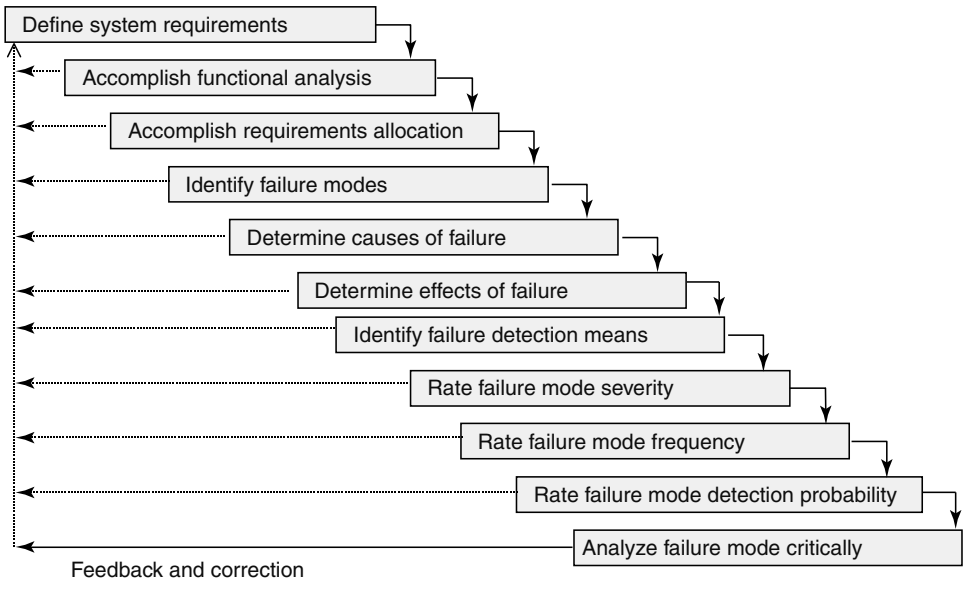

Figure 1. Steps of a typical FMECA analysis. Reproduced by permission of Pearson.

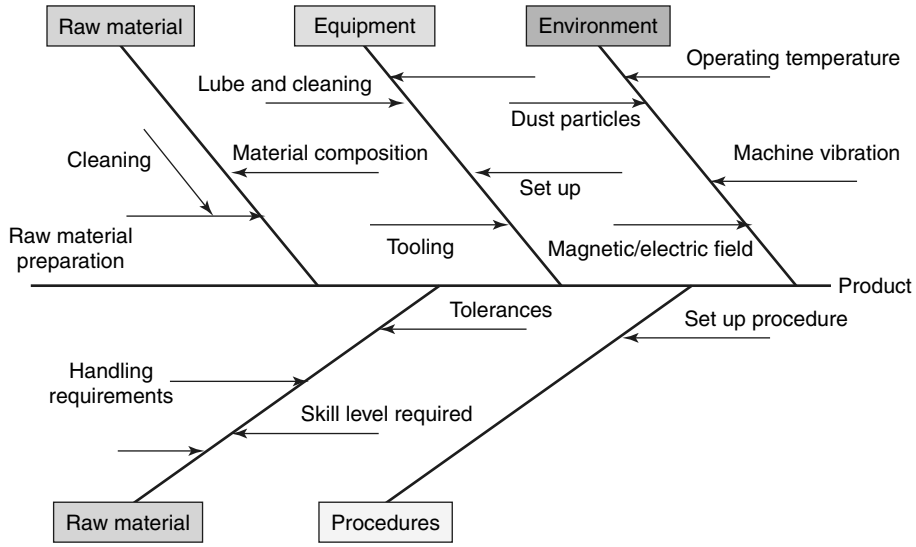

Figure 2. Fish bone diagram example: identifying faults in a manufacturing process. Reproduced by permission of Pearson.

The steps of a typical FMECA study are shown in Figure 1. More detail of each step is available applied to an example in Blanchard and Fabryky (1998).

An essential difference between FMECA and FMEA studies is that the former allocates tighter understanding of the failure data using statistical methods. This allows a more discerning study of the criticalness to be produced where many parameters are involved.

7 FAULT TREE ANALYSIS (FTA)

Fault Tree Analysis (FTA) studies failure, and thus safety, using deductive use of a graphical enumeration and analyses of the different ways in which a fault can arise. Its methodology can be applied in the above methods to tease out potential safety problems. It is a method for charting the hazards in a hierarchical manner.

Its process is similar to the widely applied decision tree method in that it is a top down procedure that identifies how issues can be broken down. Here it is used to locate causal reasons for failure.

As causes of potential failure are determined they branch out with probabilities of each arising being allocated at each branch point. Once the full tree has been identified, each of the many paths is calculated back to the start to identify each risk, thus revealing the most unsafe sets of circumstances. High-risk paths are rectified by redesign to obtain a more suitable risk distribution across the whole project.

In analysis of the safety-regime application of the decision tree concept, use is often made of the Ishikawa cause and effect or the fish bone diagram. The one used in the Blanchard and Fabryky (1998) example is given in Figure 2.

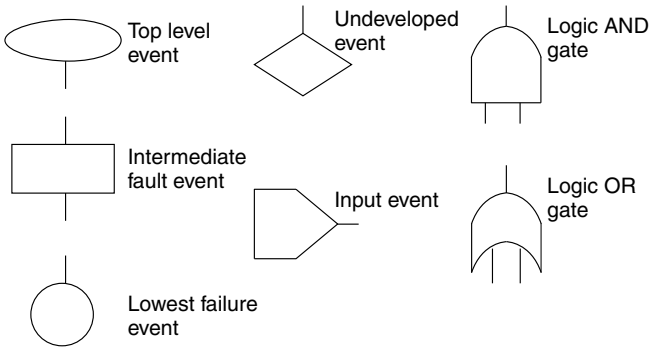

Figure 3. Some symbols used in fault tree construction.

Fault trees are constructed using commonly agreed standard symbols – see Figure 3 for the basic ones used. A more complete list, with explanations of each, is available on http://www.relexsoftware.com/reliability/brief/fta_brief2.asp.

An example Fault tree for events that can lead to failure in an elevator, drawn with the Reflex Fault Tree™ tool, is given in Figure 4.

8 HAZARD AND OPERABILITY ANALYSIS (HAZOP)

Hazard and Operability Analysis (HAZOP) was developed in the 1960s for the UK chemical industry. It was quoted as being a

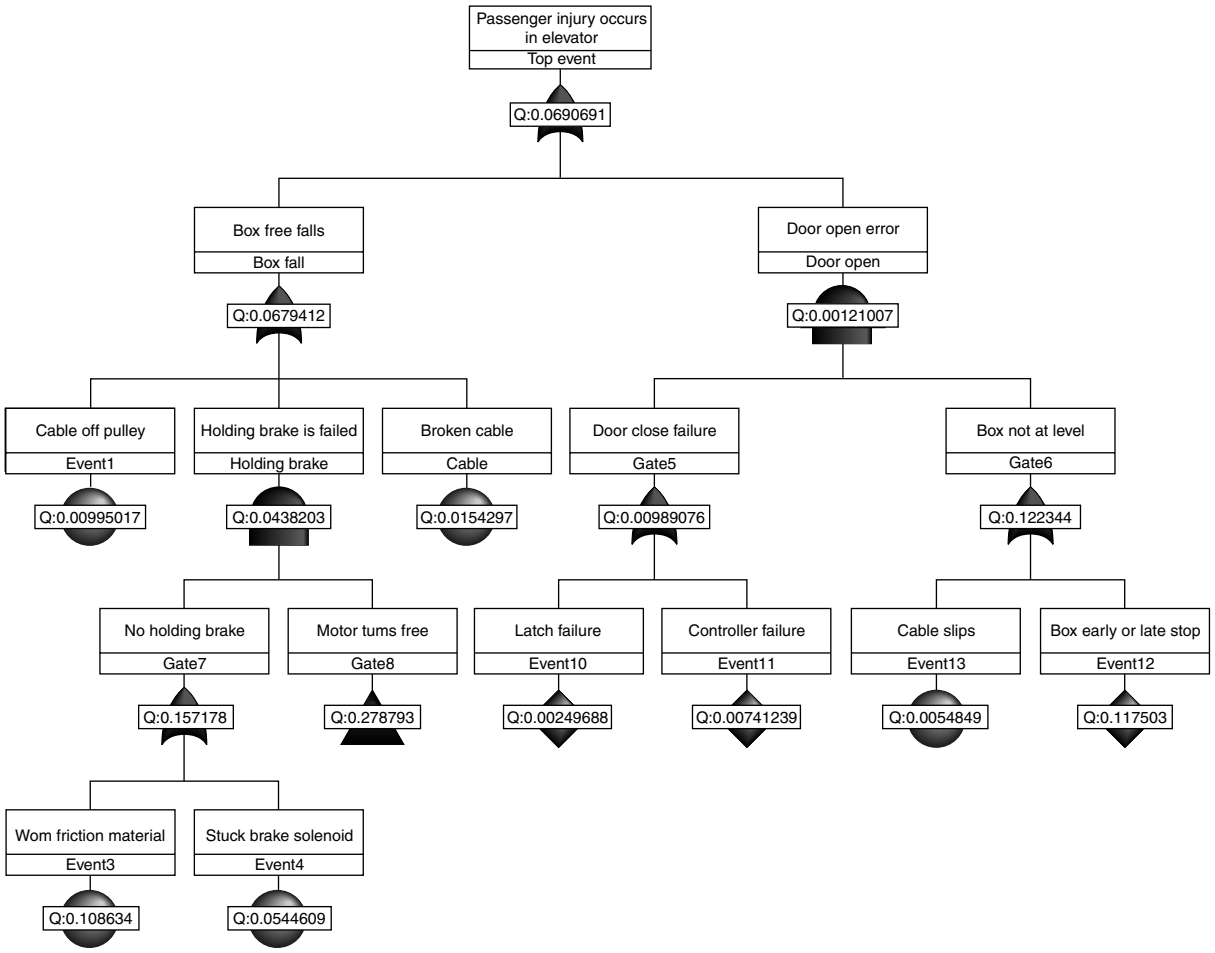

Figure 4. Example fault tree created with the Reflex Fault Tree™ tool.

> 'Qualitative technique whose purpose is to identify all deviations from the design's expected operation and all hazards associated with these deviations'

It is a systematic, creative examination of a design that is best performed by a multidisciplinary team who can bring a wide variety of viewpoints to the study.

It has been widely adapted for use in other sectors.

In use, each system component is inspected in turn keeping in mind the design intention – what is this component supposed to do?

Standardized words are used to minimize the semantic nature of normal language in this use. A selection from the thesaurus is as follows:

- NO/NOT: No part of the intention is achieved.
- MORE: Some quantitative increase over what was intended.
- LESS: Some quantitative decrease compared to what was intended.
- AS WELL AS: Some qualitative increase over what was intended.
- PART OF: Some qualitative decrease compared to what was intended.
- REVERSE: Logical opposite of intention.
- OTHER THAN: Something completely different.
- EARLY: Something happens before it is expected, relative to clock time.
- LATE: Something happens after it is expected, relative to clock time.
- BEFORE: Something happens before it is expected, relating to order or sequence.
- AFTER: Something happens before it is expected, relating to order or sequence.

The first step, identifying the system elements, for a simple example HAZOP study of a two component fuel mixer (Mugridge, 2003) is given in Figure 5.

From each such study is derived plausible (that is, may well be true but not necessarily so until investigated) deviations from the design intention. Avoid prejudgment of any issues before they are analyzed; include those that

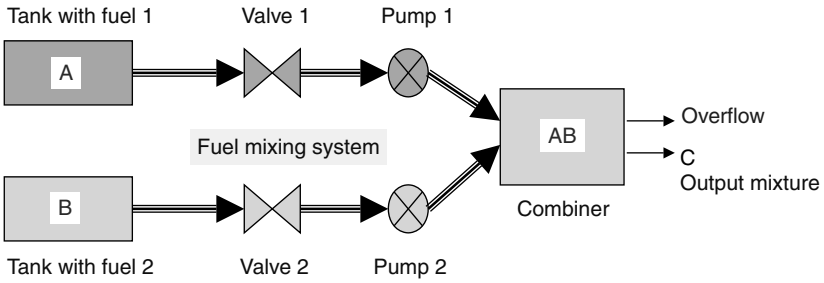

Figure 5. First step in an HAZOP study – the system block diagram.

Guide Word	Deviation	Cause	Effect
NO	No flow of A	Pump failure	Explosion
MORE	Excess flow	Valve failure	Poor quality
LESS	Reduced flow	Pump/valve failure	Explosion
AS WELL	Contamination with air	Line rupture	Fire
REVERSE	Pump reverse flow	Maintenance error	Explosion
OTHER THAN	A solidifies	Low temp	Explosion

Figure 6. HAZOP table for fuel mixer system.

seem wildly unlikely. Work on the basis that all elements are unsafe until proven to the contrary.

Figure 6 shows part of an analysis table formed from study of the system given in Figure 5.

It can now be seen that while each method has the same basic features, they variously incorporate features of their own. Each of the above analyses methods finds use according to the Standard requirements in force and the experience of the analyst. It is essential to use only one methodology for all related parts of a system; mixing methods can lead to confusion, the enemy of reliable safety studies. Safety is built up over years and can be destroyed in moments by simple design or operational changes.

1 SAFETY AS A WHOLE OF LIFE CYCLE FACTOR

Safety must be treated as a whole of system life cycle issue. Each design activity, when adding its own contribution, must carry out safety assessments as well as is possible at the time.

Overarching the individual design contributions, to ensure that they integrate and do not degrade the overall system safety, will be the duty of the Safety Board with its safety policies and practices.

Applying a well executed, top-down, System Engineering, SE planning and project management, and working within a design change management process will help in reducing rework at a later stage.

The difficulty, however, is that safety is an ongoing maturing process. A system that has been 'safe' for years can have its integrity reduced by subtle changes in the chain of circumstances in application, by new requirements of regulators, and because of the occurrence of a previously unseen event that attracts attention. All of these can require extensive system redesign.

The detailing designer should work within existing directives aiming to second-guess failure mechanisms that are then mitigated by the use of appropriate design strategies.

2 THE SEVEN STAGE PROCESS

The 'Yellow Book' of Railtrack (2000) suggests that a seven stage process be used to demonstrate that the system risks are as low as reasonably practicable (ALARP). (While ALARP is used here, this basis of safety is not the only one in use – *see* **Article 99, Safety Organization, Volume 2**.) Notes of a short course on safety (Mugridge, 2003) are summarized here to introduce the methodology for assessing the risk level of a system.

The steps of the Seven Stage process are shown in Figure 1. The sequence is as follows:

Stage 1. Identify the hazards.
Stage 2. Carry out an analysis of the causes of each hazard.
Stage 3. Analyze the consequences of the hazards. Stages 2 and 3 can be done in either order.
Stage 4. Assess the loss in terms of harm to people.
Stage 5. Consider the options for risk reduction.
Stage 6. Assess the likely cost benefits of each hazard reduction measure.

Then, after systems adjustment to reduce the risks:

Stage 7. Demonstrate that the system risks are as low as reasonably practical.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

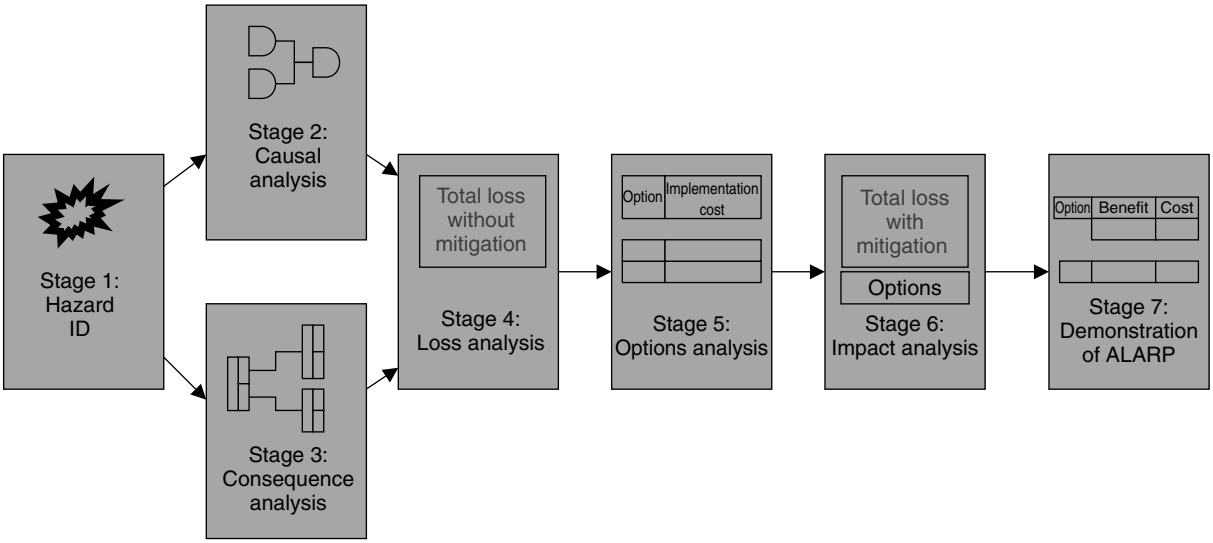

Figure 1. Seven stage process for demonstrating ALARP.

Carrying out this process needs speed, but with adequate care. If the process takes too long, the system may change significantly, making the analyses following the data used to perform the task no longer useful.

Each step is now covered in turn.

3 STAGE 1 – HAZARD IDENTIFICATION

The purpose of this stage is to identify any potential hazards associated with the system and the way in which it is to be used.

For best results, the task should not be guided by intuition to come up with likely hazards, but should be approached in a systematic and comprehensive (that is, systemic) manner. Ideas and inspiration can be found from a variety of sources such as

- expert knowledge,
- layperson experiences,
- previous experience for the same kind of circumstances, and from the prior history of the project (if recorded – all too often this has not been done!)
- new analysis of the current situation.

Some of the various techniques that can be deployed to make use of the above sources are as follows:

- Creative thinking by individuals including a wide cross section of users.
- Brainstorming that teases out ideas as members of the team spark ideas from each other's suggestions. They should make use of charts to record ideas trees and other connections between the different ideas.
- Hazard and operability (HAZOP) studies – *see* **Article 100, Safety Analysis Methods, Volume 2**.
- Empirical approaches, while not well ordered can reveal unexpected issues.
- Checklists from other projects, and the organization's safety documentation.
- Structured Walk-throughs of each likely, plausible situation.
- (FMEA) Failure Mode and Effects Analysis – *see* **Article 100, Safety Analysis Methods, Volume 2**.
- Task Analysis.

More details of these methods are available in Railtrack (2000, 2003). These methods take time to do and need care to identify issues. Bias and preconceived ideas of improvements should not be allowed to prevail as potential risks are uncovered. This is not the stage to decide whether their level of importance is such that they are not worth including. The chain effect must be remembered for even small, apparently innocent, events that might lead to unacceptable risk.

4 STAGES 2 AND 3 – CAUSAL AND CONSEQUENCES ANALYSES

The purpose of causal analysis is to determine credible combinations or sequences of causal factors that can lead to hazards.

It is carried out using a diagrammatic, functional, hierarchical representation as its main schema. A fault tree is generated from a study of drawings, component lists, and operational instructions – see Fault Tree Analysis

(FTA) and Failure Modes and Effects Analysis (FMEA) in **Article 100, Safety Analysis Methods, Volume 2**. The probability of a condition arising is best stated as the quantitative probability estimate.

FTA starts with an undesired top event being identified. Logic gates are used to form a logic network showing how the various fault-inducing conditions are related. An example is given in **Article 100, Safety Analysis Methods, Volume 2**.

Working downwards, one identifies the next immediate causes, eventually stopping when basic events are reached. Probabilities are then inserted for the basic events from an FMEA – *see* **Article 100, Safety Analysis Methods, Volume 2**.

FTA is usually carried out using a software package. The calculations can be done manually, but they are tedious. Tools must be used with great care in safety-critical situations, for a tool may have an inbuilt fault error of its own in the way it computes the calculations or in the assumptions it uses. Super safe systems usually need to have their own safety tools developed under the control of the safety process in order to keep control over all the factors of a safety assessment.

Figure 2 shows how an undesired top event (e.g. a train collides with another train) can cause a top event. In this case, an OR gate is appropriate – for one train OR the other can cause the collision.

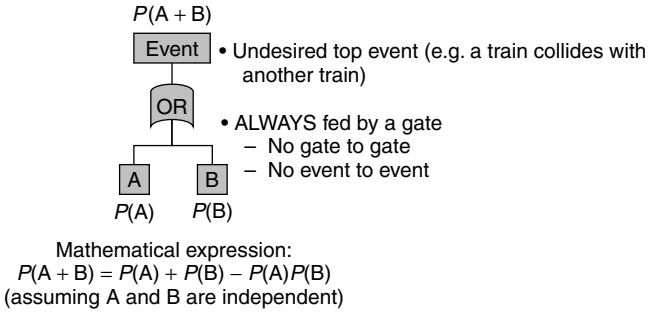

Figure 2. OR gate condition for causing an unwanted event.

Some rules of fault trees are that

- a top event is ALWAYS fed by a gate,
- no gate-to-gate states can occur,
- no event-to-event links can exist.

As well as either train causing the unwanted event, it is also feasible that both trains can cause the unwanted event together. In this case, one train AND the other is a condition to be investigated. Figure 3 shows this condition.

Stage 3 is a Consequence Analysis. The purpose here is to determine what are the intermediate conditions and the final consequences resulting from the occurrence of the identified hazards.

It is carried out using cause consequence diagrams (CCD) and Event Trees. An example of a CCD is given in Figure 4. A fire starts with ignition. If the fire protection system is operating as planned, the sprinkler systems operate and the fire is put out. If it does not operate, but the fire alarm sounds, then the severity of damage caused by the fire is

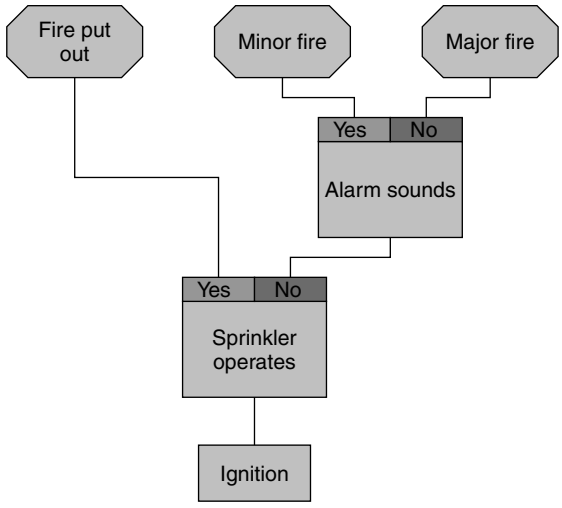

Figure 4. Simple example of a cause consequence diagram (CCD).

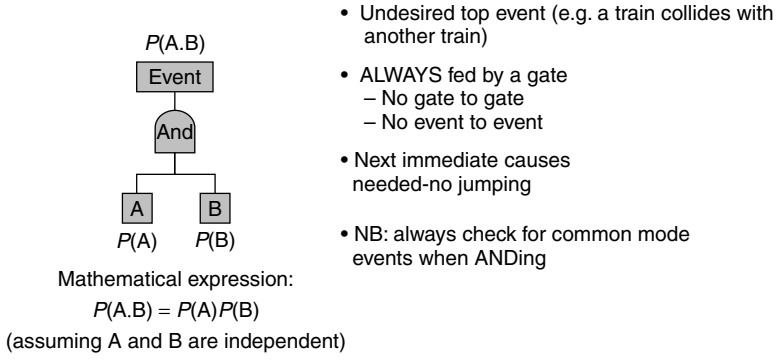

Figure 3. AND gate condition for causing an unwanted event.

lessened. Good design for least risk sets up situations that have less risk due to alternative protective states being in place.

System safety is aided by the existence of safety barriers. These are design situations that will assist in preventing the escalation of a safety risk – a barrier mechanism will have a barrier strength associated with it. Assessment of this value is needed in quantitative mathematical terms.

It is important to recognize that safety rectification temporarily put into place can lead to reduced safety because of its use. A study of such regression steps is needed as much as the main lines of expected risk.

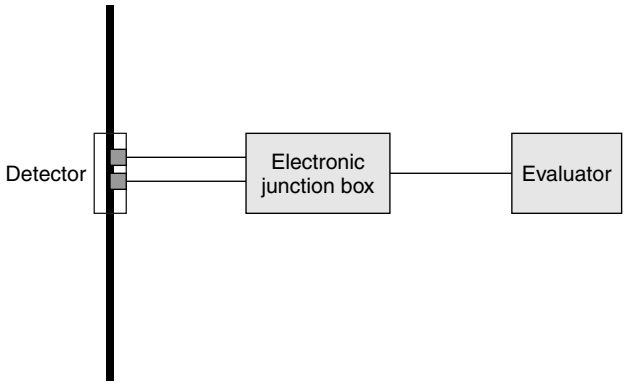

Figure 5. Schematic of a train axle detector.

5 STAGE 4 – LOSS ANALYSIS

The purpose of carrying out a Loss Analysis is to determine the loss associated with each consequence identified during Consequence Analysis. This study is done to see what the current situation is before rectification is implemented. It is not the loss of the improved system.

A loss here is harm to people, ranging from slight effects to fatalities. The principles used can, however, be adapted to take in other losses such as environmental and commercial but that is more for studies of risk assessment in general.

A Loss Analysis needs to estimate the extent of harm, damage, or disruption that could potentially arise from the identified consequences. Harm is initially expressed in qualitative terms for loss assessment and starts from guided estimates, rather than from exact measures.

For example, if a measuring system fails and causes its aircraft to crash, it is not possible to be exact about the harm to life that might arise. Guidelines commonly accepted are that 1 fatality = 10 minor injuries, and 1 major injury = 20 minor injuries. These subjective conversions allow the various levels of harm to be reduced to the common unit of fatalities per annum.

Once the subjective figures are decided, the next step is to convert them into objective values to ensure that any further work with them has minimal added subjectivity. This results in tabulation of the nature of the loss against the cost associated with each consequence.

The next step involved is arriving at the value of preventing a fatality (VPF), a value put on a human life. This varies considerably; in the rail sector, the VPF ranges over £1 to 3 million for a life, or its equivalent.

A higher figure is needed for multifatality accidents for the public is disproportionably averse to this! A weighting coefficient is used – called the *Factor of Gross Disproportion*.

Other sectors are often less open about this value. A road accident death is far less than the above, but any long-term harm to a surviving person can cost more depending on individual legal judgments.

The VPF is, therefore, project specific. Advice is needed as to what values to use; it will come from the legal fraternity. Note that these figures are used only for supporting ALARP decisions – and they are not a guide to legal settlements.

To illustrate some of these principles, consider the simple example of an axle detector set up on the side of a railway track, see Figure 5, to warn a railway gang working on the track of an approaching train.

The CCD for this element of a railway system is developed in Figure 6. The various situations are self-evident from inspection of the tree. The failure F for the base fault is decided along with the probabilities for dividing risk at each branching point. The latter values are used to decide the failure values at the end of each branch of the tree.

With the CCD now set up, it is possible to carry out the calculations needed to convert the data for the various severities of collision into monetary values. This is done in Figure 7 where the total cost is shown for major, minor, and zero collisions.

Those values can then be used – Figure 8 – to calculate the total annualized cost of the systems as it is before any improvements are carried out.

More details for conducting a Loss Analysis are available in Railtrack (2000, 2003).

6 STAGE 5 – OPTIONS ANALYSIS

The purpose of the Options Analysis is to ensure that all reasonable measures for reduction of losses have been considered. There are two ways to consider this – reduce the rate of occurrence of the hazard, or limit its consequences.

For each system hazard, it is necessary to identify physically possible and known mitigation strategies and then to calculate the cost of each option. Only direct costs are

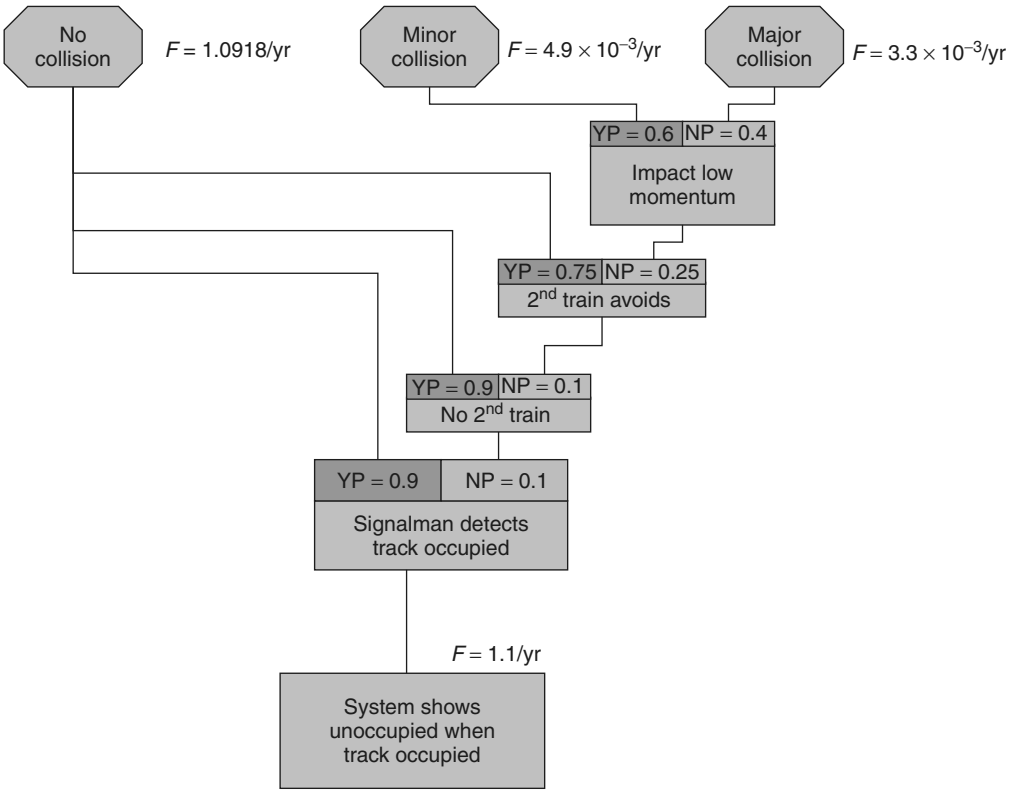

Figure 6. Cause consequence diagram (CCD) for axle detector system.

Consequence	Losses	Cost £m
Major collision	30 fatalities 50 major injuries 200 minor injuries = 36 equivalent fatalities	115.9
Minor collision	2 major injuries 6 minor injuries = 0.23 equivalent fatalities	0.3
No collision (emergency application of brakes)	2 minor injuries = 0.01 equivalent fatalities	0.01

Figure 7. Cost of the consequences of collision for the axle detector system.

included here – indirect benefits arising due to mitigation are costed into the safety assessment at a later stage.

It is done as a risk reduction exercise using the same kind of discovery methods as are listed for Stage 1. Indeed, some ideas may well already be on record as earlier stages were undertaken.

Consider an Options Analysis for the train axle detector given earlier.

Suppose two risk reduction options have been identified:

1. Rework the evaluator component's software

   - Total cost £2 million
   - Expected life 20 years

   – Annualized cost: £0.1 million

Consequence	Calculation	Cost £m
Major collision	115.9×0.0033	0.38
Minor collision	0.3×0.0049	0.01
No collision	0.01×1.0918	0.01
Total annualized loss		0.40

Figure 8. Annualized loss of the consequences of collision for the axle detector system.

2. Complete system redesign

   - Total cost £5 million
   - Expected life 20 years

   – Annualized cost: £0.5 million

7 STAGE 6 – IMPACT ANALYSIS

The purpose of an Impact Analysis is to assess the effects of implementing each of the risk reduction options. Its approach is to estimate the net cost or benefit of each option.

For each option (separately), revisit the previous stages of the analysis, inserting revised figures. The safety value of a change is calculated from the differences revealed. In this revision process, carry out each modification on the same qualitative or quantitative basis that was used originally; to change this, will not allow the baseline to be properly compared with the revision state.

Considering the two options identified for the axle counter and placing in some realistic data leads us to the following:

1. Rework evaluator software

   - Reduces failure rate by a factor of 3
   - Reduces annualized loss from £0.4 million to £0.13 million

   – Reduction in risk = £0.27 million per annum

2. Complete system redesign

   - Reduces failure rate by a factor of 10
   - Reduces annualized loss from £0.4 million to £0.04 million

   – Reduction in risk = £0.36 million per annum

Impact analysis is continued as iterative action loops until all variables under control have settled to give the safest situation for allowable factors.

From these outcomes, selection decisions need to be made using background factors existing at the time – political, financial, public pressure, and so on.

8 STAGE 7 – DEMONSTRATION OF ALARP

ALARP is a well-documented legal principle used in some health and safety activities – to see more on this topic, search the Internet under ALARP. It is used here to show the last stage of a system safety analysis. It is not, however, the only one required to be used, so always checkout the appropriate safety standard relevant to the project – *see* **Article 100, Safety Analysis Methods, Volume 2**.

Two things must be shown in order to justify that the acceptance of identified risks are ALARP:

- The overall risk, and each individual risk is below the upper limit of the tolerability that has been decided for the project and its circumstances.
- All practical and cost-effective risk reduction measures have been implemented. This is largely a scientific and engineering exercise but interpretations of what constituted such parameters as 'all practical and so on' need to be done against a background of appropriate legal advice.

Figure 9 shows the zones of the ALARP principle.

Figure 10 shows how to tabulate the cost/benefits resulting from the Loss and Impact Analyses.

Setting limits of acceptability are usually within the prerogative of the appropriate Board of Safety, or are dictated by national or international law. The task of safety analysis is to produce a Safety Case that demonstrates adherence being as low as it is reasonably practical – ALARP.

Bodies issuing the safety compliance certificate can inspect the report of the 7 Stage Safety Assessment process to ascertain that a sound and thorough study has been made.

Legal litigation is heavily based on the principle of reasonableness. This means that best practice needs to be reached in safety design because the knowledge of what can be done and how it can be achieved is available, making it reasonable to expect it to be used. This basis can, however, be slow to encourage new technology to be used, so some legal systems now include judgments that need a designer to apply current technology that would make the difference as long as that technology is reasonably available; it is not

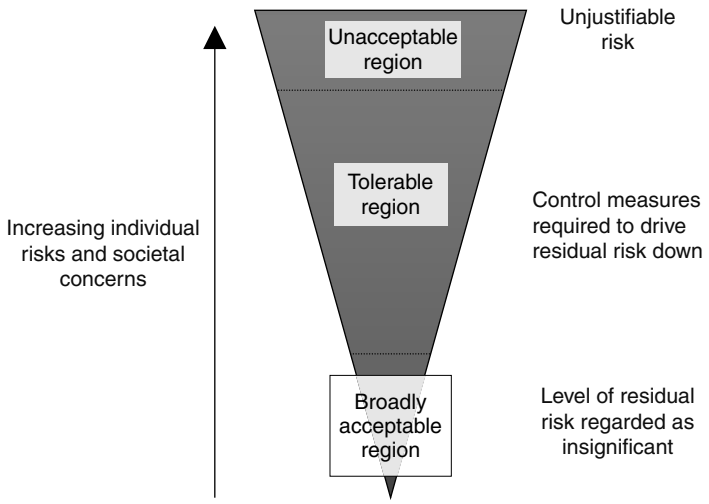

Figure 9. Zones of the ALARP principle.

	Cost/benefit calculations	Loss per year (£m)	Annual benefit over current design	Annual cost of modification (£m)	Option required?
Loss analysis	Current design	0.4	n/a	n/a	n/a
Impact analysis	Option 1 (rework evaluator s/w)	0.13	0.27	0.1	Yes
	Option 2 (complete redesign)	0.04	0.36	0.5	No

Figure 10. Table demonstrating the costs and benefits of a change to the system.

possible under those rules to retain old systems that could be made safer.

9 SAFETY PROCESS REVIEWS

It is necessary to give time to internally review the safety process put into place.

Ask these questions of that process:

- Is the hazard identification up to date?
- Have all potential accidents been assessed?
- Have all relevant probabilities been checked?
- Is probability assessment conservative?
- Has risk tolerability been assessed?
- Have the risks reduced, the system still being ALARP?

Beware of

- common cause failures,
- excessive optimism regarding systematic failures,
- the use of unstated assumptions and unexpected events – we cannot totally, definitively, predict all likely failure mechanisms! Their discovery is an ongoing process.

An independent professional review is essential to make sure internal bias does creep into assessments. The purpose of reviews is to

- provide assurance that the work that has been carried out has been (or is being) done in an adequately safe manner (i.e. in accordance with the agreed Safety Plan);
- form a judgment as to whether the risk associated with the system has been (or will be) reduced to an acceptable level.

Reviews are carried out as a series of appropriately scaled and scheduled audits and assessments that review both process and product.

External audits and assessments are also needed. These are carried out on the safety process by suitable third party authorities.

Safety Audits focus on the Engineering Safety Management (ESM) processes. Are the processes adequate? Are they being adhered to adequately?

Safety Assessments focus on the project's product; they evaluate the risk. Is the system safe? Is it fit for the purpose? Does it meet its safety claims?

In practice, there is some overlap between these two kinds of activity.

Audits and assessments must be conducted in an independent manner. The level of independence will depend upon the system involved. Several systems that are under the care of an organization may warrant different levels of independence.

These are driven by the system's defined Safety Integrity Level (SIL). Other factors, however, that may need to be considered are

- degree of developer's previous experience with a similar design,
- degree of complexity,
- degree of novelty,
- novelty of design,
- novelty of technology.

The timing of audits will generally start some way through a development when it is late enough for something to be there to be audited, but early enough to allow improvement to the processes while error correction costs are low.

Extra audits are carried out after transfer of safety responsibilities to the user agency and during all of the operational life. The system may be very well maintained and be kept within original specification, but the working environment, and political and public scene factors may have changed to degrade the ALARP levels of understanding in the originally certified system.

Assessments are done upon completion of the detailed engineering design phase. If done earlier, sufficient details will not be available. Prior checks will be carried out to uncover any obvious safety defect, but there they are more a matter of requirements and configuration control.

They will also be made immediately prior to safety case submission to ensure that all is in order right up to the minute.

The audit/assessment process starts off with the formation of a suitable plan. This includes

- familiarization with the project,
- review of previous audit or assessment,
- requirements, activities, timescales,
- project dependencies,
- audit/assessment team,
- delivery of documentation.

The plan is then carried out and the results reported to the agency calling for the assessment or audit.

Useful checklists of parameters to address in assessments and audits are given in Railtrack (2000, 2003).

1 INTRODUCTION TO LEGAL ISSUES

The sorts of legal issues that arise in measurement systems can be many and varied. This is because there are different systems of law in place, and different legal issues can occur at different stages of the design, implementation, and application times of the life cycle of a measuring system. For example, there might be specific legislative requirements such as those imposed by quality standards that have to be met in the design and production of a particular component of a measurement tool. Then, during the operational phase in which the measuring system is used, there may be other standards such as environmental standards that the designer of the measuring system needs to have in mind in setting the parameters for the measurement system. The sorts of legal issues that arise will depend on the nature of the system or product being developed and on the laws of the countries in which the instrument or system is to be developed and used.

The instrument or system designer will need to be aware of the law that will impact on the design and test processes such as the preparation of contracts and patents and, then, the legal context in which the system or product is to be tested and subsequently used.

Designers and test engineers should carefully consider how the law might impact on each step in the design, development, and test process, whether it be the contractual arrangements, protection of intellectual property, or liability, and seek appropriate advice to reduce the risk of adverse legal consequences, whether these be losses due to inadequate contracts or liability due to a failure in the system. This article covers a broad introduction to some of the legal concepts and issues that might arise. A case study about legal liability is given in **Article 103, Legal Liability Issues for Designers – A Case Study, Volume 2**.

A brief outline of some of the basic concepts follows.

2 DEFINITIONS

In most countries, the main sources of law are legislation and case law.

2.1 Case law

This is law made by the courts. The process of courts making law through judicial officers (e.g. magistrates or judges) depends on a number of factors:

- Level of the decision-making court in the hierarchy of courts. Most countries have a hierarchy of courts, and it usually follows that the higher the court in the hierarchy,

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

the more binding or persuasive its decision will be on the courts below.
- Nature of the cases or disputes coming before the courts, that is, the fact situations that allow the courts to adjudicate and make law.
- Case law from other countries, which may influence courts or be considered binding on courts in another country.
- As cases come before the courts for adjudication, a body of law is developed by judges applying judicial decisions from other cases to new fact situations. Many court proceedings are recorded in official court reports and so become available to judges and the public for future reference.

2.2 Legislation

Legislation is law made by a parliament. Legislation sets out the law relating to its subject matter in one document. Amendments can then subsequently be made by further amending legislation.

Legislation is produced following a lengthy process of debate in parliament and public consultation. The primary document is termed an *Act of Parliament*, which is usually required to be passed through parliament.

Some acts are termed *Consolidating Acts* because they consolidate legislation on a particular subject. Acts that amend legislation are usually called *amending acts*.

Some Acts adopt international conventions into the law of a particular country. An example is the Warsaw Convention, which concerns aviation liability and which has been introduced into the laws of many countries through aviation liability legislation.

Acts also allow for regulations to be made under the Act, which give effect to certain administrative matters. An example would be regulations that contain published documentary and physical SI standards. Another might be a law to protect the environment, that is passed in an act of parliament, such as 'The Environmental Protection Act'. The specific standards for emission of certain industrial gases would then be set out in regulations made under that act.

Both case law and legislation comprise the law in most countries, and both will need to be taken into consideration by all designers and testing processes at various stages.

3 LEGAL SYSTEMS IN FORCE

Many countries have different systems of law, which govern the way the law regulates processes. For instance, many countries have a system of common law such as that in England. By common law, we refer to a system of case law developed by the courts in which a complex set of precedents are gradually developed by judges considering cases coming before the courts.

Most countries that were previously in the British Commonwealth have a system based on the common law. The common law is law made by judges when they adjudicate disputes between parties. The authority to make common law is derived from the authority exercised by English judges over many centuries. A few examples of common-law countries are Great Britain, Australia, many of the states of America, and Canada. In these countries, judges have retained a significant direct role in creating law rather than just interpreting law made by legislation.

Many European countries have a different system of 'civil law', which is based on systematic legislation extending over more areas of law rather than case law being made by the judiciary. The law is 'codified' in detailed legislation and interpreted or applied by the courts.

These are just some of the systems of law in force throughout the world. It is important to interpret a situation according to the particular system in place in each country in which a system is developed or used. This also means where the system is to be used rather than where it is designed and made.

4 APPLICATION OF THE PRINCIPLES AND PROCESS OF THE LAW

In practice, the law is applied in various ways.

During the initial contract phase, this can be protecting intellectual property, compliance with standards, or dealing with a liability claim.

In the case of complying with standards, which is one of the most common applications of the law, that is, via legislation, those responsible for compliance will normally familiarize themselves with the standards relevant to their system design and incorporate the standards into the design as part of the design process. This will involve researching or obtaining advice on the standards that apply to the particular design. Most final contracts will dictate the standards to use.

An initial nondisclosure agreement is usually signed by the would-be contractor and the customer. Another preparatory legal mechanism used at the first encounter stage is the use of a Memorandum of Understanding (MOU), other names used being 'a letter of agreement', 'heads of discussion', and more.

In the case of protecting the intellectual property of a system, applications can be made for patents or by dealing with the rights of the parties in a contract. All these

processes involve the application of the law and the legal rights of the parties.

Another common application of the law is in the adjudication of liability disputes between individuals or corporations. As mentioned earlier, this is the way in which case law is developed and applied by courts in factual situations.

This is more difficult to research because case law is developing everyday on different subject matter and not all cases are officially reported. While the most significant decisions of the highest courts are reported, those decisions of lower courts may not be reported. Other sources of information on court decisions are textbooks and journals and Web services.

All jurisdictions have a hierarchy of courts. The criteria for each level of the hierarchy will determine the court in which a particular dispute is adjudicated. In most jurisdictions, the level of the court is set by criteria such as the type of crime or the monetary value of the compensation being sought. For instance, most jurisdictions have a supreme or high court at the top of the hierarchy, a district or county court at the middle level, and a local or magistrate's court at the lower level. With all the various different levels in the court system, cases on the same sort of subject matter may be subject to adjudication in different courts for the same case. You might find that the legal liability for a person injured in the same accident is being determined in different courts because each person is seeking different amounts of compensation.

5 DIFFICULTIES IN APPLICATION OF THE LAW

The common law probably presents a more difficult concept than legislation. Legislation can be obtained from most government printers and is usually identified by subject matter. Because legislation is constantly undergoing change by parliament, subsequent amendments also need to be checked. Helpfully though, many government printers will produce a consolidation from time to time, which brings together the principal act and subsequent amendments. There are also many annotated versions of legislation produced by academics and law firms.

The common law, on the other hand, requires constant research for new decisions by the courts. Judicial consideration of previous cases and facts can sometimes produce only a minor variation to the law but one that can mean the difference between liability and no liability for a particular act or omission. One of the most relevant common-law concepts for professionals is the law of torts (or wrongs). This aspect concerns civil liability for damage caused to another. For those providing professional services, the tort of negligence is probably the most frequently used common-law action.

Explaining the law of torts and the concept of negligence easily needs a large text book to introduce its many facets. In very simple terms, it involves the concept of owing a duty of care to another, the standard of that duty of care, breaching the duty, and causing damage to the other party. Unlike a situation in which you may have a contract with another party, under which you have certain remedies against that other contracting party for a breach of the contract, the duty of care in the law of torts does not depend on a contract existing between the parties. For instance, if an engineer contracts with an aircraft manufacturer to design an aircraft and if the aircraft is faulty, the manufacturer has contractual rights against the engineer. If the aircraft crashes and injures passengers, the passengers may have a claim against the engineer, under the tort of negligence.

Laws also vary from country to country and, therefore, so do standards. Those designing measurement systems for use in different countries need to be aware of the differing standards between countries. A measurement system used in one country may be subject to different thresholds of liability in another.

Fortunately, with the development of more international standards and more uniformity of standards for products between countries, it is becoming easier for a designer and manufacturer to produce a product, which will ultimately comply with the standards in a wider variety of countries. While complying is more straightforward with legislation, it is not so with the common law.

In the same way as mandatory products standards vary from country to country, the threshold for tortious liability at common law will also vary even between those countries with the same basic system of common law. For instance, the standard of care required by a design engineer in one common-law country such as the United Kingdom may be more or less stringent than in another common-law country such as Australia even where the second country's common-law system is largely based on that of the first.

Because the standard of care expected by any common-law system will be subject to change at any time by the courts, there is a much greater imposition on any designer or manufacturer, particularly one offering a professional service in the nature of expert advice, to be conscious of the relevant standard in the jurisdiction in which they operate and the likely standard in any other jurisdiction in which the expert advice is likely to be relied upon. Fortunately, many common-law countries are now incorporating the concepts of standard of care into legislation to try to provide more certainty and consistency into these concepts.

Where legislation exists, it will generally override the common law on the same subject matter. However, legislation is still subject to interpretation by the courts, so expert advice from those legally trained should be considered where there is doubt about which law or standard applies.

6 THE LITIGATION PROCESS

The litigation process is complex. Litigation involves the process by which a series of events (facts) become a dispute between two parties and ends up in court. The term often used is *suing* another party.

An event that starts the litigation process is usually one where something goes wrong, which leads to injury to a person, damage to property, or a loss to business caused by failure. For instance, it may be a failure that leads to interruption of a business activity. There are any numbers of failures that can cause such an event.

The party (person or corporation) suffering the loss can make a claim for compensation against the other. If a contract exists between the parties, the usual claim is for breach of contract. If no contract exists, the claim can be in tort if such a right is recognized by law.

The process of litigation often starts with a letter of demand written between the parties to try to resolve the problem or to negotiate a settlement for money. A lawyer may be consulted at this stage or the parties may chose to try to reach a resolution between themselves. They may have consulted a lawyer to find out their rights under the law or the strength of their respective positions. In more serious events, most corporations involve lawyers from the time of the event.

If a letter of demand is not successful in providing resolution, lawyers are often called in to advise the parties on their rights. These rights may include commencing litigation in the courts. There are other alternatives such as further negotiation, mediation, and arbitration. Each has pros and cons in terms of cost and effectiveness.

7 COMMENCING LITIGATION

Litigation is usually commenced with a formal document called a *writ* or *summons*. This document is filed with the court and served on the other party being sued. The formal court process is called an *action*. The receipt of a writ or summons may be the first notice a party has of a claim or action against them.

Once the litigation process has commenced, the suing party may then file a more detailed statement of its claim against the other, called a *statement of claim* or *particulars of claim*.

The defending party is then usually required by the court rules to file a responding document called a *defense*. If no defense is filed, the court rules usually provide for the suing party to enter judgment by default. It is, therefore, extremely important that a party being sued responds to the service of a letter of demand or writ. Usually, a lawyer is consulted when either of these documents is received. The statement of claim and defense are called the *pleadings*. They define the issues of fact and law in dispute between the parties and are usually drafted by lawyers.

The type of claim and the monetary value of the claim determine the forum in which the court action is commenced. The process of commencing the claim is the same for both individual and corporation.

The action then proceeds through the court list toward a trial. Certain steps need to be taken by the parties before trial. These are

- finalization of the pleadings;
- disclosure of all relevant documents to each other;
- formal pretrial conference to facilitate settlement of the dispute.

At any stage, the possibility for a negotiated settlement or other form of resolution such as mediation can be explored. In general, 90% of all litigated disputes settle before going to trial. This is because the outcome of a trial is considered to be uncertain and many parties prefer to reach a compromise between them.

At all times during the process, parties (clients) are expected to cooperate with the court and their lawyers by providing frank and timely instructions and by making evidence available. Evidence can be in any form such as products, components, data, information either written or recorded in any other form, or oral testimony.

8 EVIDENCE AND DOCUMENTATION

In any situation in which legal issues are concerned, but especially in a litigated case, evidence is crucial to the way the case is conducted.

Because a party must prove its case to a court, it is by the evidence called at a trial that this is achieved. Whether the evidence is the oral testimony of a witness, documents or data, or expert evidence, the case will only be as good as the evidence available to prove the case.

It is, therefore, important that good quality and complete information of the various steps in the design and implementation of measuring systems is recorded and retained. Claims may not arise for many years after the product or system is released into the public environment, and disputes may not reach trial for many years. Memories as to

what took place will fade and the information recorded by the individuals involved will often be the only reminder of what took place. There are legislated time limits imposed on claims for damages and under the law of contract in most jurisdictions, but these can still be many years and extensions to these are possible in some cases.

Information and data that might be needed to trace a process for those involved should therefore always be stored in a secure environment for long preservation. Legal advice can be obtained before information is generated to ensure it is likely to be suitable. Legal advice is needed before destruction as to the relevant time limits that might apply for claims.

Good preservation of sound and relevant information is one of the best risk-management procedures for litigation.

The important issue for each designer to keep in mind is to inform themselves of the relevant legislative standards and the relevant common-law duties that they are required to comply with.

In most common-law jurisdictions, for instance, the standard of care likely to be used to judge a professional service, such as might be provided with expert advice in the design of a measuring system, is that of a test of reasonableness. While it is often difficult to identify the precise standard as to reasonableness, the best guide is usually what is considered to be appropriate industry practice by one's peers. A rider to this is that today what is reasonable to use because of technological change also needs to be considered. All this becomes quite difficult when the technology is considered to be at the very cutting edge of industry practice and standard or where, for instance, research into a completely new system is being carried out.

9 REDUCING LIABILITY

In order to reduce the risk of legal liability arising during the design and development of a system, and to best assist in defending a claim if it does arise, an organization or individual should

- be familiar with the applicable law and standards that apply and that will apply to the system, test environment, and the final system or product;
- maintain and preserve clear and comprehensive records throughout the entire design and test process, whether it is written notes, data, or hardware;
- seek appropriate expert advice to establish a sound and comprehensive contractual basis for any activity to protect intellectual rights and to deal with possible consequences such as by maintaining adequate insurance to cover all potential liabilities;
- seek timely expert legal advice in responding to all major incidents and threats of legal action such as a letter of demand or writ.

Following these basic principles will not, of course, guarantee a litigation-free project, but it should help reduce the numbers of adverse situations and assist in dealing with such a situation, if it arises, in the best and most efficient way. By being prepared and being able to demonstrate, a case can be well defended and will deter claims being made.

Some useful reference texts for further material on the legal processes are given.

1 INTRODUCTION

A general introduction to the legal aspects of engineering applications is presented in **Article 102, Introduction to the Legal Process, Volume 2**. It is shown in that article that there are many legal situations to guard against and that expert legal assistance is often essential throughout a project.

This case study extends that discussion by illustrating some of the legal liability issues that can arise in the perspective of an application. It is intended to highlight issues, not to constitute legal advice: it is important to note that legal advice must be taken on a case-by-case basis using experts who can chart the way through the law and its processes.

In particular, this study demonstrates how a system designed for measurement during the design phase of a sophisticated product, such as a commercial aircraft, can fail, leading to legal liability being attached to several parties including, perhaps, the measuring system designer. The liability might be for damage to person, property, or for loss of business.

It is quite easy to see how an omission, however minor, during the test and evaluation phases of a part of the design of an instrument or system can lead to catastrophic consequences for the testing body, the manufacturer, and any third parties injured by the omission.

The legal concepts in the example can be readily applied to systems designed for measuring or testing or those that might be used during the operation and performance of a system or product. Equally, the concepts can be applied to the provision of advice as well as the provision of services that are based on software or data.

Legal risk is not totally avoidable but it can be mitigated by taking appropriate actions from the start of a project. This is covered in Section 9.

2 FACTS AND BACKGROUND OF ROLE STUDY

The case study example involves a fictitious university research unit, which has tendered for a contract concerned with testing the accuracy of a navigational instrument to be installed in the cockpit panel of a commercial aircraft. The navigational instrument incorporates the use of a novel method for processing the output signals from a conventional directional gyroscope, which indicates the direction of flight to the flight crew.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

The university unit decides to tender as a joint venture with a private technology company. In particular, the university brings to the contract the expertise of one of its senior researchers on the behavior of measuring instruments under extreme temperatures. Temperature is a critical feature in the proper operation of the new instrument.

A contract is drawn up between the university and private company for each to provide certain aspects of the tender services. The tender is successful and provides a significant grant to the research budget of the university department.

This university has never really been overly concerned about its exposure for liability on these sorts of projects and, therefore, decides that its normal insurance arrangements are adequate for the joint venture.

The contract goes ahead without event until there is a change in personnel within the university department. The senior researcher with the expertise in temperature effects has a major disagreement with the head of the department and resigns on short notice. His area is quite specialized, and the university finds it hard to replace his expertise. The head of department assures the private company that they can continue the contract with other researchers and so it continues.

The testing process is completed and the instrument is rated to perform satisfactorily at its declared operating temperatures. However, due to a miscalculation by one of the researchers during testing, it is actually out of specification and indicates incorrectly when subject to very low temperature.

The instrument is fitted to a prototype aircraft by the manufacturer for final operational test and evaluation. On its first test flight, the directional instrument fails to function accurately at high altitude (due to the low temperature there) and the prototype aircraft crashes, resulting in the loss of the test crew.

3 LEGAL CONSEQUENCES IN GENERAL

A number of significant legal consequences can flow from this scenario. The key issues are

- liability for the deaths
- liability for damage to property, that is, loss of the aircraft and damage to any buildings it destroyed while crashing
- public inquiry to ascertain what went wrong
- criminal investigation
- product recall if the component has already been placed into service.

These are addressed below as separate issues but they usually will be interdependent in reality.

These are each likely to be very expensive and time-consuming exercises. Their impact on the providing parties and their affiliations can be very harsh, leading to loss of employment, criminal penalties, corporate collapse, payment of compensation, and loss of goodwill in the market place, to name a few.

4 LIABILITY FOR THE DEATHS OF THE TEST CREW AND DAMAGE TO PROPERTY

There is likely to be a claim by the dependants of the test crew killed during the test flight. This claim may be brought under one or more of the following

- aviation law
- at common law
- under fatal accident legislation
- under employee/employer liability.

In each case, there is likely to be a complicated legal analysis of the various competing claims.

Any claim brought by the dependants is most likely to be against the manufacturer of the prototype, but it may also be contemplated against the contractors such as the university and private technology company or the flight licensing authority. To make matters more complex, those influencing the legal forces at play can be constantly changing.

Even if the claim, or claims, is brought against the manufacturer and not the university unit/private company, the manufacturer or their insurer will almost certainly seek to recover its losses from the university/private company. These losses may include compensation for the loss of the prototype hull and/or for loss of profits.

The contracts for the project may (or may not) have included detailed clauses providing for indemnities between the parties in the event of certain types of claims. This may further complicate (or possibly simplify) matters as to which party is ultimately liable.

The same could be said in the case of claims by any person injured on the ground or any property of such persons damaged by the falling wreckage.

If the various companies involved have insurers, each is likely to become involved with their own team of lawyers in addition to the lawyers involved for the parties, adding further complexity and cost to the resolution of any claims arising from the crash.

In all the legal scenarios above, the manufacturer, university, or private company could be exposed to considerable loss. A potential lack of adequate insurance could also expose the university to severe financial embarrassment,

depending on the level of insurance arrangements for the university, under normal circumstances.

5 PUBLIC INQUIRIES

In many countries, the crash of an aircraft will involve an official investigation by the local air safety bureau. Human fatalities in such circumstances will usually also result in an investigation by the local coroner.

In each case, an investigation can take months or years to complete, will cause much anxiety for all those involved (particularly those who will appear as witnesses), and will potentially expose the organizations to adverse publicity during the investigations, not to mention the close scrutiny each organization will undergo during any legal process.

During the safety bureau investigation, documents and design material will be taken and fully considered by a whole series of experts. Those personnel involved in all stages of the design and test process including the university team, both past and present, will be interviewed a number of times for witness statements. For instance, it is possible that each could be interviewed up to four to five times by the crash investigators, coroner's investigators, police, and lawyers in connection with each legal part of the case. Each legal inquiry may result in significant consequences for each of the parties involved.

The coronial investigation may result in findings, which lead to criminal investigations or recommendations, which affect the licence of the manufacturer or the way in which the aviation research industry is regulated.

The air safety bureau investigation and its findings may also lead to further investigations by the police or to recommendations for regulation of the industry.

All of these actions will produce adverse publicity for all those involved but particularly for the commercial reputation of the aircraft manufacturer. In this example, there are likely to be at least two unavoidable public hearings irrespective of the compensation claims. Prior to the hearings and for the hearing itself, staff time and traveling costs will be needed to prepare maternal and to attend the inquiries when called.

6 CRIMINAL INVESTIGATIONS

This is a third category of possible legal process that may affect this example. In disastrous events such as plane crashes, train collisions, or building collapses where lives are lost, there is an increasing trend for those in positions of responsibility to be held publicly accountable for their actions or omissions.

Historically, the corporate veil provided a shield for individuals against criminal prosecution for reckless or irresponsible acts that led to the loss of life. In many countries, that situation has been changing over recent years. Courts are now more prepared to look into the inner workings of a company to find those persons whose key actions may have led directly or indirectly to the event.

So, in this example, an investigation might reveal that the head of the university department misled the manufacturer as to their ability to continue the project and consider that his or her actions led directly to the failure of the instrument.

Also, one of the directors of the manufacturer may have known or suspected that the university did not have the competence to satisfactorily complete the project but may have remained silent for the sake of the project being completed.

In all cases, prosecutions for these sorts of disasters can carry significant penalties for companies and the individuals. Companies can be fined; individuals can be imprisoned or fined. The more severe the disaster, the more severe the penalties for those found to be responsible.

7 PRODUCT LIABILITY AND RECALL

In addition to the above legal issues, another costly allied liability situation, which could occur if any component has already been distributed in another product or in addition to the above types of liability is product liability. For a component that has already found its way into the market place in a product, the need to carry out a product recall may result. This is usually done to correct a defect in a design or its manufacture or to call back products with subsequent refund of purchase price and possibly compensation.

When these involve large numbers of a product item, they are commonly seen advertised in newspapers for such things as defects in automobiles, consumer goods, and foodstuffs. Where it is not possible to accurately identify all customers, these notices are directed at the purchaser or user.

In the notice issued for the defect, the serial numbers and product names of the defective lot are identified. The defect is explained in lay terms and the recommended immediate action to be taken is stated. Persons who believe they have a defective item are asked to make contact to arrange for withdrawal and refund, replacement, or rectification, free of charge.

Other less publicly noticeable statements are sent to wholesalers, franchisers, distributors, and retailers.

In the case of a defect in a sophisticated aircraft and where there are a low number of early models, the manufacturer will be aware of all sales and can make rapid contact with the buyers, and a public notice will not be needed.

Where it is not economic to rectify the item, the maker will usually need to recover it, compensating the buyer.

In some cases, it will be economic and prudent to make a modification to each item via a rework activity through provision of parts to be replaced or added by the owner, or as a factory operation by the supplier.

Recalls can be surprisingly expensive exercises. The overall cost might well not only take an individual project into a loss balance sheet but also place the organization into liquidation.

One way to demonstrate what is involved is by listing the factors involved for the example given, along with likely costs; refer to Table 1.

In this case study, assume that the maker had also delivered the same incorrectly calibrated prototype gyro and its data processor unit to an aircraft instrument systems' supplier. Also assume that no unit, apart from the one in the crashed aircraft, had yet been sold for deployment.

For safety reasons, the maker needs to immediately notify the supplier to not sell or use any of the units and to retrieve them for design alteration or destruction.

Many of the costs of a recall are for tangible items. Some items, however, are less easy to identify in clear-cut monetary terms, examples being the value of loss of goodwill and the impact of disturbing normal design and manufacturing operations.

Assume that the defect in this case study was shown to be quite simple, being that an electrical resistor involved in the calibration could marginally overheat, changing its resistance, which in turn could alter the gain of a critical signal-processing preamplifier.

Table 1. Costs associated with recall to repair or withdraw a defective low volume item.

Item	Time estimate (h)	Cost ($)	No. of units	Recall to fix option	Refund and withdraw product option
Designing a change fix					
Engineer labor (20 h @ $75/h^{-1})	20	75	All units	1500	
Drawings, part lists, work instructions	20	80	All units	1600	
Press release to lessen impact					
Media labor costs	8	80		640	640
Newspapers/radios costs				5000	5000
Freight and handling					
Freight of units back from customer		100	10	1000	1000
Tracking costs for 20 days	100	2	10	2000	2000
Outward dispatch labor	1	60	10	600	
Freight of units to customer		200	10	2000	
Compensation paid for inventory changes – not for any liabilities				2000	10 000
Media relations costs				5000	5000
Execution of repair					
Disassemble labor	10	80	10	8000	
Repair assemble	10	80	10	8000	
Test and recertification	40	80	10	32 000	
Other costs					
Loss of other production due to diverted staff – assessed as $1000 per recalled item repaired		1000	10	10 000	
Replacement loan gyros		500	10	5000	
Legal advice on change made				5000	
Total cost estimate of recall and repair of defective instruments				89 340	
Total cost to withdraw and refund for items					23 640
Minimum cost for option chosen				89 340	23 640
Sales income for 10 units			5000	50 000	
Overall income (loss in this case) for option chosen				($39 340)	($23 640)

Note: The assumption is that 10 instruments have been sold and all need to be rectified. They were sold for $5000 each, with a profit margin of 20% of sales. The problem was soon found to be quite simple, being that an electrical resistor's power-carrying capacity was inadequate and could overheat, changing the gain of a critical signal-processing amplifier.

This problem could have arisen from such reasons as

- supply of the wrong part by errors of specification or purchasing, or selection;
- ventilation around the resistor had been reduced from the design value to save cost and size;
- another component generating local heat was placed next to this critical resistor;
- the whole unit was placed in an environment hotter or colder beyond specification.

From the details of Table 1, several points are clear:

- The costs of the 'recall to fix' and the alternative 'refund and withdraw' options are both major – but one has to be chosen. The cost of recall cannot be avoided.
- The 'recall to fix' option is marginally the dearest to implement, but it will possibly be seen to be necessary for business to continue and for more sales to be made.
- The 'refund and withdraw' option is the least costly option, but it loses not only goodwill but also considerable income from sales of the product.
- The cost of either option may well exceed the costs of development, influencing the future of the project.

These costs are apart from any legal liability arising from the aircraft crash but would involve a commercial decision taken after the legal consequences have been considered. It is often the case that commercial decisions are taken in conjunction with advice from lawyers. Clearly, design errors like this need to be controlled early to reduce legal risk.

8 LEGAL PROCESS

In all of the legal consequences mentioned above, the process will begin with the personnel being contacted for interviews. Either the air safety investigators or the police or the coroner's investigators will be the first to investigate. They will request documents and other materials such as data, software, and hardware for preservation and for the purposes of their inquiries. Equipment and files may be impounded.

One would also hope that the companies have contacted their own lawyers and insurers at the earliest opportunity to assist with responding to the investigations.

The quality of the documentation made during the various processes used in design and testing becomes critical while responding to any allegations. All the documentation and other materials have the potential to become evidence during the investigation. Notes made by each of the personnel during the project will become their aide memoires when called upon to give statements. Human memory is notoriously inaccurate after time has elapsed and the notes made may be the difference between accurately recalling ones actions or not. That is why the concept of proper record keeping is reinforced constantly by the legal profession. When a person gives evidence to a court, their credibility to recall events is often determined by whether they have properly recorded their past actions.

9 LEGAL RISK MITIGATION

The above examples show how legal liability will affect all concerned if a design causes harm in some way in its normal or abused use. Designers need to be able to defend any design that has been practiced to 'best practice' standards.

Some indicators on how to limit that risk as design proceeds are now presented. It would be ideal to have a lawyer in the design team to give advice on every decision made but that is often not practical. Designers must exercise judgment and make use of regular legal reviews of the project.

The main line of defense will usually be the ability to demonstrate 'sufficient standard of care' or that 'due diligence has been practiced'. Where a situation cannot be formally described in complete reductionist terms – most of those that give rise to litigation – the case will be argued on the basis of 'reasonableness', a highly subjective cognitive concept that lawyers are experienced in arguing one way or the other.

Preparation for legal defense starts when the project commences. Following practices of reasonable design and keeping a suitable document trail are absolutely necessary. Without these, it would be difficult to provide the evidence needed to withstand scrutiny during any of the legal processes discussed above.

If adequate records are not made at the time, it may well be impossible to later find the documented evidence needed to support witnesses or the defense case. It is acknowledged that detailed documentation will impose significant additional overhead on a project and record information that may never be called upon. Taking such precautions is, however, much like taking out additional insurance; one hopes it is never needed but it is a comforting thing to have in place when needed.

The design team is not expected to provide for every possible circumstance in a design, as that would suppress creation and cost-effectiveness. The team should allow for that which is reasonable. Allowance has to be made for all situations that can reasonably be expected to arise.

Some key points to assist in the better defense of a legal liability suit are:

- description of, and adherence to, a formalized design process by project personnel;
- peer design review and approval of project design information and documentation;
- management of system safety by a formally constituted Safety Board, with a sound and documented safety and design change process;
- reference and adherence to Standards and Regulatory requirements for the appropriate aspects of the design;
- appropriate training for designers, with records of attendance and achievement in learning;
- findings of independent quality audits conducted during the execution of project activities that confirm that adequate duty of care has been exercised;
- availability of the above evidence that is suitably framed to suit legal requirements;
- maintenance of records of appropriate calibrations and certifications;
- availability of information to show that current practice used in the project is in accordance with other similar designs;
- well-run risk and safety assessment process that has been in place.

Adequate security of records and equipments is also necessary to support the veracity of any case made. Relevant details must be secured and staff access controlled.

Just how far these various issues should be addressed will depend on factors such as

- nature of the project (such as defense, government, sea, air, land, utilities, commercial, personal, health, etc.)
- kind of system delivered (benign, hazardous, domestic, factory)
- environmental impact, guidance being found in an environmental impact statement (EIS) for the project, if one exists
- locality and extent of application (office, city, country, international)
- level of perceived public acceptance (automobile safety vs aircraft safety, natural environment, low or heightened public interest, child or adult user)
- lifetime of system use (days to decades)
- business issues (profits made, risks to be accepted)
- potential population affected by the system.

Clearly, legal advice is crucial when considering procedures and processes to minimize the risk of legal consequences for any project. Lawyers can anticipate the consequences and advise on how to protect the project from such risk.

A well-prepared set of documentation and a sound best practice process form a sound basis for fending off claims; either an adverse consequence will not occur or, if it does, a claimant will find it harder to argue that standards have been breached, leading to liability. Sound processes will also make it much easier for a legal team to assess whether a claim will succeed and so assist them to properly manage the consequences and reduce public and commercial damage.

A corollary is that a legally sound process being in place is highly likely to avoid litigation in the first place because the delivered system is less likely to incur difficulties because of its greater integrity.

Further information on this topic is available in Sydenham (2004). An extensive table of issues to address at each phase of the project life cycle is presented there.

1 MEASUREMENT AS A COMPARISON MODEL

Measurement is an operation of data acquisition and presentation, aimed at expressing in symbolic form the information empirically obtained on a system about a quantity, the measurand (we accept the common ambiguities of calling 'measurand' both the system under measurement and the measured quantity, and the latter in both its general and specific forms, for example, length and length of a given object in a given time).

Peculiar to measurement is the requirement of being objective and intersubjective, where objectivity implies that measurement results convey information only related to the system under measurement and not its environment, and intersubjectivity requires that measurement results convey the same information to different subjects. As such, these properties appear an ideal target, justifying the efforts to constantly enhance measurement devices and procedures.

To achieve an acceptable degree of objectivity and intersubjectivity, measuring systems are adopted, which include selective and repeatable sensors and traceable standards. Indeed:

- Although human beings are able to directly sense a fair amount of quantities and are well trained to express in linguistic form their perception (e.g. 'it is rather cold', 'this is heavier than that'), their statements are affected by subjectivity, that is, they report information on both the sensed system and the perceiver state; to avoid the influence of the latter, and thus to enhance the objectivity of the operation, the measurand is transduced by a sensing system whose output ideally depends only on the measurand and is unaffected by influence quantities and internal imperfections.
- While related to the measurand, the quantity provided by sensors still depends on their specific behavior; as a consequence, distinct sensors, even if perfectly repeatable, produce different outputs from the same input; furthermore, in many cases the sensor output quantity, appropriate for signal conditioning and for driving presentation devices, is not dimensionally homogeneous to the measurand. The sensor output must then be dealt with as an instrument reading, not as a measurand value. To make the information obtained by the measurement intersubjective, a common reference must be adopted so that measurand values are expressed in comparison to such a standard. Therefore, the possibility of tracing the readings to the agreed standard is critical, a condition operatively ensured by instrument calibration.

The requirement of empirical comparison to traceable standards is so fundamental that it can be assumed as distinctive of measurement; generic scale-preserving evaluations can be formalized as homomorphisms from empirical to symbolic relational systems, as shown in Figure 1 (*see also* **Article 8, Formal Theory of Measurement, Volume 1**). In the case of measurement, such mappings are

Figure 1. A generic scale-preserving evaluation.

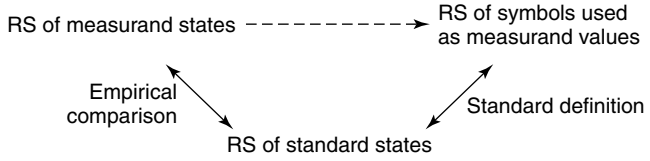

Figure 2. Measurement as a scale-preserving evaluation obtained by the comparison to a standard.

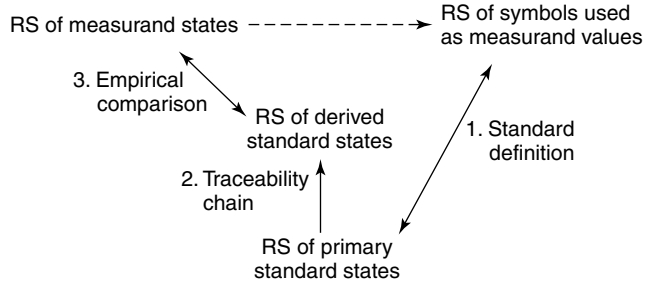

Figure 3. Measurement as a scale-preserving evaluation obtained by the comparison to a standard derived by a primary standard.

not direct but mediated by the comparison to standards, as shown in Figure 2. Finally, the situation in which primary standards are not directly available can be schematized as in Figure 3. In such a case, operations 1 and 2 are usually carried out before measurement: nevertheless, measurement cannot be completed without them and therefore such operations play an essential role in the definition of measurement itself.

As a consequence, measurement results must state a measurand value with reference to the adopted standard, usually expressed in the form of a measurement unit (*see also* **Article 43, Units, Volume 1**).

2 THE OUTPUT/INPUT BLACK BOX MODEL

It is a well-known fact that different methods of measurement exist, each of them corresponding to a specific technique to perform the comparison between the measurand and the standard (see Figure 4). While some methods require the synchronous presence of the measurand and the standard (e.g. following the paradigm of the two-arm balance provided with a set of standard weights: a direct comparison), many others are based on the usage of devices acting as serializers of the comparison, so that a

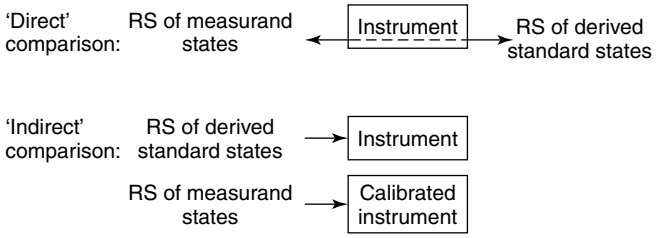

Figure 4. The different usages of the measuring systems as comparators.

measurement involves (at least) two interactions: standard-instrument and measurand-instrument.

In its interaction with the measurand, the instrument generates an output; a general problem of measurement can then be stated as follows: *from the output of the measuring instrument ('the reading') its input (the state of the system under measurement and its environment) must be reconstructed, and from this state a measurand value must be inferred*.

To cope with this input-from-output inference problem, two basic strategies can, in principle, be followed:

- The analytical model of the measuring system behavior is identified and the obtained characteristic function is inverted, so that from the output readings the input signals are computed. Because of its complexity, this approach is seldom adopted.
- The system is regarded as a black box and only its input–output behavior is taken into account: the instrument operates by interacting with a set of (known) standard states and the corresponding output readings are recorded; by a suitable interpolation, this collection of couples becomes the so-called *calibration curve*, shown in Figure 5, which can be thought of as a mapping from measurand values to instrument readings. This function is then inverted so that each instrument reading can be associated with a measurand value.

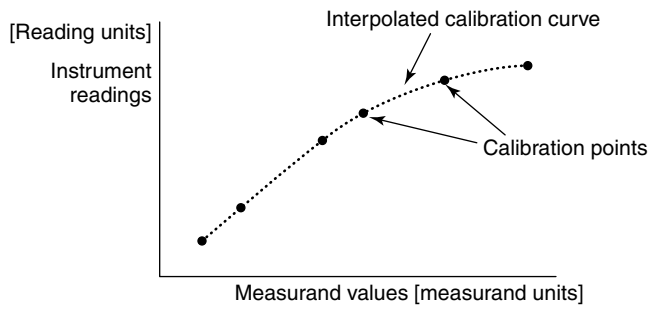

Figure 5. A diagram with the example of a curve generated by calibration.

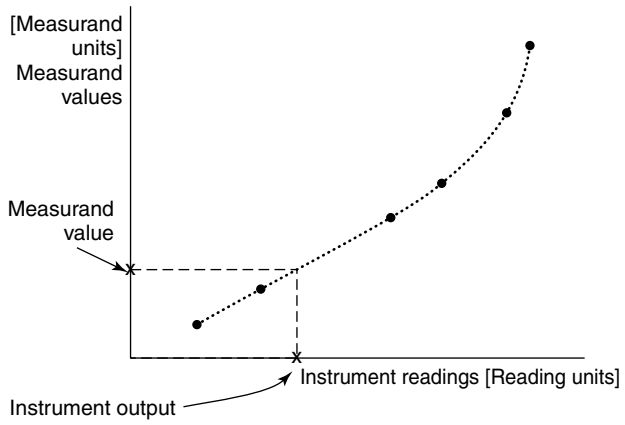

Figure 6. The example of an inverted calibration diagram, for usage in measurement.

The interactions standard-instrument and measurand-instrument have therefore a complementary function: while the former is aimed at creating a calibration diagram, the latter uses the inverted diagram, shown in Figure 6, to find the measurand value that corresponds to the obtained reading.

To enhance the user-friendliness of the measuring systems, it is customary to set up their presentation component so that the data they display are expressed directly in measurand units, that is, the calibration diagram is embedded into the systems. While measurement always requires calibration information, in these cases one can specifically speak of calibrated instruments.

3 SET-THEORETICAL MODEL

The sensor behavior, therefore critical for both calibration and measurement, is usually expressed as a characteristic function formalizing the input–output conversion performed by the sensor itself.

The sensor input, a couple $(x, \overline{w})$ where $x = x(t) \in X$ is the measurand and $\overline{w} = \langle w_1, \ldots, w_n \rangle = \langle w_1(t), \ldots, w_n(t) \rangle \in \overline{W}$ is a collection of further quantities influencing the sensor behavior, is transformed to its output $y \in Y$. Therefore, the sensor characteristic function:

$$f : X \times \overline{W} \times T \to Y \tag{1}$$

takes the measurand $x(t)$, the influence quantities $\overline{w}(t)$ and the current time t, included to take into account possible time-dependent effects, and associate them with the output signal $y(t) = f(x(t), \overline{w}(t), t)$ to which both the measurand ('the signal') and the influence quantities ('the noise') contribute.

This simple formalization allows us to introduce some basic parameters describing the static behavior of a sensor:

- *Sensitivity*: ideally, $x_1 \neq x_2$ implies $f(x_1, \overline{w}, t) \neq f(x_2, \overline{w}, t)$, that is, distinct measurand values always produce distinct outputs; the ratio $\Delta y / \Delta x$ expresses the aptitude of the sensor to reproduce measurand variations to output values.
- *Selectivity*: ideally $f(x, \overline{w}_1, t) = f(x, \overline{w}_2, t)$ even if $\overline{w}_1 \neq \overline{w}_2$, that is, the sensor output is not affected by the variations of influence quantities; the less is the variability of y due to $\overline{w}$, the better is the sensor (therefore, selectivity corresponds to nonsensitivity to influence quantities: the relative contribution of the measurand to the output can be formalized as a signal-to-noise ratio).
- *Repeatability and stability*: ideally $f(x, \overline{w}, t_1) = f(x, \overline{w}, t_2)$ even if $t_1 \neq t_2$, that is, the sensor output is not affected by short-term (fluctuations) and long-term (aging) time effects; the less is the variability of y due to t the better is the sensor (a stable sensor does not require frequent recalibrations).
- *Linearity*: ideally $y = ax + b$ (where a and b are given coefficients, possibly with $b = 0$), that is, f is a straight line, the better the actual sensor behavior is approximated by this equation, the better the sensor is usually considered to be (a linear, zero-crossing sensor is calibrated in a single operation, aimed at determining the slope a).

In addition to these static parameters, the dynamic behavior of the sensor is synthesized by parameters such as its frequency response (*see also* **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**; **Article 27, Signals in the Frequency Domain, Volume 1**; and **Article 36, Systems in the Frequency Domain, Volume 1**).

The technical specifications for sensors usually include some quantitative evaluation for these parameters in the nominal conditions of usage, expressed by the allowed ranges of measurand and influence quantities.

4 GENERALIZED MODEL

The inference process that leads to the evaluation and the expression of a measurand value is always only plausible in its results, and in general nothing can be inferred with certainty about the measurand value. The causes of this lack of certainty are various, and in particular the following:

- The model of the measurement system has not identified all of the relevant influence quantities, and any one of them may have a significant variability, such that the

environmental conditions (including human operators) change after the calibration.
- The measuring system is less stable than expected when the calibration procedure was defined, that is, the instrument would require a recalibration before its usage.
- The interpolation shape of the calibration curve does not adequately map the actual instrument behavior (e.g. it is significantly nonlinear where a piecewise linear interpolation was chosen), so that for some instrument reading subsets the instrument is wrongly calibrated – *see* **Article 58, Description of Accuracy, Linearity, and Drift, Volume 1**.

All these cases can be formally characterized by recognizing that the certainty implied in the choice of a single-valued association between instrument readings and measurand values is not adequate. In the interaction with the measuring system during calibration, each measurand value generates an instrument reading that should be considered a sample drawn from a whole set of possible readings.

Such variability can be formalized according to a set-theoretical model, so that the information obtained in the calibration is expressed by a calibration strip, in which an interval of possible readings, whose center and width can be considered as the nominal reading and an uncertainty interval respectively, is associated with each measurand value (see Figure 7). (Note the changes of the calibration strip width along the measurand axis, taking into account nonuniformities in the uncertainty evaluation.)

As in the previous (certain, and therefore ideal) case, this diagram is used in its inverted form during measurement: for any given instrument reading, an uncertainty interval of possible measurand values is obtained together with a nominal value (*see also* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**).

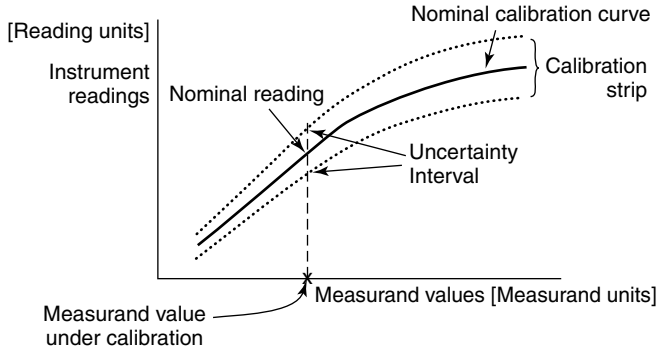

Figure 7. A diagram with the example of a strip generated by a calibration in which uncertainty has been taken into account.

An even more general approach could be adopted by expressing the uncertainty estimation as a standard deviation, and therefore in a probabilistic framework, as recommended by the ISO *Guide to the Expression of Uncertainty in Measurement* (1993) (GUM). The *Guide*, based on a recommendation by the International Committee for Weights and Measures (CIPM, 1981), states that measurement uncertainty can be estimated on the basis of both statistical and nonstatistical methods, and specifies a procedure to combine such components into a combined standard uncertainty. The set-theoretical formalization can then be regarded as a specialization of this framework: if the combined standard uncertainty is multiplied by a coverage factor, then an expanded uncertainty is obtained, which is thought of as the half-width of an uncertainty interval.

The inherent presence of uncertainty justifies the fundamental assumption that the result of a measurement must state not only a (nominal) measurand value but also its uncertainty estimation. Uncertainty in measurement is covered in **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**.

1 GENERAL OVERVIEW AND NATURE OF THE LabVIEW™ ENVIRONMENT

LabVIEW (**Lab**oratory **V**irtual **I**nstrument **E**ngineering **W**orkbench) is the trademark of National Instrument Corporation (NI). It is a programming environment including all of the tools necessary for instrument control, data storage, data analysis, and data presentation. It uses graphical programming and a graphical language called *G*. The main goal of LabVIEW is the creation of virtual instrumentation.

1.1 Virtual instruments

Virtual instruments are computer-controlled instrumentation systems. The physical instruments, which exist in the background of the computer (Figure 1), may be controlled using the computer keyboard, mouse, and display. Also, a wide variety of the computer-based applications for process modeling, instrument simulation or animation of the execution of the measuring system are possible using virtual instruments. In this sense, all LabVIEW programs are Virtual Instruments, called *VI*s for short.

1.2 Graphical programming language G – VI components

The graphical programming language G uses icons and wires to create graphical source code. In graphical language, icons are used instead of text-lines, which are used in the sequential text-based programming languages. Graphical code is created on the Block Diagram behind the user interface called the *Front Panel* (Figure 2). The SubVI icon represents a program placed as a subprogram within another VI. During program execution, data are transferred between the Front Panel and the Block Diagram and carried between icons on the block diagram. The VI connector pane gives the possibility of passing data to/from the VI. The path of data flow on the block diagram is determined by wire connections. LabVIEW is a system based on the data flow principle.

1.3 Data sources

Data used by the program can be supplied by controls on the front panel, loaded from files as off-line data, and received

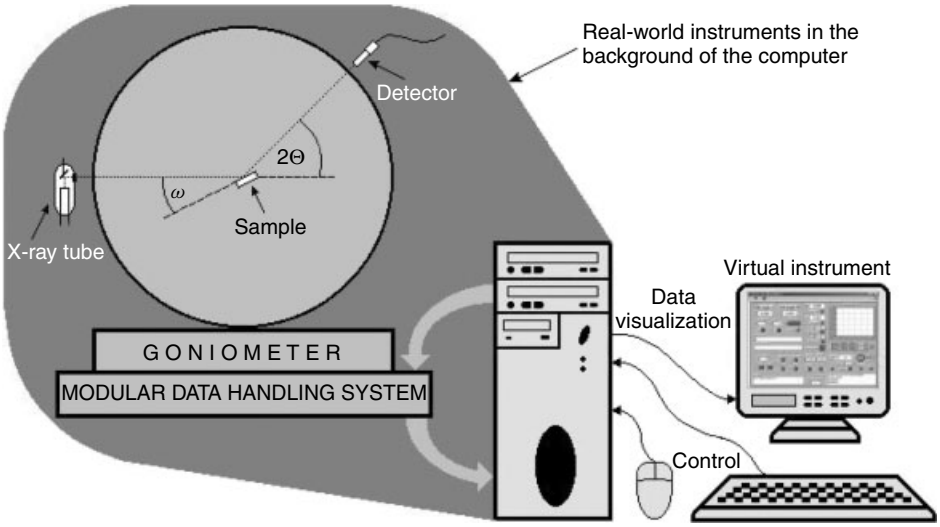

Figure 1. Virtual instrument presentation.

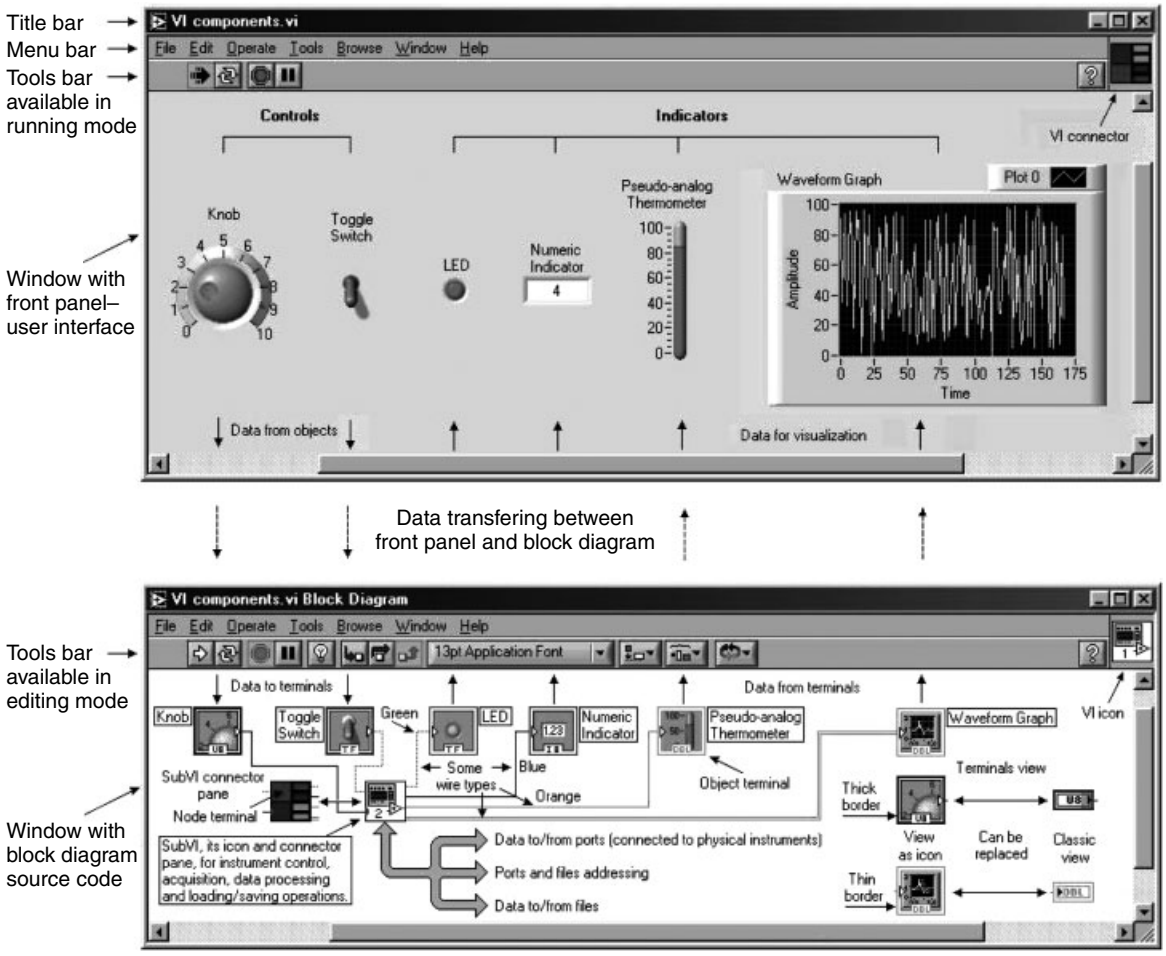

Figure 2. VI components.

through ports from physical instruments as on-line data and also from the Internet.

After modification, data can be displayed by indicators on the front panel, saved to files, or sent back to peripheral physical instruments.

Each control and indicator placed on the front panel is represented by its corresponding terminal, which appears automatically on the block diagram when VI is built.

Data are passed to/from the object on the front panel through the object terminal on the block diagram.

2 LabVIEW G-PROGRAMMING RAPID INFORMATION

After launching the LabVIEW application, the start-up screen appears and a user can select a New VI. A new VI named *Untitled 1(2,3...)* appears as a composition of two windows that comprise a VI, the front panel, and its associated block diagram. At the initial stages of building a new VI, it is helpful to see both windows side by side to determine what can be done from the menu bar.

2.1 Editing tools

Editing tools used to build a VI are the Tool bar and Tools, Controls, and Functions palettes (Figure 3). Palettes can be visible after selecting them from the menu bar.

The Tool bar contains buttons and indicators to build, edit, debug, and run VIs.

The Tools palette is a graphical panel that contains various tools used to create and operate VIs. A tool is a special mouse cursor for performing specific operations such as positioning, wiring, labeling, operating, scrolling, setting breakpoints, probes and shortcut menus, and also for operations usually used in a paint program. The Tools palette is common to both front panel and block diagram operations.

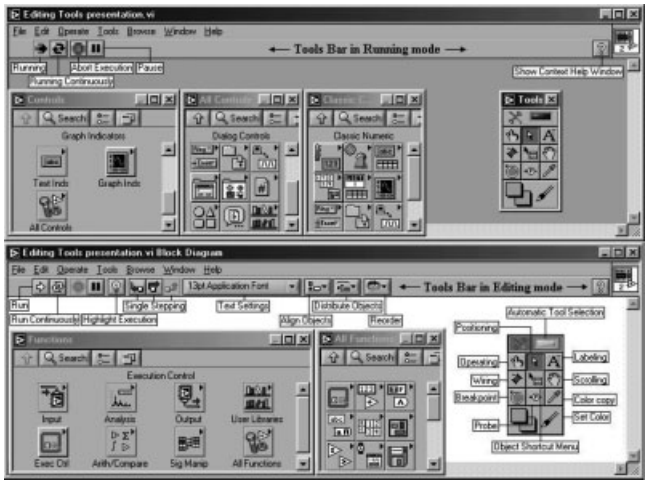

Figure 3. LabVIEW editing tools.

2.2 The front panel

The front panel window contains various types of controls and indicators and models a real-world instrument front panel. Front panel design activity needs to place on it objects used by a user to control VI and to display data produced by the program. Figure 4 shows, as an example, the front panel of the virtual X-rays diffractometer, which gives a user possibility to calibrate the sample and detector positions; select parameters for the scanning; acquire and present data; and save data in the file.

The complete set of front panel objects is available from the Controls palette and the All Controls subpalette.

2.3 The block diagram

The block diagram window contains the program code in a graphical form. It contains terminals of the front panel objects, programming structures, functions, constants, subVIs, and wires.

The complete set of block diagram functions is available from the Functions palette and All Functions subpalette.

Objects can be placed on the front panel/block diagram by dragging and dropping, or copying. Front panel objects and constants on the block diagram can be also created by selecting from the shortcut menus of the objects placed earlier on the block diagram.

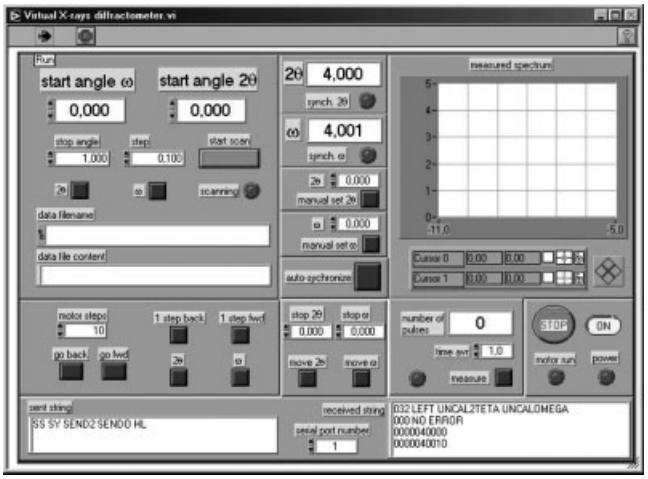

Figure 4. The front panel of the X-rays diffractometer. The application has been developed by M. Sarzyński, a PhD student at the faculty of physics in WUT, under the author's direction.

2.4 Wires and terminals

Wires are used to carry data from one terminal to another. Wires are analogous to variables in traditional programming languages. Terminals are objects or regions on nodes through which data pass.

3 DATA, WIRES, AND TERMINAL TYPES IN LabVIEW

3.1 Data types

Data type is a format for information. Data can be the instrument status information data, reference data representing node properties or status, data obtained as results of measurements, or data used for addressing. Data types used in LabVIEW and acceptable for most VIs and functions are numeric, Boolean, string, waveform, array, cluster, refnum, enumeration, and path.

3.2 Wire types

Wires can be of different types, colors, line styles, and thickness, depending on carried data types. Wire types are unique for each data type. For example, orange color is reserved for floating point numbers, blue for integers, green for Booleans, and pink for strings. Basic wire styles used in block diagram are as follows: thin, solid lines are used to carry scalars; a bit thicker solid lines for 1D arrays; double lines are reserved for 2D arrays of numbers; and thick lines are used to carry 2D arrays of Booleans or strings. A broken wire appears as a dashed black line. To find out why the wire is broken, the Wiring tool is moved over the broken wire to display a tip strip with an error description.

3.3 Terminal types

Control terminals and node outputs terminals have thick borders, while indicator terminals and node inputs terminal borders are thin. Terminal color indicates what data type will be supplied or accepted by this terminal. The programmer can open the Context Help window, move the cursor onto the selected node, and get information about data types accepted or supplied by the terminal. The Context Help window also displays the function and VI parameters, the object description, and the parameter type definitions. It can be opened by selecting the same from the menu bar. A broken wire can be removed by selecting and deleting it.

3.4 Debugging techniques

The broken Run button appears on the tool bar in the case of a broken VI. A broken VI is a VI that cannot compile or run because of programming errors. LabVIEW has many built-in debugging features like Execution Highlighting, Probe and Breakpoint tools, Pause, and Single-Stepping through a VI.

With the Execution Highlighting, an animation of the execution of the VI block diagram can be viewed. Using Probes, the intermediate values created during VI execution can be checked. Single-Stepping through a VI and its subVIs can be used to execute a block diagram node by node. Breakpoints can be set at certain locations of the VI using the Breakpoint tool. The Pause button temporarily stops execution.

The programmer can also open the Error List window by clicking the broken Run button and locate the object reporting error.

4 QUICK START WITH LabVIEW – VI EXAMPLE

4.1 Building VI

As an example, consider the VI created for presentation of the ^{137}Cs spectrum data loaded from the file. For building a user interface as shown in Figure 5, there is need to create a waveform graph, a slide, and path objects. These are created as objects by selecting them on the Controls palette. The Positioning tool is used to rearrange or resize selected objects. Right-clicking the object and selecting Properties from its shortcut menu can open the dialog box to configure the object. The Labeling and Operating tools change the defaults for the object. Data paths between output terminal and input terminals on the block diagram are defined using the Wiring tool.

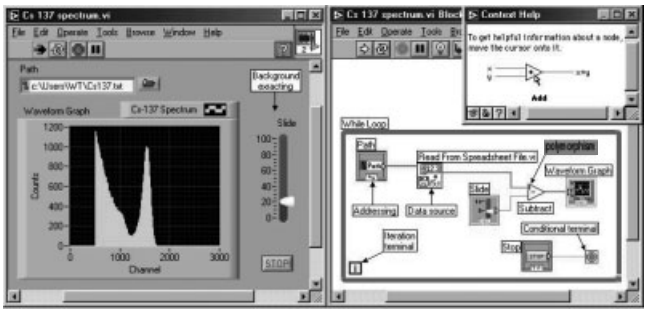

Figure 5. Simple VI example – its front panel and block diagram.

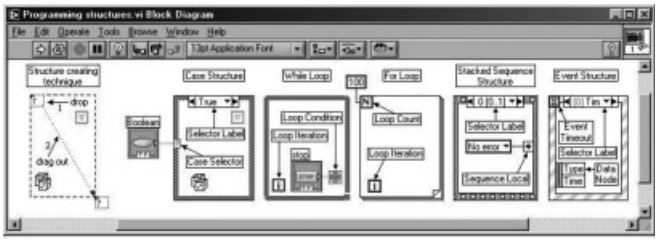

Figure 6. LabVIEW programming structures.

For VI execution control, the While Loop is created by selecting the same on the Functions palette. The While Loop is a structure used to repeat the subdiagram inside it until a conditional terminal receives a particular Boolean value. The iteration terminal provides the current loop iteration count.

4.2 Programming structures

Programming structures, shown in Figure 6, are program control nodes, such as Flat/Stacked Sequence structures, Case structure, Event structure, For Loop, or While Loop. Structures can execute code repeatedly or conditionally. They are not created on the block diagram immediately after being selected. Instead, a small icon representing the structure appears in the block diagram, giving the programmer the opportunity to size and position it to encompass all the objects that need to be placed inside the structure and then execute within it. The structure-creating technique is shown on the left-hand side in Figure 6.

4.3 Running VI

A user can run a VI by clicking its Run button. If a user runs the VI, LabVIEW compiles it and starts the VI execution. While the VI is executing, the Run button changes appearance to indicate that the VI is running.

A user can stop execution by clicking the Abort Execution button or by using the Stop button placed on the front panel. The program will stop immediately when the Abort Execution button is selected, but data can be corrupted this way. The VI will reach the end before stopping when the Stop button is used. This is the recommended stopping mechanism. The continuous Run button causes the VI to run over and over until the Abort Execution button is pushed.

5 GENERAL APPLICATION TO DIFFERENT CLASSES OF MEASURING SYSTEMS WITH VIs

5.1 Where can LabVIEW be used?

Areas of the typical uses of LabVIEW are electrical and mechanical engineering, physics, chemical engineering, biology, biomedical engineering, civil engineering, and many others. For example, scientists at NASA used LabVIEW to analyze and display Mars Pathfinder Sojourner rover engineering data (Bishop, 1999). At the Laboratory of Dielectrics and Magnetics at Warsaw University, X-ray measurements of the layer spacing in the SmA phases were performed using the diffractometer (Figure 4) controlled by the software developed in LabVIEW (Pociecha *et al*., 2002).

5.2 LabVIEW in industry and research

LabVIEW applications are implemented worldwide in many industries and in research for test and measurement applications, process monitoring and control, machine monitoring and control, and design process control. For example, Construzioni Apparecchiature Elettroniche Nucleari (CAEN) S.p.A, offers a VME (Versa Module Eurocard) controller which can be operated from the parallel port of a standard PC using LabVIEW software developed in CERN. Analog Devices (AD) and Crossbow Technology, Inc. used LabVIEW software for the demonstration dual axis, 2 g accelerometer.

5.3 LabVIEW in universities

LabVIEW programs used in university laboratories improve the didactic process. These applications can be used in e-learning and distance learning. With its Remote Panel, the LabVIEW application can be turned into a remote laboratory. With their Web browser, users can open a link to a remote application, and control it using the Remote Panel, and observe how an experiment runs. Such a panel, as an example, is shown in Figure 7. This is the statistical distribution analyzer for remote control of the experiment devoted to the statistical character of the gamma decay investigations (*see also* **Article 106, Virtual Instrumentation in Physics, Volume 2**).

5.4 Communicating with LabVIEW

LabVIEW simplifies the tasks of communicating with GPIB, USB, serial, Ethernet, VXI, and PXI instruments. For

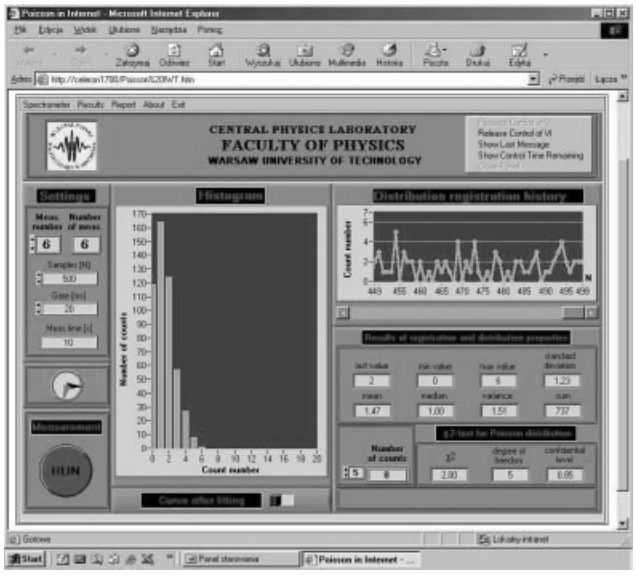

Figure 7. The front panel of the poisson distribution analyzer as a web page.

example, the Metex M-3660D multimeter uses the built-in RS 232 port for serial communication, and with the Pt100 (*see also* **Article 197, Metallic Resistance Temperature Detectors (RTDs), Volume 3**) element, it can be used as a digital thermometer controlled by a computer in thermodynamics experiments. The GPIB (General Purpose Interface Bus) interface is optionally installed in the Hameg HM-507 oscilloscope and can be use to communicate between a PC and the HM-507. It is relatively easy to build applications using LabVIEW to control these real-world instruments.

5.5 Data analysis with LabVIEW

LabVIEW provides more than 400 built-in functions for extracting useful information from acquired data and for signal processing and analysis. Tools available from advanced libraries can be used for solving systems of linear algebraic and ordinary differential equations; for integration and differentiation (with G Math Toolkit); for probability and statistics analysis; for curve fitting; and for signal generation and signal processing with DFT (Discrete Fourier Transform) and FFT (Fast Fourier Transform) analysis (*see also* **Article 143, DFT and FFTs, Volume 3**), windowing and filtering.

6 RELEVANCE TO PRESENTED APPLICATIONS

In Figures 4 and 7 are shown two front panels of the exemplary VIs built to control the different types of experiments. One of them is used to control X-rays diffractometer (Figure 4) and the other to perform experiments devoted to the statistical character of gamma decay investigations (Figure 7).

The presented graphical user interfaces are intuitive in operation and simple to apply. Designing of similar interfaces using a traditional computer language can take many days. With LabVIEW, this can be done in an extremely short time, even with very little experience in G-programming.

LabVIEW terminology and the block diagram representation of VIs (Figure 8) are easy to interpret and natural to use by scientists and engineers. Typical advanced operations usually needed for communication or analysis have been encapsulated in VI libraries for quick application.

The productivity with LabVIEW is significantly higher, and generally, a system's development time is much reduced compared to traditional programming. For example, the LabVIEW flexibility allowed rapid modification of the virtual diffractometer (Figure 4) to then make it applicable (Figure 7) to measurements devoted to the statistical character of gamma decay investigations. The modification can be made easily because both instruments use the same subVIs needed to control gate time, collect data in the time limited by the gate, present acquired data on the XY graphs, and communicate through serial RS 232 interface with peripheral instruments.

LabVIEW also improves the teaching process and the way by which students learn in universities. The applications used during the laboratory work help students to understand better how an experiment is running because VIs can provide a lot of useful information that is quickly available from the menu bar.

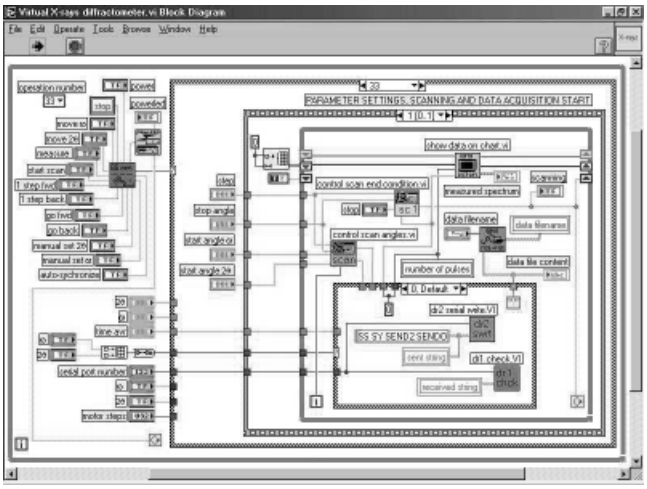

Figure 8. The block diagram of the X-rays diffractometer.

7 COMMUNICATION AND DATA TRANSFER INSIDE AND OUTSIDE VI

7.1 Local variables

A local variable can be used to represent the front panel object in several locations on the block diagram of a single VI. It can also be used to pass data between nodes that are not connected by a wire. It is necessary to use local variables to control several While Loops by using one switch. The local variable can be created from the shortcut menu of the object or its terminal. Figure 9(a) shows how data passes in the VI A using local variables. A local variable always contains the value of its associated terminal.

7.2 Global variables

Global variables can pass data between several VIs. A global variable can be used to represent the front panel object in several locations on the block diagrams of the several VIs. The global variable can be created by dragging the Glob from the All Structures panel and then dropping it on the block diagram. From the shortcut menu of the global variable, the front panel of the special kind of VI has to be opened first and the controls that define the data types accepted by this global variable have to be placed on it. A global variable always contains the value of the selected item placed on the global front panel. Figure 9(b) shows how data passes between the VI B and the VI C using global variables.

7.3 Serial communication

The program developed for communication between serial instruments using Virtual Instrument Software Architecture (VISA) is shown in Figure 9(c). The VISA Configure Serial Port initializes the selected port to the specified settings. VISA Write writes a value in a string to the port. VISA Read reads the number of characters specified by the requested byte count from the port after a timeout period controlled by the Property Node. VISA Close is used to terminate communication.

The sequence of the operations in this program is determined by wiring the output terminals to the input terminals used for addressing in the line of nodes. GPIB (*see also* **Article 170, IEEE-488 Instrumentation Bus, Volume 3**) communication can also be performed using the VISA.

7.4 In/out port communication

Most of the peripheral devices in the PC are controlled using the I/O ports. Figure 9(d) shows the VI built for data loading to counter card using Out Port functions and Sequence structure. The first frame of the Sequence is used

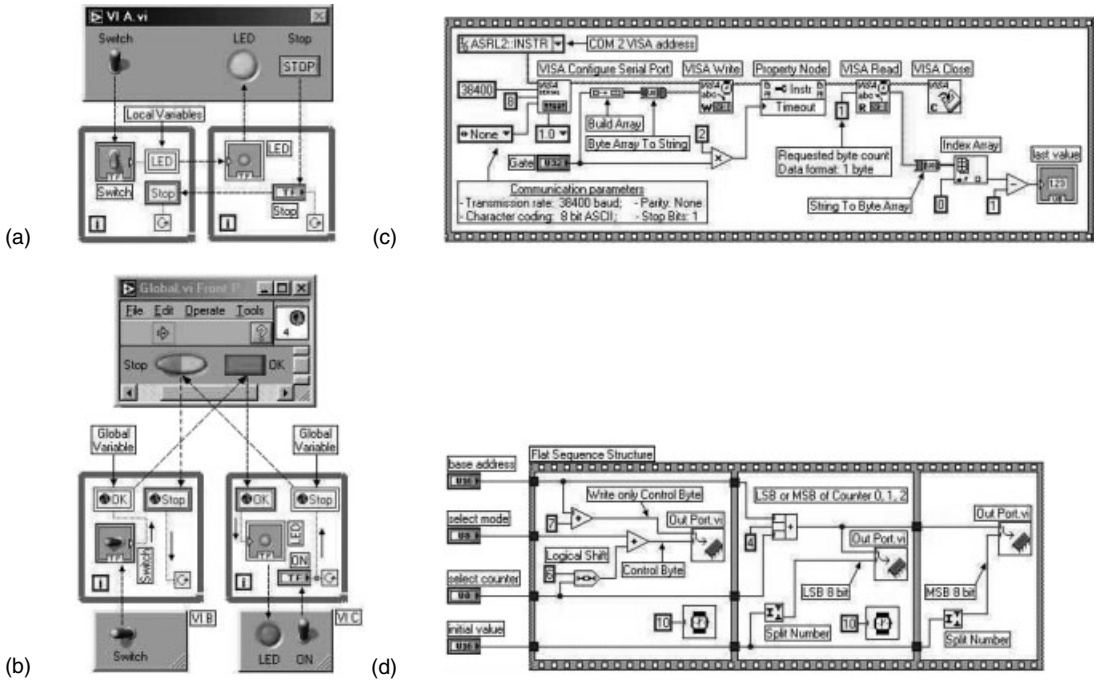

Figure 9. Communication and data transfer inside and outside VI.

for the Control Byte writing to the card through the Out Port before the initial count is written. Then, the initial count in two bytes is loaded to the card, LSB byte followed by the MSB byte.

8 VI BEHAVIOR CUSTOMIZING

After the VI building, a user can customize the VI Menu bar by its editing and the VI behavior using the VI Properties dialog boxes.

8.1 Customizing the menu bar

The custom menu template can be built at the time of editing after opening the Menu Editor window by selecting the Run-Time Menu from the default menu bar. In Figure 10(a), for example, the Menu Editor window for the virtual spectrum analyzer (VSA) is shown (*see also* **Article 106, Virtual Instrumentation in Physics, Volume 2**). On the left-hand side of this window, the menu hierarchy is displayed. The tools needed for the menu hierarchy editing are available from the Menu and Tools bars. After the highlighting of the menu item in the menu hierarchy, the item properties appear on the right-hand side of the window. A user can select the item type, write the item name and tag identifier, and define for it the shortcut key combination. A user item can be enabled/disabled and checked/unchecked by setting the respective attributes. The built menu can be viewed in the Preview area. A tag identifies the custom item in the block diagram from the output of the Get Menu Selection function (Figure 10b). The current VI's Menu bar returns the menu bar refnum of the current VI. The Item Tags are strings and can be used, for example, to select the subVIs or functions placed in the different frames of the Case structure.

The VI documentation, user's manual, and so on, can be selected from the custom menu bar, for example, to instruct a user on how the instruments can be executed and how the measurements can be performed.

8.2 Customizing the VI properties

By popping up the VI icon in the top right of the front panel corner and selecting the VI Properties, a user can open the dialog boxes and turn on/off all the properties available for the current VI.

From the Window Size category, for example, the width and height of the front panel window can be determined. From the Execution category, the dialog box, used to turn on/off the execution options, and the Window Appearance category (Figure 10c), used to turn on/off the window appearance options available for the current VI, can be accessed. The window options apply to VI when in the execution mode.

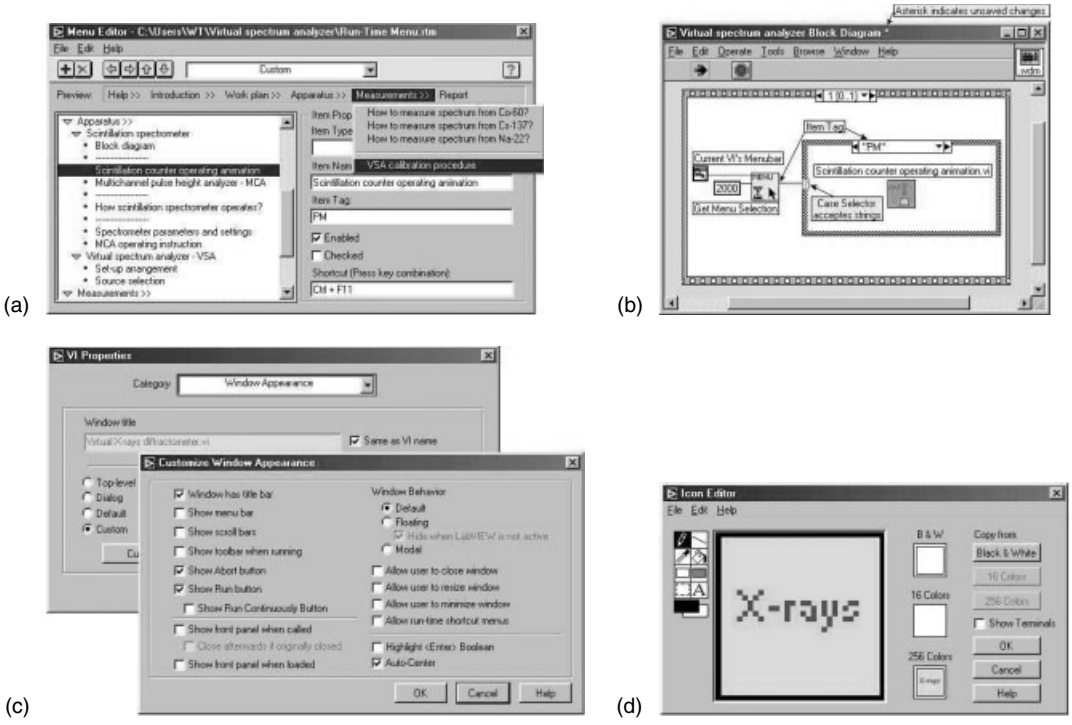

Figure 10. VI customizing windows.

The customizing of VI also needs the icon editing, which can be done in the Icon Editor window (Figure 10d) by accessing the pop up on the VI icon and then selecting the Edit Icon.

9 MODULARITY AND HIERARCHY

VIs are modular in design, so any VI can be used as the top-level program and can run by itself or as a subprogram within other programs. A programmer can divide an application into a set of simple subtasks and then build VIs to accomplish all the subtasks and finally combine those VIs on the top-level block diagram to complete the larger task. The concept of the modular programming, promoted by LabVIEW, gives a user possibility to execute each subprogram by itself, making debugging relatively easy. Furthermore, many low-level subprograms often perform tasks common to different applications and can be used independently by every individual application.

The hierarchy nature is also the significant characteristic of LabVIEW and VIs. From the VI Hierarchy window (Figure 11a), a user can simply find the file path for every subVI, open it selectively by double clicking, and customize individually. There is an unlimited number of layers in the hierarchy structure of every VI. Each subVI can be also opened from the VI Browse available in the menu bar (Figure 11b).

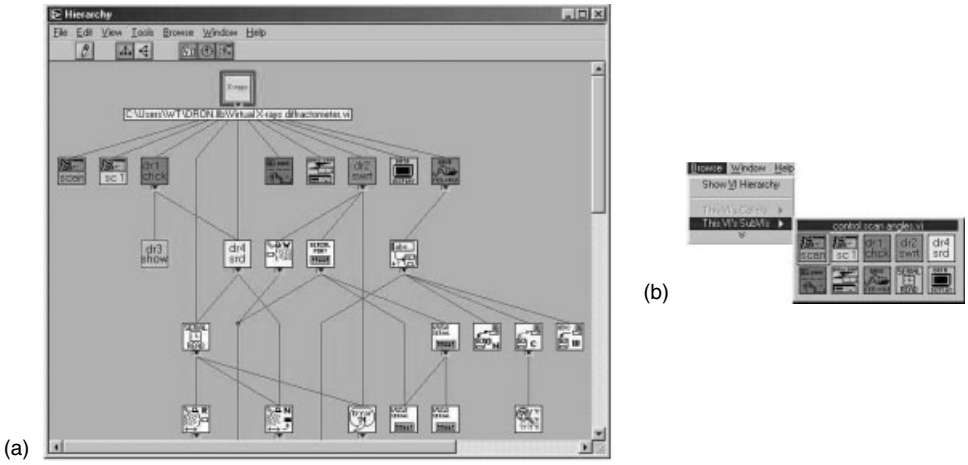

Figure 11. The VI hierarchy window.

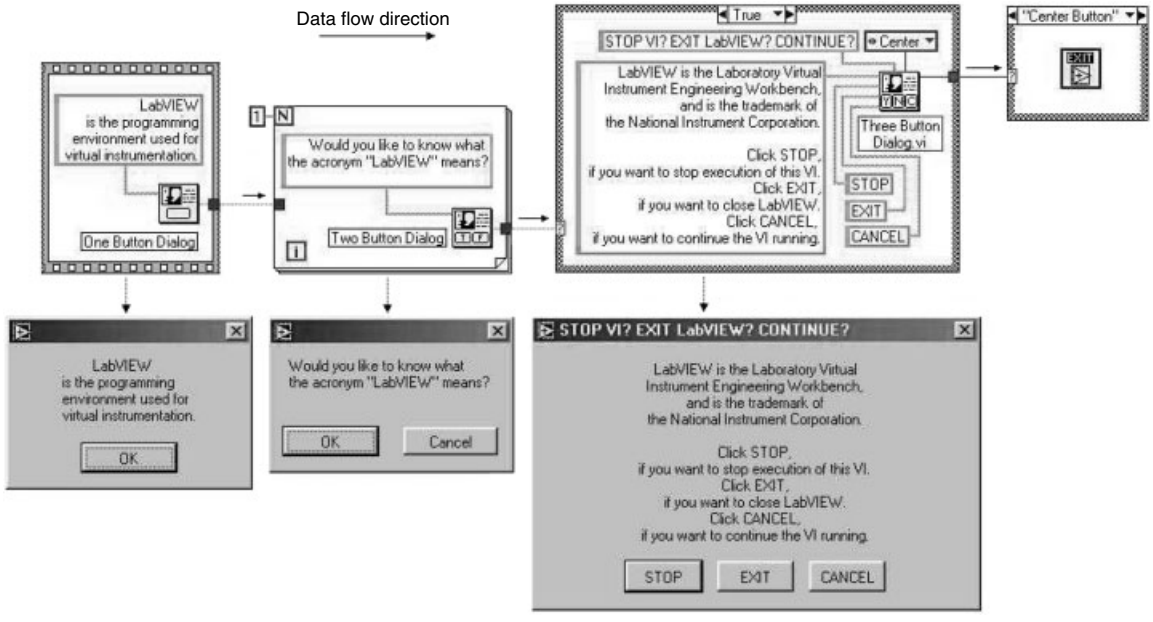

Figure 12. The data flow principle presentation.

10 DATA FLOW PRINCIPLE PRESENTATION

10.1 The Data Flow principle

LabVIEW is a programming environment based on the Data Flow principle. In practice, it means that the nodes execute only when they receive all required input data and produce the output data immediately when they execute. Because the path of the data flow on the block diagram is determined by the wire connection, the wiring can be used to control the VI execution order. Such a solution is applied in the program shown in Figure 12, presenting different types of dialog functions responsible for the messages that appear on the VI front panel in the order determined by wire connections between corresponding structures.

10.2 Application–user communication

For the application–user communication, LabVIEW offers the One/Two/Three Button Dialog functions (Figure 12), which automatically display the messages in the situation where a user needs to be instructed or has to take a decision about what to do next. They are available by selecting the same from the Time & Dialog panel on the Functions palette.

The Button Dialog function displays a dialog box that contains a message addressed to the user and a set of the buttons, one, two, or three, on the VI front panel. The dialog box has a standard form view and stops VI execution until the moment a user pushes selected button. A message should be prepared earlier as a string constant on the block diagram and wired to the corresponding input of the dialog function. Usually, it is placed inside the Case structure and appears when the frame containing it is selected. The button names can be edited. By default, they are Yes, No, or Cancel. The programmer can replace them by wiring the string constants with the needed names to the corresponding dialog function inputs.

The One/Two Button Dialog functions return a value of True or False depending on which button is pushed. This output value can be used to select the following VI behavior.

The Three Button Dialog .vi is a more advanced function and can be edited in a more advanced form. A programmer can use one, two or three buttons for the application–user communication, justify message, place the Window Title on the box, and select the keyboard shortcuts and the window close button, which allow a user to close window without selection. The Yes, No, or Cancel buttons can be edited. The enumerated output of the Three Button Dialog .vi indicates which button was selected.

1 NUCLEAR PHYSICS LABORATORY FOR A STUDENT TRAINING WITH VIs

The Central Physics Laboratory (CPL) is where students of the Warsaw University of Technology study the fundamentals of physics in practice. The Nuclear Physics Laboratory (NPL) is a part of the CPL. The basic equipments used in the NPL are six scintillation spectrometers, for performing basic nuclear physics experiments. Three of them are presented here as examples of the use of LabVIEW™. An introduction to the use of LabVIEW is given in **Article 105, Modeling with LabVIEW™, Volume 2**.

1.1 Determination of the energy of γ-rays

The exercise aims at instructing students about how the scintillation spectrometer works and what typical spectrums of γ-rays look like. Two sources, ^{137}Cs and ^{60}Co, are used to calibrate the spectrometer. The third one, ^{22}Na, is then examined with respect to the energy of γ-photons emitted by it. The front panel of the spectrum analyzer, used in this real experiment to control data receiving, its analysis and presentation, is shown in Figure 1.

1.2 Nuclear decay statistical character

In this exercise, students compare the experimental distributions of emitted particles with theoretical distributions known to be true for a small number of events, which can be described mathematically using the Poisson distribution theory. The front panel of the Poisson distribution analyzer, used in this experiment to control data acquisition, its analysis and presentation, are shown in Figure 2.

1.3 Absorption of γ-rays passing through matter

This exercise helps students to obtain elementary knowledge about the different types of nuclear radiation interactions with matter. The front panel of the Gamma-rays Intensity Analyzer (GIA) used in this experiment to control data acquiring, its analysis and presentation, is shown in Figure 3.

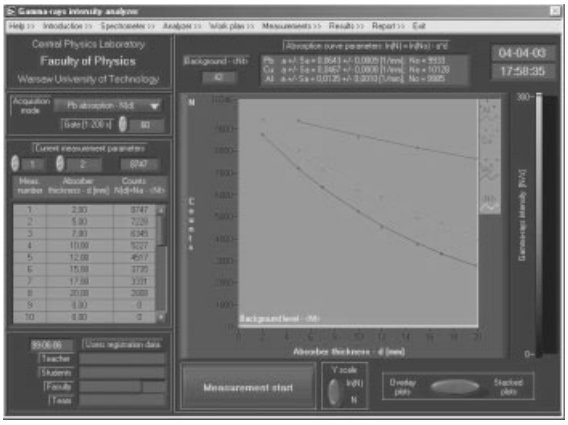

Figure 3. Front panel of the γ-rays intensity analyzer.

2 GAMMA-RAYS INTENSITY ANALYZER – VI EXAMPLE

The absorption coefficient is a quantity, which is characteristic of the absorbing material. A beam of photons passing through matter interacts with it. Students measure the γ-rays with respect to the thickness of Pb, Cu, and Al by using a GIA (Figure 3). The acquired data are then used to examine the attenuation law and calculate the absorption coefficients.

Using the analyzer, a user can obtain the radiation source spectrum, measure the apparatus background or the radiation intensity by selecting the corresponding acquisition mode.

The front panel of the analyzer contains graphical objects used for mode and parameter settings, measurement control, measurement data presentation, and registration data display. The measurement parameters can be set using numeric controls. With the Measurement start button, a user can start/stop measurement. The analyzer takes data from the counter card connected to the scintillation spectrometer. The current Counts number and the average apparatus Background value are displayed in corresponding numeric indicators.

The current gamma intensity value is indicated by the Color Ramp. The set of collected data is visible in the table and presented on the XY graph. The Exponential Fitted Curves are plotted on the same graph. Currently, after every measurement, the absorption coefficients and their errors are computed and presented in the string indicator as the Absorption curve parameters. From customized pull-down menus, the user can open programs, which help perform measurements.

3 DATA ANALYSIS AND PRESENTATION WITH LabVIEW

A beam of photons passed through matter is attenuated in intensity. The fraction of photons surviving a distance, d, is exponential with respect to the thickness. The logarithmic form of the attenuation law is shown in (1)

$$\ln N(d) = \ln N_0 - \mu d \tag{1}$$

where N_0 – the incident intensity; d – thickness of the absorber; μ – absorption coefficient.

Measurement of γ-rays' intensity with respect to the thickness of Pb, Cu, and Al are performed with the GIA. Obtained data are used to examine the attenuation law and calculate the absorption coefficients for different types of absorber using the Least Squares Method (LSM).

The program shown in Figure 4(a) considers the operations used for the curve fitting performed by the GIA.

If the data set is collected as a 2D array, like those presented in Figure 4(b), it is first necessary to transpose it using the Transpose 2D Array function, and then to reshape it into a 1D array with the Reshape Array. Next is the need to extract elements, which represent the data

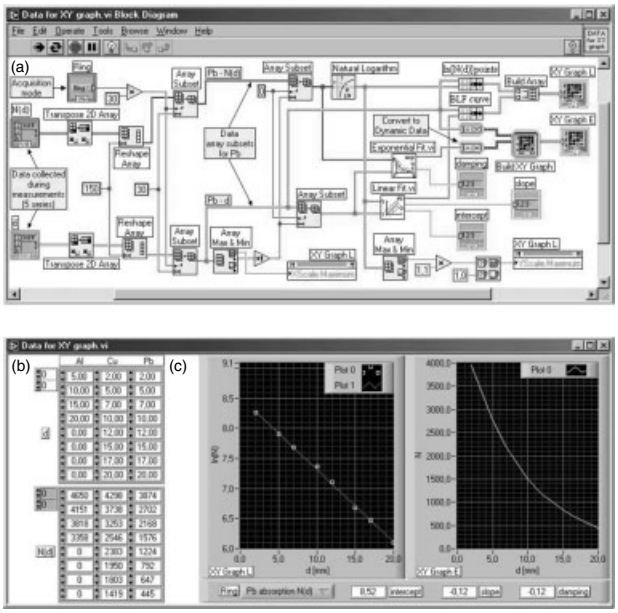

Figure 4. Data analysis and presentation with LabVIEW.

set for a particular curve. For this operation, the Array Subset functions and the Array Min&Max function are used twice. In this way, two arrays are extracted, $[d_i]$ and $[\ln N_i]$, which represent an 8-point data set for γ-rays attenuation for Pb. Obtained this way, the data set is used for the curve fitting with the Exponential Fit. vi. Before fitting with Linear Fit. vi, the data has to be computed with the Natural Logarithm function. After fitting curves to the data, they can be presented on the graphs.

Two methods are used for this purpose. One, the classic method, uses the Bundle functions to prepare two sets of clusters $(d_i, \ln N_i)$, placed on the XY Graph L after building an array with them.

The second method, Express VI method, uses the Build XY Graph subVI, which needs only to convert arrays with the Dynamic Data Converters before wiring them to the corresponding inputs. This method was used for data preparation before placing them on the XY Graph E. The Linear Fit. vi also finds the slope and intercept coefficients, and the Exponential Fit. vi finds the damping coefficient. The slope gives the gamma absorption coefficient. The Array Min&Max and X/YScale. Maximum property nodes are used for X/Y Axis scaling. In Figure 4(c), two XY graphs are shown with data points and fitted curves, and numeric indicators that display the curves coefficients.

4 MULTIUSER MEASURING SYSTEMS WITH VIs

With virtual instruments it is easy to build relatively low cost multiuser measuring systems. This is particularly important when multiple measuring systems are needed in the laboratory for training students. Scintillation spectrometers are the base parts of the instrumentation used for data taking in the NPL.

The analog signal from the detector is shaped by the amplifier and then sent to the pulse height analyzer devices, which are of different types in different experiments.

4.1 Multiuser measuring systems

The multiuser measuring systems used in NPL are presented in Figure 5. In two measuring systems, threshold discriminators are used for pulse height selection. The measuring systems used for the statistical distribution, Figure 5(a), and gamma absorption investigations, Figure 5(c), need data only in the logical form. The discriminators deliver a standard logic signal for every analog signal with its amplitude higher than a given threshold. In each of the presented multiuser system, the discriminator output signals are distributed with fan-out circuits to four computers.

In the experiments shown in Figure 5(a), the 16-bit counters, controlled by the microcontrollers, (*see also* **Article 158, Microcontroller Systems, Volume 3**) are used for data collection. The counter cards with the microcontrollers are serial instruments and communicate with the VI through RS 232 (*see also* **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**) port. In this measuring system, one spectrometer delivers signals continuously to four computers, but users perform measurements independently.

In the experiments shown in Figure 5(c), counter cards are used for data collection. Digital I/O ports control the counter cards by using the VI developed for gamma absorption investigations. In this measuring system, one spectrometer supplies signals continuously to four computers, but users are asked to perform measurements synchronously.

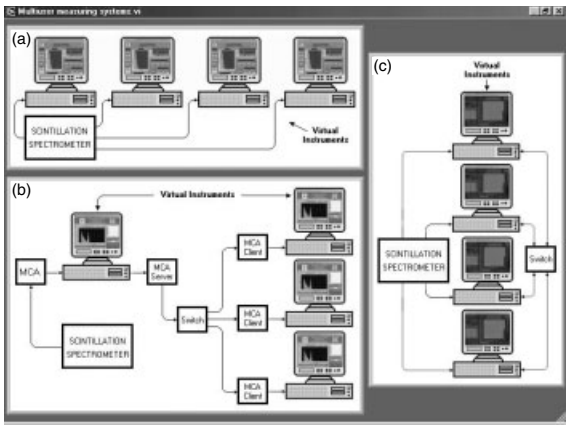

Figure 5. Multiuser measuring systems with VIs.

The local area network (LAN) (*see also* **Article 171, Local Area (LANs) and Wide Area Networks (WANs), Volume 3**) is used for message sending that allows synchronized measurements to be performed with computers working in parallel. In these experiments, users can also obtain a radiation source's spectra. In this case, the threshold discriminator is replaced with a single-channel analyzer.

Figure 5(b) shows the multiuser measuring system using a LAN for data distribution. In this measuring system, only one computer is equipped with the multichannel analyzer (MCA) used to take spectra. Data acquired by the MCA are distributed by the server-client software combination, which is a communication option available in LabVIEW.

Remote computers receive online data as soon as the MCA sends it to the MCA server, which then distributes it to the MCA clients. Data acquisition is synchronized by the MCA, but remote users can still analyze the spectra independently.

5 VIs APPLICATION TO A TEACHING PROCESS

LabVIEW can be used not only for VI building of real-world measurements but also for building applications that simulate real-world instrument operation, useful in the teaching process, for example, teaching the fundamentals of physics or to demonstrate experiments in physics.

5.1 Planck's Law and Wien's Displacement Law

Figure 6 shows how LabVIEW application can be used for demonstration of the Planck's Law and the Wien's Displacement Law. When the temperature of the object is known, the distribution of the radiating energy is given by the law of black body radiation, the Planck's Law, as shown in (2)

$$M(\lambda, T) = \frac{b}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1}, \tag{2}$$

where $b = 10^7$ in relative units; λ–wavelength; h–Planck constant; k–Boltzmann constant; c–speed of light in vacuum; T–temperature in Kelvin degrees.

The block diagram, built to place on the graph the radiation emission curves for objects at different temperatures, is shown in Figure 6(b). The relative radiation intensity as a function of the wavelength and temperature is plotted by the implementation of (2), using the Formula Node structure.

The Formula Node is similar to other structures available in LabVIEW (*see also* **Article 105, Modeling with LabVIEW™, Volume 2**), but instead of containing a subdiagram, it contains one or more formula statements delimited by a semicolon. Using the Formula Node, a user can enter algebraic formulas directly into the block diagram. The input and output terminals of the Formula Node can be created by selecting it from the shortcut menu. After creating terminals, a user has to enter variable names into the input/output boxes.

The data for one point is calculated in one iteration of For Loop 1 using the Formula Node. The data set for one curve is collected in the tunnel with an array symbol, during calculations performed in 10 000 iterations. After For Loop 1 completes all iterations, the data collected in the tunnel are provided to the XY graph using the Bundle function, which also determines the scaling factors, such an offset – λo and a multiplier – $\Delta\lambda$. Using For Loop 2, a user can observe one by one the set of 31 curves at the temperatures in the range 200 to 6200 K. Also, it is possible to observe how the peak of the black body spectral distribution shifts to the shorter wavelengths as the temperature increases. This relationship is described by the Wien's Displacement Law,

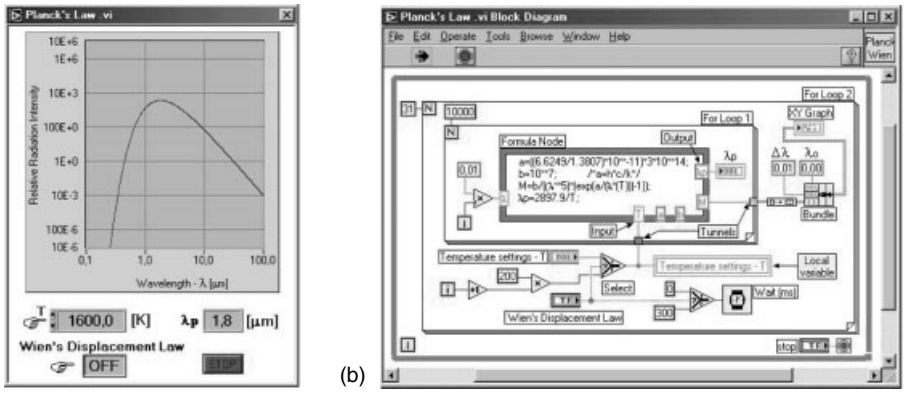

Figure 6. A model of Planck's Law and Wien's Displacement Law.

as shown in (3)

$$\lambda_p T = 2897, 9, \tag{3}$$

where λ_p – wavelength of peak energy in microns; T – temperature in Kelvin degrees.

A user can select a static or dynamic presentation by switching on/off the Wien's Displacement Law button.

Tunnels are terminals on a structure used to get data into the structure and to pass data out of the structure. Tunnels created on the For Loop or While Loop border can be used with the Enabled Indexing for arrays or the Disabled Indexing for scalars.

6 VIRTUAL SPECTRUM ANALYZER (VSA) – VI EXAMPLE

6.1 The virtual spectrum analyzer (VSA)

The Virtual Spectrum Analyzer (VSA) front panel is visible in the background of the window, with the signal converting simulation opened from the VSA menu bar (Figure 7). The buttons, switches, selectors, graphs, and so on are used to select the type of spectrum to acquire, save and load data, calibrate the spectrometer, start and stop data acquisition, present the spectrums, and finally present the calibration curve. The complete VSA front panel is presented in Figure 9.

The VSA not only helps a user to conduct an experiment but also gives the full information concerning it, for example, elementary knowledge about the γ-rays interactions with matter, how to turn on electronics, set correct parameters and run experiments, how to collect and analyze data then verify obtained result, and also how to prepare a laboratory report. This information can be selected from the VSA menu bar. A user can also open animation programs developed for demonstrating how scintillation spectrometer and electronic devices, like a scintillation detector, an amplifier, and the MCA (Figure 7), operate.

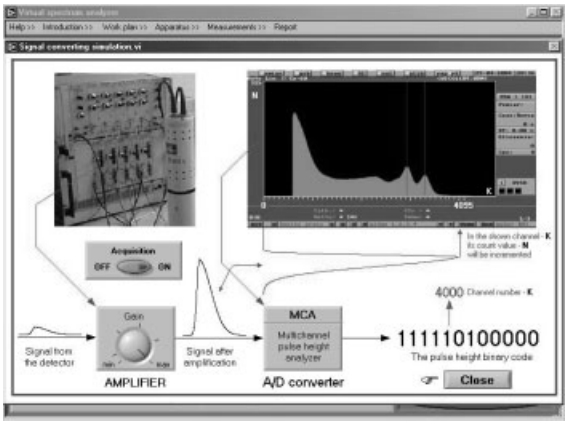

Figure 7. LabVIEW application for the spectrum building animation.

With the VSA a user can virtually measure spectrums of the γ-rays source, calibrate the spectrometer and finally, determine energy of the photons emitted by ^{22}Na. The data collected in the virtual experiment are similar to the data acquired in the real physics laboratory.

6.2 Virtual physics experiments

Several virtual physics experiments were built, using LabVIEW, in the Warsaw University of Technology (WUT) to demonstrate physics phenomena or the methodology of the measurements. There are nuclear physics experiments, thermodynamics experiments based on the Ångström Law, experiments for the Hall effect and Curie temperature investigations, and electric resonance measurements. These experiments can be run through quickly during a lecture or in the 'real' time mode in a virtual physics laboratory for training students. One of these experiments is devoted to determination of γ-rays energy. This experiment, likewise other experiments, has its prototype in the real experiment existing in the CPL (see Figure 1) and simulates it.

6.3 Determination of γ-rays energy – a virtual nuclear physics experiment

The experiment aims at instructing students as to how the basic nuclear apparatus works, how the typical spectrum of γ-rays looks, and how to perform measurements to determine energy of the unknown γ-photons. Two sources, ^{137}Cs and ^{60}Co, are used to obtain calibration curve of the scintillation spectrometer. The third source, ^{22}Na, is then examined with respect to the energy of γ-photons emitted by it.

7 VIRTUAL NUCLEAR PHYSICS EXPERIMENT FOR E-LEARNING

After switching on the apparatus, the parameters setting (Figure 8(a)), and the source selection (Figure 8(b)), a user can start to perform the virtual experiment. The experiment for energy determination needs at first the spectrometer to be calibrated. It can be done to measure the energy spectra of the sources with emissions of the known energies.

7.1 Spectrum acquisition and presentation

The calibrating sources used in the virtual experiment are ^{137}Cs and ^{60}Co. To perform the measurement for obtaining

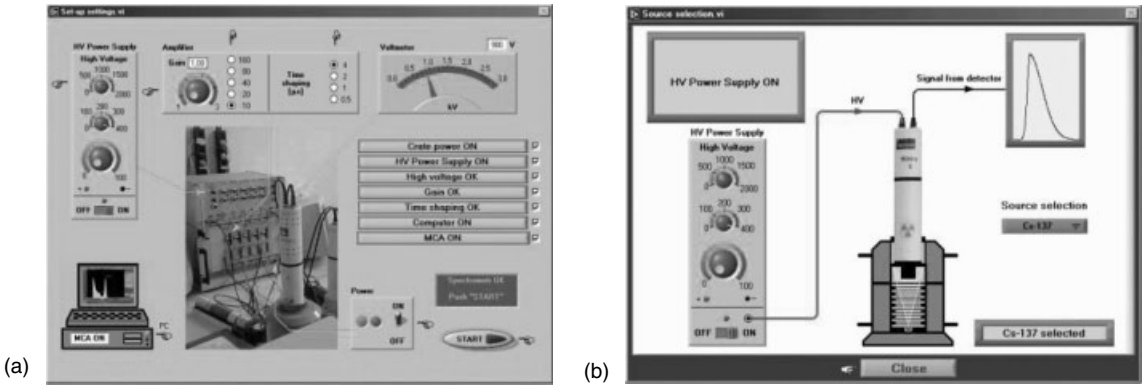

Figure 8. LabVIEW applications for the experimental setup arrangement and the source selection.

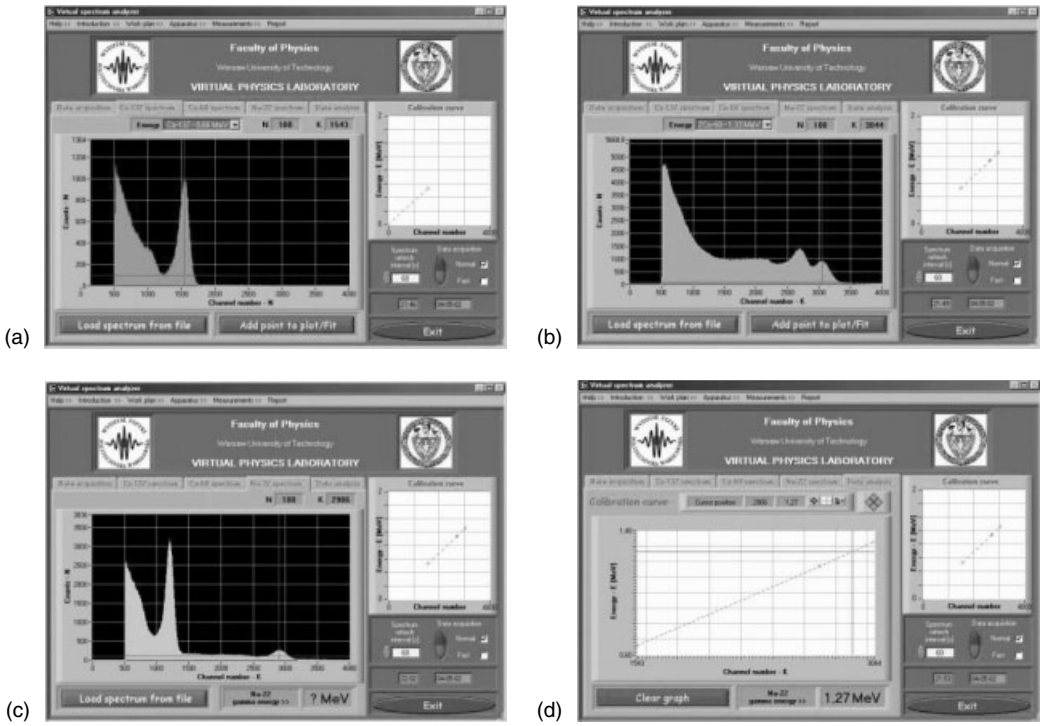

Figure 9. Spectra for the VSA calibration and the ^{22}Na gamma energy determination.

the ^{137}Cs spectrum, a user has to select the Data acquisition mode, the Normal or Fast mode on the VSA front panel, then select the Data acquisition window, and finally push the Cs-137 button. After some time, depending on the acquisition mode to be selected the ^{37}Cs spectrum will be obtained.

7.2 VSA calibrating and data analysis

After finishing data acquisition, performed with two calibrating sources, a user can calibrate the spectrometer by determining the calibration line. For this, a user has to identify the peaks with the aid of the isotope tables, or by selecting the needed values in the Ring control labeled Energy, which is visible on the VSA front panel when the windows with spectrums of ^{137}Cs and ^{60}Co are selected. The spectra obtained during the experiment are collected in Figure 9(a–c).

After selecting the channel number of the characteristic peak on the calibrating source spectrum with the help of the graph cursor, and selecting the corresponding energy value in the Ring control, placed above the graph, the one point can be plotted on the calibration curve graph, using the Add point to plot/Fit button. A correspondence between the MCA channel number and energy can be made this

way. With the ^{137}Cs and ^{60}Co spectrums, three such points are plotted on the graph. The VSA automatically draws the calibration curve by taking the best fitting straight line through the points. The energy scale is indicated on the left-hand side, but the MCA channel numbers are indicated on the X-Axis of the graph shown after opening the Data analysis window.

After taking the ^{22}Na spectrum (Figure 9(c)) and selecting a corresponding peak, the energy value of the γ-rays emitted by ^{22}Na can be read by using the calibration curve available in the Data analysis window.

The data collected in the virtual experiment are not simulated. They are similar to data obtained in a real physics laboratory because they are based on the real measurement results, which have been incorporated in the software when the application was built.

1 THE NATURE AND SCOPE OF SENSOR SCIENCE

Sensors and transducers are manufactured systems (McGhee, Henderson and Sydenham, 1999), which extend the human abilities to sense the two highly relevant problems of measurement described in **Article 5, Humans in the Real World, Volume 1**. Hence, since they are the front-end elements in Instrumentation and Measurement Technology, or I&MT, they are of basic importance in all fields of science, industry, and commerce. I&MT, which may also be referred to as *Information Technology*, or IT, is that field of scientific activity where humans use machines to extend their ability to perform the information handling operations associated with measurement, calculation, communication, and control (**Article 14, Hierarchical Aspects of Measurement Systems, Volume 1**). It is also concerned with the design, analysis and utilization of these machines.

A transducer is a device that transforms the input signal of one energy form into an output of another energy form. It does this in such a way that a prescribed relationship is maintained between the input and output signals. An example is the mercury-in-glass thermometer in which heat energy is converted into mechanical energy, forcing the mercury to move along the glass as it expands or contracts.

To provide a wide view of sensing and transduction, it is important to examine what constitutes the science of sensors. Sensor Science is closely akin to Measurement Science (Bentley, 2004; Finkelstein and Grattan, 1994; Sydenham, 1982, 1983; Sydenham and Thorn, 1992; Sydenham, Hancock and Thorn, 1992).

This article focuses upon sensors, sensing and sensing systems. The specific goal of the article is to analyze the elements of sensor science. An analytical approach leads to proposals that specify the constituent parts defining the ordered study of sensors.

The extensive literature on sensors is the principal tool of this analysis. The article shows that Sensor Science has a sufficiently distinct and noteworthy constitution, which demands both greater emphasis by measurement scientists and more recognition in the wider scientific community.

Calling the discipline under consideration Sensor Science may be controversial. However, there has been notable success in developing specific types of sensors and sensor systems as exemplified by the authoritative 8-volume treatise edited by Göpel, Hesse and Zemel (1989), with its subsequent update (Baltes, Göpel and Hesse, 1996), and the handbook of Fraden (1996). In addition, the excellent texts by Hauptmann (1993), Sinclair (2000) and Usher and Keating (1996), have emphasized the importance of organizing the basic material of sensors. This need is also strongly supported by other books grouped according to

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

the COMETMAN energy form classification due to Stein, which is described in some detail in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. Good examples of books according to this grouping are as follows:

- For Chemical sensors (Göpel *et al*., 1989; Janata, 1989; Taylor, 1996), including gas (Maskell, 1996; Moseley and Tofield, 1987), immunological (Ngo, 1987), pharmaceutical (Cosofret and Buck, 1992) and food industry units (Kress-Rogers, 1993; Karube, 1994);
- For Optical sensors (Wagner, Dendliker and Spenner, 1994; Agousti, 1996; Wolfbeis, 1991; Krohn, 1992; Dadswell and Dean, 1995);
- For Mechanical sensors (Bau, de Rooij and Kloeck, 1994) such as in manufacturing (Soloman, 1994), robotics (Everett, 1995; Ruocco, 1987), robotics and medicine (Webster, 1988) as well as in mechatronics (Bradley *et al*., 1991);
- For Electrical sensors, Chapter 15 in Fraden (1996);
- For Thermal sensors (McGee, 1988; Michalski *et al*., 2001; Nicholas and White, 2001; Scholz and Ricolfi, 1990);
- For Magnetic sensors (Boll and Overshot, 1990; Maenaka, 1994);
- For Acoustic sensors (Crocker, 1998; Lerch, 1994; Lynnworth, 1994);
- For Nuclear sensors, Chapter 14 in Fraden (1996).

In addition to the classification of sensors by the energy form, alternative schemes are grouped by the sensor manufacturing technology. Examples using this approach are solid state and semiconductor sensors (Gardner, 1994; Middelhoek and Audet, 1989; Sze, 1994) and their on-chip compatibility (Wolffenbuttel, 1996) as well as thin film type sensors (Ciureanu and Middelhoek, 1992).

Mention also needs to be made of smart sensors (Barney, 1988; Chapman, 1995; Frank, 1996) as well as the associated conditioning and support circuits (Carr, 1993; De Sa, 1990; Pallas-Areny and Webster, 1991; Regtien, 1992; Van Putten, 1996) – *see* **Article 160, Smart Sensor System Features, Volume 3**.

Complementing the multitude of published books about sensors, there are also a large number of technical articles that have contributed to the overall understanding of sensors. Journals where these articles appear, are *Measurement; Sensors and Actuator – A Physical, Sensors and Actuators: B Chemical; IEEE Trans on Instrumentation; Instrument Science and Technology; and Measurement* and *Sensor Review* to name only five.

Achievements in the area of classification of sensors, which can be traced back to the work of Kurt Lion (1969), have been built upon by Peter Stein (1969) and more recently by many other researchers. Significant progress has been made possible by the cataloging and classification of physical material effects (Ballentyne and Lovett, 1980; Schubert, 1984), by sensor modeling (Finkelstein and Watts, 1983; Neubert, 1973), sensor design (Finkelstein and Finkelstein, 1983; Cook, 1993a,b; Sydenham, 1994a,b; Finkelstein *et al*., 1993), system reliability (Cluley, 1974; Hoyland, 1994; O'Connor, 2002; Ramakumar, 1993; Lyn, 1996) and fault diagnosis (Patton, Frank and Clark, 1989), all of which represent a selection of these contributions.

In spite of this progress, the constituent body of coherent principles of the discipline lack the organization necessary before that group of principles may be referred to as a science.

The purpose of this article is to address this question. By doing so, proposals are made as to what constitutes the science of sensors and giving an approach to its systematic organization is achieved.

As shown above, there is substantial literature dealing with all aspects of sensors, sensing, and sensor systems. Included in this area are those given specific reference above and at different points in this article.

2 THE CENTRAL ROLE OF SYSTEMS ENGINEERING

Many different methods and theories are used in Sensor Science. The bubble and block diagram of Figure 1 is a good way to visualize some of these Sensor Science disciplines. In the search for these contributory disciplines an important key is found in the definition that sensors are *systems*, which refine and extend the human faculties of *sensing* and perception. Because sensors are systems, the science of sensors must be holistic by always using the whole-life-whole-system approach characterizing the methods of Systems Engineering described in **Article 63, Outline of Systems Thinking, Volume 2**; **Article 64, Executing A Measuring System Design, Volume 2**; **Article 66, Phases of System Life Cycle, Volume 2**; **Article 65, Life Cycle Concept, Volume 2**; **Article 67, Principle of Concept of Operations (ConOps), Volume 2**; **Article 68, Setting the System Boundaries, Volume 2**; and **Article 69, Requirements Allocation, Volume 2** (Sandquist, 1985; Weinberg, 1975).

Thus, sensors and sensor systems should be regarded as information machines. This class of machine performs a diversity of sensing functions involving the holistic relations among specific sensor structures within different energy domains for the acquisition, capture, communication, or distribution of information.

The information, which is acquired about the states of equilibrium and motion of solids, liquids, gases, and

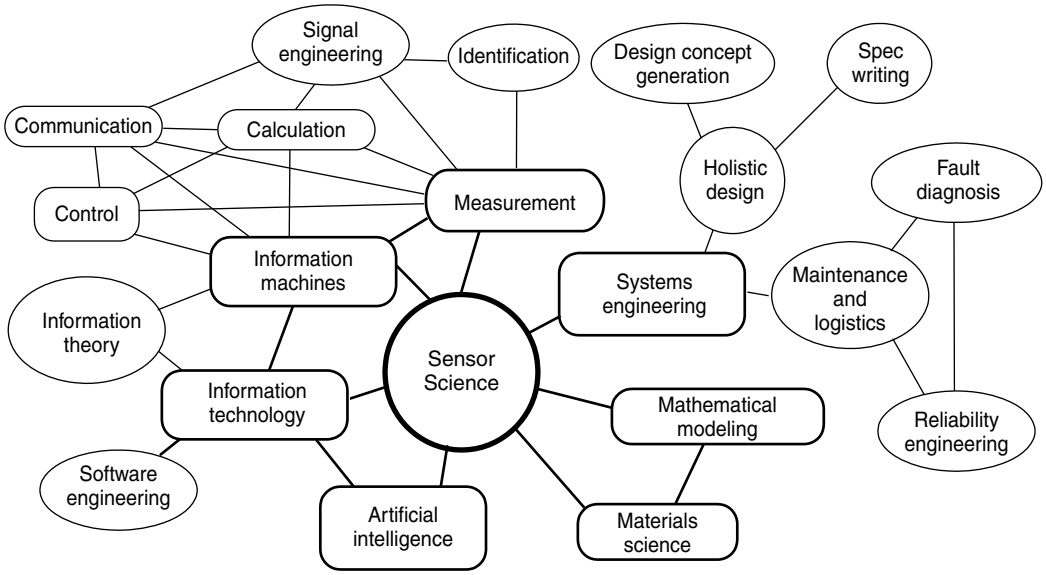

Figure 1. A bubble and block diagram illustrating the constituent disciplines of Sensor Science.

their constituent systems, may be carried or captured in a variety of signal forms. This statement is similar to the definition given in **Article 2, Organization of Instrument Science, Volume 1**. As both function, or 'what they do', and structure, or 'how they do', are specified in these definitions, the importance of considering sensors as embedded within sensor systems is reinforced. In other words, sensors are human-made elements embedded within human–machine systems, which help humans to acquire information, by the process of sensing, and to handle data, by performing information handling operations.

Sensor systems possess physical, also called *organic*, structure. The systems approach to their specification and design is basic to Sensor Science.

3 RECURSION AND RETICULATION PRINCIPLES

Important tools for use in Sensor Science, taken from the Systems Engineering approach, are the techniques of reticulation and recursion. Reticulation is that approach to the analysis of systems, which allows them to be successively subdivided down to the simplest element.

Recursion is that property of a procedure that allows operations to be performed in a nested manner using the same basic method of analysis. By this means, all of the subdivided portions or elements of the sensor system may themselves be individually analyzed using the approach of Systems Engineering. It is the systems aspect of sensors, with its holistic implications, which provides the key to the nature and scope of their science.

4 IMPORTANCE OF CLASSIFICATION IN SENSOR SCIENCE

A science is a systematically organized body of knowledge. Hence, since Sensor Science possesses a corporate body of knowledge with an organized structure, it is as necessary to organize it as it is to organize other scientific fields. The nature and scope of the constitution of Sensor Science may be objectively examined using the methods of taxonomy. When applied in Sensor Science, taxonomy requires the identification of that series that depends upon the increase or decrease of some variable in the scheme of ordering.

A taxonomy of Sensor Science will be erroneous if it is based upon its ends, as this will only lead to a cataloging of sensors. Hence, the only legitimate scheme of sensor classification will ensure that all of the divisions of Sensor Science are always determined by one common principle. Indeed, only by organizing the constitution of the topic on the basis of contributory disciplines can Sensor Science be arranged according to its basic nature and inherent characteristics. This will ensure that its arrangement is only based upon its basic nature and inherent characteristics. It will also make sure that its organization is not based upon either its ends or upon anything lying outside itself. In other words, applying classification in Sensor Systems is not about the sum of their ends but about coordinating the science of sensors so as to give it an organized or systematized structure. The systemic nature of sensors leads to the holistic approach in their classification as shown above.

By considering the nature and scope of the disciplines constituting the taxonomy, analysis, design, and utilization of sensors and sensor systems, this article shows that Sensor

Science is important in its own right. Hence, it should be given the attention it deserves by all of the scientific community, despite the close relationship it shares with other aspects of Measurement Science within IT.

The Four Orders or Problems of Classical Taxonomy are considered in **Article 2, Organization of Instrument Science, Volume 1**. An understanding of Sensor Science requires the application of the principles of classical taxonomy.

Previous work has well established the application of these principles within the context of I&MT. Sensor systems, as the front-end elements in information machines, form one of the two divisions of the machine kingdom. These require an identifiable body of scientific principles, which depend upon the holistic relations among specific but diverse sensors and sensor systems. Classical taxonomy has always been used in the life sciences to bring order into the questions of likeness between different living entities (Daly and Linsley, 1970). It is also important in the earth sciences (Von Engelhardt and Zimmermann; 1988) for the classification of minerals, in technology transfer, and in Knowledge Engineering or KE.

Bringing order to Sensor Science recognizes the universality of the four principal orders or problems of classification **Article 2, Organization of Instrument Science, Volume 1**. The classification task in Sensor Science depends on discriminational criteria using reticulation, which requires the whole system to be 'broken down' by a process of subdivision.

These criteria are based upon two main approaches. In the life sciences, ordering may be built around evolutionary, or phyletic, analysis.

Phenetic analysis, based upon physical appearance or structure, is also widely used in bioscience classification. In the theory for classifying sensors and sensor systems, the same names may be adopted. Hence, the phyletic and phenetic approaches are also appropriate for machine kingdom grouping.

Phyletic analysis in the life sciences is based upon genetic considerations. Functional analysis, which is similar to evolutionary/propagative analysis, concentrates upon the functions performed by physical systems in the machine kingdom. Hence, analyzing the function of a machine may be called *phyletic analysis*. For the same reason, structural analysis, performed using methods analogous to the phenetic criteria of bioscience taxonomy, may also be called *phenetic* in machine kingdom classification. These represent some of the necessary modifications to the theory of bioscience taxonomy before it can be applied to instrumentation.

A taxonomy has three objectives and three functions. These are also relevant to Sensor Science. Thus, the three objectives of sensor classification are

1. the concrete discrimination between different sensors,
2. the consensus regarding standards for the principles of description,
3. the bringing of order or systematization to sensor systems.

Similarly, the three functions of classification should allow

1. the organization of the means of communication and retrieval of the descriptions used for sensors,
2. the acquisition of new information in the extension of sensor descriptions,
3. the highlighting of unifying factors between sensors without diminishing the importance of any existing differences.

The materials of taxonomy in Sensor Science are the diverse types of sensors and their operating principles. Assembling the various sensor types is the main activity of classification in Sensor Science, because it allows the possibility for further study. Assembling sensors into progressively larger groups to obtain a hierarchical ordering by function, structure, and energy form constitutes the final ingredients of discrimination and ordering in Sensor Science.

5 SENSOR SYSTEMS AS INFORMATION MACHINES FOR MEASUREMENT

Sensors are important elements belonging to the class of Information Machines, which is made up of machines for measurement, calculation, communication, and control – *see* **Article 14, Hierarchical Aspects of Measurement Systems, Volume 1**.

Consequently, the underlying theory of information handling is also relevant to Sensor Science. This theory indicates that an economical, possibly minimum, number of alphabet symbols should be coded as messages for carrying or capturing information.

This distinction between information carrying and information capturing is important. While information carrying (i.e. communication) machines perform the primary function of high fidelity information transmission, information capturing (i.e. measuring) machines perform the primary function of high precision information capture. As is stated in **Article 5, Humans in the Real World, Volume 1**, precision measurement may be concerned with either direct or inferential measurement.

Both of these problems of measurement require the use of sensors. In the sensing role, the flow of information and energy, characterizing the states of equilibrium and motion of solids, liquids, and gases, are captured. Identification,

essentially a problem in precision measurement, captures information about those features of a system's ability to store, transform, transmit, or dissipate energy and/or information by a process of interrogation.

This discussion indicates the important contribution made by signal design (Godfrey, 1993; Henderson, McGhee and El Fandi, 1997) and signal processing (Bellanger, 1989; Ludeman, 1987) in Sensor Science. The interrelationships between these contributors to Sensor Science are shown in Figure 1.

6 HOLISTIC DESIGN

Sensing in real environments can only be performed with real structures. These sensor forms and the systems within which they are embedded need to be purposefully designed. It could be argued that, like Measurement Science, Sensor Science should be considered within the context of design rather than solely analysis.

This valid point of view deserves widespread support. However, another point of view concerning design needs to be expressed. It is highly unlikely that all measurement technologists will find themselves involved in the actual design of sensors. It is much more likely that they will be involved in including existing sensors into new designs of sensing systems. Consequently, design would seem to be better addressed within the context of measurement system design.

Effective design methodologies in Sensor Science require a combination of design processes, which involve a number of phases (Finkelstein and Finkelstein, 1983). These include (i) a feasibility assessment, (ii) a specification formulation, which may use KE in the same way as (iii) design concept generation. Further knowledge on how systems engineering impacts engineering detail design is found in Sydenham (2003).

7 MAINTENANCE ENGINEERING

Maintenance engineering, an important branch of all engineering activity, is also essential for the efficient day-to-day activities in Sensor Science where it is now receiving the attention it deserves. Three important aspects of this technology are

- hardware (Cluley, 1974; Hoyland, 1994; Lyn, 1996; O'Connor, 2002; Ramakumar, 1993) and software reliability engineering (Henderson *et al*., 1991; Lyn, 1996);
- fault diagnosis and prediction (Henry and Clarke, 1993; McGhee, Henderson and Baird, 1997; Patton, Frank and Clark, 1989);
- signal processing (Bellanger, 1989; Ludeman, 1987).

When equipment is referred to as *faulty* there is an implication that some abnormality in the operating conditions exists (McGhee, Henderson and Baird, 1997).

A more general definition of faults is that there is a substantial degradation in system performance. This may be due to gradual (graceful degradation) or abrupt changes (catastrophic failure) in the parameters of some system or process parameter or malfunction of equipment causing uncertainties in measured values.

The most common way of implementing such a philosophy is by using some scheme of maintenance or plan for maintenance, which will replace 'worn out' parts before they malfunction.

A second way of preventing malfunction of a process is to provide some monitoring scheme.

Thus, it appears that fault detection, fault location, fault diagnosis and fault correction are the principal functions constituting a monitoring scheme.

In short, such a monitoring scheme may be called *Fault Detection and Isolation*, or (FDI). For fault diagnosis purposes, the system has three subsystems. These consist of the actuators, the main structure of the plant or process and the instruments or information machines making up the technical instrument subsystem. For this reason, the three FDI schemes are

1. Actuator Fault Detection, or AFD, scheme,
2. the Process Fault Detection, or PFD, scheme,
3. Instrument Fault Detection, or IFD, scheme.

Sensor Fault Detection, or SFD, constitutes an important part of IFD. In the case of SFD, the field of both sensor validation (Henry and Clarke, 1993) and *in situ* testing are the focus of some interest (Kerlin, Hashemian and Petersen, 1982; Michalski *et al*., 1993; McGlone, McGhee and Henderson, 1998).

Although many diagnostic systems are in use, they only provide testing for most of the sensing conditioners up to the point where the sensor signal is available. At the moment, it is unusual to find sensor system diagnostics where the sensor is one of the system elements to have both its static and dynamic behavior tested. In the search for more reliable systems, the importance of whole-system-each-element-in-situ-testing will almost certainly lead to more sophisticated fault diagnosis and prediction. Detection and prediction of faults uses similar processes as found in system safety assessment – *see* **Article 99, Safety Organization, Volume 2**; **Article 100, Safety Analysis Methods, Volume 2**; and **Article 101, Assessing and Demonstrating Safety, Volume 2**.

8 PRINCIPLES OF SENSOR MODELING

Since sensing essentially ascribes numbers to physical variables in such a way as to describe both them and the relations between them, it is necessary to develop quantitative methods to describe these numerical assignations. Although sensors must be considered within the wider context of Information Technology, there are aspects of their analysis and design, which require a specialized, unique treatment. An important example illustrating this assertion is the contribution made by the theory of modeling (Abdullah *et al*., 1994).

Sensor models also allow a deeper understanding of sensor behavior to be gained. Sensor models were originally visualized as extensions of those widely used for most other dynamic systems (Finkelstein and Watts, 1983; Neubert, 1973). Although this approach was very useful for the visualization of the state and rate variables, it has some shortcomings in the representation of the states of the local mass element in a material and how they relate to the environmental states. The only approach that accepts this possibility uses mathematical models to describe the flow of energy and information (Kwaaital, 1993; Van Duyn, 1993; Van Duyn and Middelhoek, 1990; Ylilammi, 1989). Developments in this area have shown that sensor modeling should be based upon the three laws of thermodynamics (Van Duyn, 1993).

This indicates that as the acquisition and communication of information are impossible without the flow of energy or matter, considerations of energy form and material type are essential.

The diversity of energy forms in which systems are manifest are described in **Article 109, Structure and Energy in Sensor Systems, Volume 2**. These may be summarized using the COMETMAN acronym. Consequently, the underlying nature of all physical effects in diverse materials, and in whatever energy form, must play an essential role in all aspects of the modeling of sensors and their systems. The concepts of *intensive* and *extensive* state variables may be used to describe the equilibrium relations of the local mass element and the manner in which these are coupled to the environmental conditions respectively. In most cases, this representation is useful for implementing computer-based solutions for the analysis of sensor design candidates. However, it lacks the transparency necessary for deep and simplified qualitative understanding. Nevertheless, the complexity of the model should be of such a level as to be of practical use.

The process of modeling consists of six main steps, which may form a recursive process. When the important objectives of the model are fixed, it is then necessary to gather whatever knowledge is appropriate for the modeling purpose.

In order to simplify the process of modeling, it is necessary to apply methods of abstraction, which have five discriminable levels depending upon the purpose of the abstraction. The three main processes of abstraction allow increasing generality, objective approximation, or reduction, and perspectivization, or partial viewing.

In most cases of sensor modeling, it is necessary to conduct some kind of decomposition so that one large problem to be solved is broken down into a number of smaller more manageable and presumably more easily solved problems.

Formalization is another important aspect of the modeling process where formal models take the form of linguistic groups, pictorial representations, functional representations, or mathematical models. Since all models require validation, this is an important step in all modeling activity.

The modeling process, which may also be summarized as shown in Figure 2, covers the three main problems associated with the

- system, plant or process under measurement,
- goal or aim of the measurement,
- result of the measurement.

The central focus is placed upon the sensor whose dynamic properties are to be modeled and determined. This element, which is characterized by its input and output, may be visualized by humans who represent a valuable source of prior knowledge about the sensor.

This knowledge allows the proposal of appropriate mathematical models as well as the design of appropriate model validation experiments.

Deriving the model of most dynamic sensor systems is intimately connected with the principles of conservation of mass, energy, and momentum in time and space.

Consequently, modeling starts with the equations describing this balance. These relations are typically nonlinear, partial differential equations. Since these equations are difficult to solve, they are not really of much practical use.

Most practical systems are so complex that it is difficult to find an accurate model to describe the behavior of the process by physical modeling.

To give models that are practically useful and still realistic, the experimenter needs to make some well-informed assumptions for the purposes of simplification.

The first of these steps is the routine of linearization. By assuming typical average operating conditions, all of the parameters are represented by nominal values at the operating points of the process. Parameters may be material properties, environmental conditions, and other physical influences. In most industrial systems, it is possible to recognize some geometrical property of its structure. Such a property can be employed usefully by using the ideas

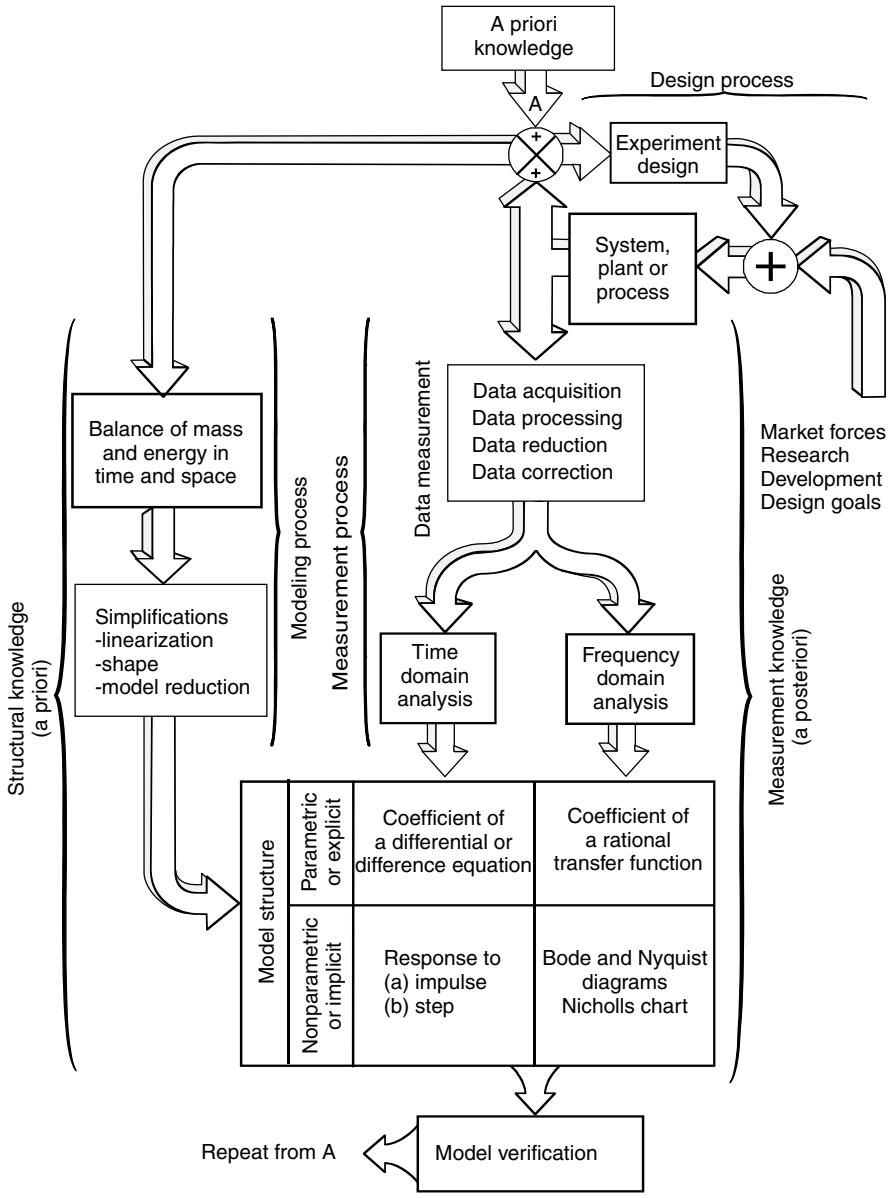

Figure 2. Steps in the modeling problem.

of shape simplification. Examples of this occur when there may be cylindrical symmetry in the real physical object.

Having linearized the model and introduced geometrical features in model simplification, the resulting mathematical model may still be difficult to understand and use. In such a case, the experimenter may be forced to apply a process of *model reduction*. Model reduction usually replaces linear partial differential equations with constant coefficient ordinary differential equations. McGhee, Henderson and Sydenham (1999) apply these techniques to the modeling of a resistance thermometer in its sheath. Modeling in measurement systems pursuits is found in many places – *see* **Article 71, Modeling Methodology, Volume 2**; **Article 114, Models of the Sensor Interface, Volume 2**; and **Article 105, Modeling with LabVIEW™, Volume 2**.

9 PARAMETRIC AND NONPARAMETRIC MODELS

Mathematical models obtained by the process described above have parameters that depend on physical materials used in the structure of the system. Hence, they are called *parametric models* or *explicit models*.

It often happens that a model based on physical behavior contains a number of unknown parameters even if the structure is derived from physical laws. Experimentation, which can help by inferring the values of these parameters from measurements, is an essential part of the model validation process.

The two most common parametric models refer to either the time domain description of the system, normally in the form of systems of linear difference equations, or the frequency domain description as rational transfer functions.

Other types of models make a minimum number of assumptions appropriate for the purpose of the model. These models are generally referred to as *nonparametric models* or *implicit models*. As with parametric models, nonparametric models may characterize the behavior of the system in either the time domain or the frequency domain.

The impulse response of a linear physical system, which is a statement of the time domain output of the system when the input is an impulse, is of basic importance. If the impulse response is known, either explicitly, from a parametric model, or implicitly, from a nonparametric model, then the response of the system to any other type of input signal may be predicted. The frequency domain equivalent of the impulse response is called the *frequency response function* sometimes simply called the *frequency response*. This model is a representation of the way in which a system responds to sinusoidal signals of different frequencies. Consequently, when the system is linear, it can be used to predict the response of the system to any signal that can be modeled by a number of composite frequency components.

When the process of modeling has reached an appropriate stage, the next stage involves the problems of identification. Identification is concerned with the synthesis and analysis of signals used in inferential measuring instruments. Inferential measurement, also called *identification*, is defined as the second problem of measurement in **Article 5, Humans in the Real World, Volume 1** and also by McGhee *et al*. (2001). DSP is widely used in identification.

10 MATERIALS SCIENCE FOR SENSORS AND SENSING

From thermodynamic modeling, it has become even more apparent that Materials Science plays a major role in Sensor Science, quite apart from the pivotal role it plays in the general science of machines. This role, although predominantly concerned with those physical effects that may be used to realize the sensing or transduction function, is also important from other points of view. Examples are mechanical rigidity or flexibility, chemical inertness or sensitivity in adverse environments, relative ease of manufacture or processing and so on (Cahn, Haasen and Kramer, 1993; de Podesta, 1996; Gardner, 1994) – *see* **Article 117, Materials in Measuring Systems, Volume 2**.

Because of the vast amount of published information on materials, it is essential to discriminate between those general aspects of materials science and the more specific requirements of sensor science. This may be achieved using a scheme of classification based upon the COMETMAN classification of measurand energy form.

It has been noted above that Knowledge Engineering, or KE (Charniak and McDermott, 1985; Finkelstein, 1994) is an area of growing importance in Sensor Science. It is likely that this has much promise for the resolution of many cognitive issues in Sensor Science even though it is an area where there are a number of outstanding problems. Some proposals concerned with these issues have been made (Cropley, 1994, 1997; Cropley and Cropley, 1994; Ferris and Sydenham, 1994) – *see also* **Article 160, Smart Sensor System Features, Volume 3**.

1 DEFINITION OF A TRANSDUCER

A transducer is an essential part of any information processing system that operates in more than one physical domain. These domains are characterized by the type of quantity that provides the carrier of the relevant information. Examples are the optical, electrical, mechanical, and magnetic domains. A transducer is the part of the instrument that converts information about a measurand from one domain into another, ideally without information loss. So, a transducer can formally be defined as *a device that converts one form of energy into another*, with the intention of preserving information.

A transducer has at least one input and one output. In measuring instruments, where information processing is performed by electrical signals, either the output or the input is of electrical nature (voltage, current, resistance, capacitance, etc.), whereas the other is a nonelectrical signal (displacement, temperature, elasticity, etc.). A transducer with a *nonelectrical input* is an *input transducer*, intended to convert a nonelectrical quantity into an electrical signal so as to measure that quantity. A transducer with a *nonelectrical output* is called an *output transducer*, intended to convert an electrical signal into a nonelectrical quantity so as to control that quantity. So, a more explicit definition of a transducer is *an electrical device that converts one form of energy into another*, with the intention of preserving information.

According to common terminology, these transducers are also called *sensor* and *actuator* respectively (see Figure 1).

So, a sensor is an input transducer and an actuator is an output transducer. It should be noted, however, that this terminology is not standardized. In literature, other definitions are found. In particular, some authors make a clear differentiation between a *sensor* and a (input) *transducer*, stressing a distinction between the element that performs the physical conversion and the complete device, for instance, a strain gauge (transducer) and a load cell with one or more strain gauges (sensor), or even vice versa. Modern sensors not only contain the converting element but also contain part of the signal processing (analog processing such as amplification and filtering, Analogue-to-Digital-conversion and even some digital electronics). Many such sensors have the electronics integrated with the transducing part onto a single chip. Present day sensors may have a bus compatible output, implying full signal conditioning on board. There is a trend to also include transmission electronics within the device, for instance, in biomedical applications.

Signal conditioning may be included

- to protect the sensor from being loaded or to reduce loading errors;
- to fit the sensor output to the input range of the Analogue-to-Digital Converter (ADC);
- to enhance the S/N (signal-to-noise ratio) prior to further signal processing;
- to generate a digital, bus compatible electrical output;
- to transmit measurement data for wireless applications.

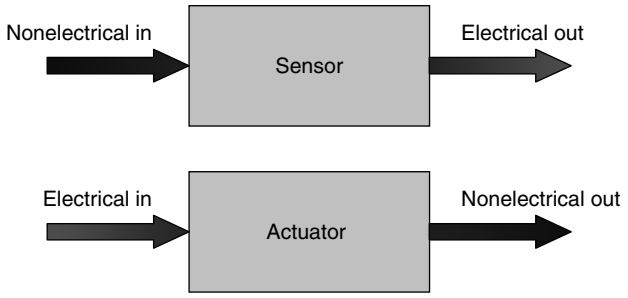

Figure 1. Input transducer (sensor) and output transducer (actuator).

In conclusion, the boundaries between sensor and transducer, as proclaimed in many sensor textbooks, are disappearing or losing their usefulness: the user buys and applies the sensor system as a single device, with a nonelectrical input and an electrical (analog, digital, bus compatible) output.

2 CATEGORIZING SENSORS

A sensor (or input transducer) performs the conversion of information from the physical domain of the measurand to the electrical domain. Many authors have tried, more or less successfully, to build up a consistent categorization of sensors (*see also* **Article 112, Systematic Description of Sensors, Volume 2**). It is not easy to create a consistent systematic description encompassing all sensor principles. There is at least consensus on a division into two groups of sensors: direct and modulating sensor types (see Figure 2). The distinguishing property is the need for auxiliary energy.

Direct sensors do not require additional energy for conversion. As information transport cannot exist without energy transport, a direct sensor withdraws the output energy directly from the measurement object. As a consequence, loss of information about the original state of the object may occur. There might also be energy loss, for instance, heat. An important advantage of a direct sensor is its freedom from offset: at zero input, the output is essentially zero. Examples of direct sensors are the thermocouple and the piezoelectric force and acceleration sensor.

Indirect sensors or *modulating sensors* use an additional energy source that is modulated by the measurand; the sensor output energy mainly comes from this auxiliary source, and just a fraction of energy is withdrawn from the measurement object. In this respect, modulating sensors do not significantly load the measurement object and hence are more accurate than direct sensors. Most sensors are of the modulating type, for instance, all resistive and capacitive sensors and many inductive sensors.

There are many sensors on the market, over a million types worldwide. A categorization of sensors would help make the proper choices and also make it easier to understand, but a useful basis for categorization is difficult to define. There are various possibilities such as

- according to the measurand,
- according to the conversion principle,
- according to the domain of the measurand,
- according to application fields.

All of them have their limitations. For instance, the number of measurands is rather large, making the first option not very practical. Figure 3 gives an overview of the most common physical quantities for which sensors are available, after Middelhoek and Noorlag (1981). However, the list is not complete. Moreover, many quantities can be measured by a variety of sensor types. For example, position can be measured using resistive, capacitive, inductive, acoustic, and optical methods.

The second option, according to the conversion principle, is often used for the reason that the sensor performance is mainly determined by the physics of the underlying principle of operation. On the other hand, a particular type of sensor might be suitable for a variety of physical quantities and in many different applications. For instance, a magnetic sensor of a particular type could be applied as a displacement sensor, a velocity sensor, a tactile sensor, and so on. For all these applications, the performance is limited by the physics of this magnetic sensor, but the limitations manifest in completely different ways.

A closer look at the various conversion effects may lead to the observation that the electrical output of a sensor depends either on a material property, or the geometry, or a movement. Figure 4 tabulates these three phenomena, for various types of sensors. The figure gives the material parameter, the geometric parameter, and the velocity induced parameter, together with associated sensors.

Figure 3. Parameters for which sensors are on the market (after Middelhoek and Noorlag (1981)).

Type	Material property	Geometry	Relative movement
Resistive	Resistivity (piezoresistor,LDR)	Relative length (potentiometer; metal strain gauge)	
Capacitive	Permittivity (fluid level sensor)	Relative electrode distance capacitive displacement (LVDC)	
Magnetic	Permeability (magnetoresistor)	Distance source-detector (magnetic displacement sensor)	Induction (magnetic velocity sensors)
Inductive		Inductance, self-inductance, mutual inductance reluctance (inductive displacement sensors, LVDT, resolver)	Induction (inductive velocity sensors)
Optical	Index of refraction; absorptivity (fibre optic sensors)	Distance transmitter–receiver (intensity modulation sensors; interferometer; TOF sensor) transmissivity, reflectivity (optical encoder, tachometer)	Doppler frequency (Doppler velocimeter)
Acoustic	Acoustic impedance	Distance transmitter–receiver (TOF displacement sensors)	Doppler frequency (Doppler velocimeter)
Piezoelectric	Polarization (piezoelectric sensors)	Deformation (piezoelectric sensors)	

Figure 4. Three groups of parameters, with examples of sensors.

A categorization based on the domain of the measurand is too coarse, and domain definitions are not unambiguous.

Finally, an application field provides no restricted set of sensors, since in each field (biomedical, automotive, agriculture), almost all types of sensors could be applied.

3 TERMINOLOGY OF SENSORS

We have defined a sensor as a device that performs the conversion of information from the physical domain of the measurand to the electrical domain. For instance, a position sensor converts position information into an electrical signal (a voltage, current, etc.). Obviously, a position sensor measures position. However, there are different names for different applications and situations, for instance,

Distance sensor: measures the length of the straight line between two defined points;

Position sensor: measures the coordinates of a specified point of an object in a specified reference system;

Displacement sensor: measures the change of position relative to a reference point;

Proximity sensor: (i) determines the sign (positive or negative) of the linear distance between an object point and a fixed reference point;
(ii) a contact free displacement or distance sensor for short distances (down to zero);

Level sensor: measures the distance of the top level of a liquid or a granular substance in a container with respect to a specified horizontal reference plane;

Angular sensor: measures the angle of rotation relative to a reference position;

Encoder: displacement sensor (linear or angular) with digital output:

Tilt sensor: measures the angle relative to the earth's normal;

Tachometer: measures the rotational speed;

Vibration sensor: measures the motion of a vibrating object in terms of displacement, velocity or acceleration;

Accelerometer: measures acceleration.

Sensors for the measurement of force and related quantities are as follows:

Pressure sensor: measures pressure difference, relative to either vacuum (absolute pressure), a reference pressure or ambient pressure;

Force sensor: measures the (normal and/or shear) force exerted on the active point of the transducer;

Torque sensor: measures torque (moment);

Force–torque sensor: measures both forces and torques (up to six components);

Load cell: force or pressure sensor, for measuring weight;

Strain gauge: measures linear relative elongation (positive or negative) of an object, caused by compressive or tensile stress.

Many sensors have been given names according to their operating principle or construction. Examples are as follows:

LVDT: or linear variable displacement transformer, a device that is basically a voltage transformer, with a linearly movable core;

Gyroscope: a device for measuring the angular velocity, based on the gyroscopic effect occurring in rotating or vibrating structures;

Hall sensor: measures magnetic field on the basis of the Hall effect, after the American physicist Edwin Hall (1855–1938).

Some sensors use a *concatenation* of conversion steps. A displacement sensor combined with a spring can act as a force sensor. The measurand (force) is converted to a displacement, which in turn is converted into an electrical signal. In combination with a calibrated mass, a displacement sensor can serve as an accelerometer: the measurand (acceleration) is converted into a force (by the inertial effect), the force into a displacement (by the spring), and the displacement into an electrical signal. The performance of such transducers not only depends on the original sensor but also on the added components: in the case of the accelerometer, it depends on the spring compliance and the seismic mass respectively.

Information about a particular quantity can also be obtained by *calculation* or by additional electronic *signal processing* using relations between quantities. The accuracy

of the result not only depends on the errors in the quantities that are measured directly but also on the accuracy of the parameters in the model that describes the relation between the quantities involved. For instance, in an acoustic distance measurement, the distance is calculated from the measured time-of-flight (with associated errors) and the sound velocity. An accurate measurement result requires knowledge of the acoustic velocity of the medium at the prevailing temperature.

Speed and acceleration can be measured using a displacement sensor, by differentiating its output signal once or twice respectively, and vice versa: by integrating the output signal of an accelerometer, a velocity signal is obtained, and by a second integration, a position signal is obtained. Obviously, the performance of the final result depends on the quality of the signal processing. The main problem with differentiation is the increased noise level (in particular in the higher frequency range), and integration may result in large drift due to the integration of offset.

4 SENSOR PERFORMANCE

Imperfections of a sensor are usually listed in the data sheets provided by the manufacturer. These sensor specifications inform the user about deviations from the ideal behavior. The user has to accept technical imperfections, as long as they do not exceed the specified values.

Any measuring instrument, and hence any sensor, has to be fully specified with respect to its performance. Unfortunately, many data sheets show lack of clarity and completeness. Gradually, international agreements about formal error descriptions are being established. An extensive description of measurement errors and error terminology can be found in IOS (1995). Further, there is an international standard on transducer nomenclature and terminology ISA (1975). Finally, various international committees are working toward a uniform framework for specifying sensors.

The characteristics that describe sensor performance can be classified into four groups:

- static characteristics, describing the performance with respect to very slow changes;
- dynamic characteristics, specifying the sensor response to variations in time and in the measurand (the quantity that has to be measured);
- environmental characteristics, relating the sensor performance after or during exposure to specified external conditions (pressure, temperature, vibration, radiation);
- reliability characteristics, describing the sensor life expectancy.

First, we define some common specifications that apply to sensors:

- sensitivity;
- nonlinearity and hysteresis;
- resolution;
- accuracy;
- offset and zero drift;
- noise;
- response time;
- frequency response.

4.1 Sensitivity

The sensitivity of a sensor is defined as the ratio between a change in the output value and the change in the input value that causes that output change. Mathematically, the sensitivity is expressed as $S = \partial y/\partial x$, where x is the input signal (measurand) and y is the output (an electrical signal). Usually, a sensor is also sensitive to changes in quantities other than the intended input quantity, such as the ambient temperature or the supply voltage. These unwelcome sensitivities should be specified as well, for a proper interpretation of the measurement result. To have a better insight in the effect of such unwanted sensitivities, it is often related to the sensitivity of the measurement quantity itself.

Example 1 The sensitivity of a particular displacement sensor with voltage output is specified as $10\,\text{mV mm}^{-1}$. Its specified temperature sensitivity is $0.1\,\text{mV K}^{-1}$. Since 0.1 mV corresponds to a displacement of 10 mm, the temperature sensitivity can also be expressed as $10\,\text{mm K}^{-1}$. A temperature rise of 5 °C results in an apparent displacement of 50 mm.

Example 2 The sensitivity of a particular type of temperature sensor is $100\,\text{mV K}^{-1}$, including the signal conditioning unit. The signal conditioning part itself is also sensitive to (ambient) temperature and appears to create an extra output voltage of 0.5 mV for each °C rise in ambient temperature (not necessarily the sensor temperature). So, the unwanted temperature sensitivity is $0.5\,\text{mV K}^{-1}$ or 0.5/100 = $5\,\text{mK K}^{-1}$. A change in ambient temperature of ±10 °C gives an apparent change in sensor temperature equal to ±50 mK.

4.2 Linearity and hysteresis

If the output y is a linear function of the input x, the sensitivity S does not depend on x. In the case of a nonlinear transfer function $y = f(x)$, S does depend on

the input or output value. Often, a linear response is preferred to reduce computational burden in, for instance, multisensor control systems. In that case, the sensitivity can be expressed with a single parameter. The transfer of a sensor with a slight nonlinearity may be approximated by a straight line, to specify its sensitivity by just one number. The user should be informed about the deviation from the actual transfer; this is specified by the nonlinearity.

The linearity error of a system is the maximum deviation of the actual transfer characteristic from a prescribed straight line. Manufacturers specify linearity in various ways, for instance, as the deviation in input or output units: $\Delta x_{\max}$ or $\Delta y_{\max}$, or as a fraction of FS (full scale): $\Delta x_{\max}/x_{\max}$. Nonlinearity should always be given together with a specification of the straight line. The following definitions are in use:

- *Terminal nonlinearity*: based on the terminal line–a straight line between 0 and 100% theoretical full-scale points.
- *End-point nonlinearity*: based on the end-point line–the straight line between the calibrated end points of the range; coincides with the terminal (theoretical) line after calibration of zero and scale.
- *Independent nonlinearity*: referring to the best-fit straight line, according to a specified error criterion, for instance, the line midway between two parallel lines enclosing all calibration points; if the least-square error criterion for the best-fit straight line is used, this linearity error is as follows.
- *Least-square nonlinearity*: based on the least square line, the line for which the summed squares of the residuals is minimized.

Hysteresis is the maximum difference in output signal when the measurand first increases over a specified range, and next returns to the starting value. The traveled range should be specified because hysteresis strongly depends on it.

4.3 Resolution

The resolution indicates the smallest detectable increment of the input quantity. When the measurand varies continuously, the sensor output might show discontinuous steps. The value of the corresponding smallest detectable change in the input variable is the resolution: $\Delta x_{\min}$. Sometimes this parameter is related to the maximum value $x_{\max}$ that can be processed (full-scale value), resulting in the resolution expressed as $\Delta x_{\min}/x_{\max}$.

Example 3 The resolution of a particular type of wire-wound linear potentiometer with range 10 cm is specified as 10^{-4}; assuming this is relative to the full-scale value, it means that the output changes discontinuously in steps equivalent to input displacements of 10 mm.

Example 4 A particular type of optical encoder that has a resolution of 14 bit. The smallest change in angle that can be detected by this encoder is $2\pi/2^{14} \approx 1.9 \times 10^{-4}$ rad or 0.022°.

4.4 Accuracy

Formally, the accuracy reflects the closeness of the agreement between the actual measurement result and a true value of the measurand. The accuracy specification should include relevant conditions and other quantities. Many sensor manufacturers specify the sensor performance in terms of accuracy. This specification should be viewed with suspicion, because it may or may not include particular imperfections of the sensor (nonlinearity, hysteresis, drift), and may be only valid under strict conditions.

4.5 Offset and zero drift

Most sensors are designed such that the output is zero at zero input. If the transfer characteristic does not intersect the origin (x,y = 0,0) the system is said to have offset. The offset is expressed in terms of the input or the output quantity. Specifying the input offset is preferred to facilitate a comparison with the measurand.

Example 5 The sensitivity of a particular type of force sensing system is $0.1\,\mathrm{V\,N^{-1}}$. At zero force, the output appears to be 3 mV. The (input) offset of this system is the output offset divided by the sensitivity, so 0.03 N.

A nonzero offset arises mainly from component tolerances. Offset compensation can be performed in the interface electronics or the signal processing unit. Once adjusted to zero, the offset may nevertheless change, owing to temperature variations, changes in the supply voltage or aging effects. This relatively slow change in the offset is called *zero drift*. In particular, the temperature induced drift (the *temperature coefficient* or t.c. of the offset) is an important item in the specification list.

Sometimes a system is deliberately designed with offset. Many industrial transducers have a current output ranging from 4 to 20 mA. This facilitates the detection of cable fractures or a short circuit, producing a zero output clearly distinguishable from a zero input.

4.6 Noise

Electrical noise is also specified in terms of the input quantity, to show its effect relative to that of the measurand. *White noise* (noise with constant power over a wide frequency range) is usually expressed in terms of *spectral noise power* (W/Hz), *spectral noise voltage* (V/$\sqrt{}$Hz) or *spectral noise current* (A/$\sqrt{}$Hz). Thermal noise is an example of 'white noise'.

Another important type of noise is *1/f noise* (one-over-f noise), a collection of noise phenomena with a spectral noise power that is proportional to f^{-n}, with $n = 1$ to 2.

Quantization noise is the result of quantizing an analog signal. The rounding off results in a (continuous) deviation from the original signal. This error can be considered as a 'signal' with zero mean, and a standard deviation determined by the resolution of the AD converter.

4.7 Response time

The response time is associated with the speed of change in the output upon a stepwise change of the measurand. The specification of the response time always needs to be accompanied by an indication of the input step (for instance, FS – full scale) and the output range for which the response time is defined, for instance, 10 to 90%. Creep and oscillations may make the specification of the response time meaningless or at least misleading.

4.8 Frequency response

The sensitivity of a system depends on the frequency or rate of change of the measurand. A measure for the useful frequency range is the *frequency band*. The upper and lower limit of the frequency band are defined as those frequencies for which the output signal has dropped to half the nominal value, at constant input power. For voltage or current quantities, the criterion is $1/2\sqrt{2}$ of the nominal value. The lower limit of the frequency band may be zero; the upper limit has always a finite value. The extent of the frequency band is called the *bandwidth* of the system, expressed in Hz.

All specification items only apply within the operating range of the system, which should also be specified correctly. It is given by the measurement range, the required supply voltage, the environmental conditions and possibly other parameters.

Despite the specified limitations of sensors, a sensing system can be configured in such a way that the effect of some of these limitations are eliminated or at least reduced. Various possibilities of error reduced designs are described in **Article 16, Reduction of Influence Factors, Volume 1**.

5 ROLE AND USE OF ACTUATORS

Similar to the definition of a sensor (or input transducer) an actuator (or output transducer) can be defined as *a device that converts information from the electrical domain to another physical domain*, with preservation of information. Actuators and sensors can be considered as each other's opposites. Actually, many transduction principles are reversible (notably the direct conversion types), which means that the same device can act as both – a sensor as well as an actuator (for instance, a piezoelectric sensor and actuator). However, an actuator should, in general, be able to deliver output energy, whereas a sensor operates best when the amount of energy taken from the measurement object is close to zero. Reversibility does not imply that both options can be combined in a single device.

Since an actuator has to produce output energy, its construction and dimensions differ largely from that of sensors. There are far less physical conversion principles suitable for actuation than for sensing. However, the variability in types is larger, according to the application and the required energy.

Some actuator types, grouped according to the physical domain of the output are as follows:

- *Mechanical output*: induction motor; permanent magnet electromotor; stepper motor, piezoelectric actuators (linear and rotating movements), relay;
- *Optical output*: light emitting diode (LED), solid state laser diode (SSLD); incandescent lamp;
- *Thermal output*: electric heater; (thermo)electric cooler;
- *Acoustic output*: piezoelectric ultrasound transmitter; electrostatic ultrasound transmitter.

As with sensors, actuators too can operate either in a direct way or in a modulating mode. Most actuators are of the direct type: no auxiliary energy is required. Examples of modulating actuators are an oscilloscope (the electrical signal modulates the deflection of an electron beam and hence the position of the light spot on the screen) and an LCD (the electrical signal modulates the transmission of an auxiliary light source by influencing the transmittance of the crystal material).

The performance of a sensor system can sometimes be improved by including the sensor in a feedback loop. The electric output of the sensor is amplified and supplied to an actuator, having the inverse conversion characteristic. So its output is of the same nature as that of the measurand, or at least is closely related.

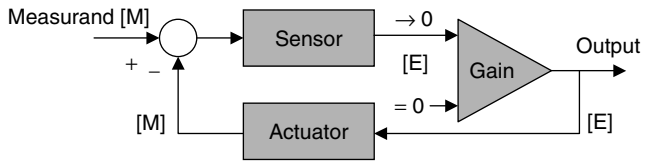

Figure 5. Feedback sensor configuration; [M] denotes the domain of the measurand, [E] the electrical domain.

In the steady state, and assuming stability and a high loop gain, the input of the sensor is compensated (made zero) by the feedback action, see Figure 5. The compensating signal is delivered by the actuator, and hence its input equals the output of the measurement system. Since the input signal of the sensor is zero, its static characteristics (sensitivity, nonlinearity, limited range) are irrelevant to the measurement result. The only requirement is zero offset. The performance of the measurement completely relies on the characteristics of the actuator. Further details of feedback sensing systems are discussed in more detail in the article **Article 113, Force-feedback Sensors, Volume 2**.

Like with sensors, also some actuators operate on the basis of a concatenation of conversions. Examples are as follows:

- *Thermal microactuator*: a particular element of the microstructure that is heated by an electric current upon which it expands, producing a displacement of the tip.
- *Reed switch*: a coil around the switch that is activated by a current, producing a magnetic field, which closes the contacts of the switch.
- *Incandescent lamp*: electric current heats up a filament that emits visible light above a particular temperature.

In the past decades, sensors tended to get smaller and actuators larger. Development in microtechnology, however, allows the creation of microactuators as well see, for instance, Tabib-Azar (1997). Consequently, such microactuators can produce little energy, and are therefore only useful as part of a microsystem, including (micro)sensors, signal processing, and actuation.

The role of an actuator in a measurement system can be

- indication of the measurement result (optical display),
- registration of the measurement result (magnetic or optical head; driving a plotter pen),
- control of the measurement system (scanning in 1, 2, or 3 dimensions),
- control of a process to perform measurements (for instance, in wear detection, fatigue tests)
- control of the sensing part of the measurement system (feedback sensors).

1 BOUNDARY PERSPECTIVE OF SENSOR SYSTEMS

When analyzing sensor systems, the Systems Engineering approach described in **Article 5, Humans in the Real World, Volume 1**; and **Article 14, Hierarchical Aspects of Measurement Systems, Volume 1**, can fruitfully be applied by combining the ideas of the boundary view of a measurement system and the information and energy tetrahedron as described in **Article 6, Substructure of Human–Machine Systems, Volume 1** to obtain Figure 1. This approach is consistent with that used in the application of the Systems Engineering boundary view to the measurement system described in **Article 68, Setting the System Boundaries, Volume 2**. The existence of intrinsic and extrinsic boundaries allows the discrimination between internally and externally arisen effects respectively. In this way, internally caused errors, which give rise to 'eigen' errors, or characteristic errors (Solopchenko, 1994), are noted to be qualitatively different from externally arising effects. From this boundary view, it can also be seen that inputs and outputs, which can be subdivided by energy form, can also be classified as within the resource, information, or contamination groups of boundary impacts.

Interfering influences – which arise from inside the sensor, are due to either parameter sensitivity or internal fundamental fluctuations. Parameter sensitivity is caused by the inexorable aging of all of the components that make up the sensor structure. Fundamental fluctuations occur as a result of equipartition of energy between the thermodynamic state and the states of the other energy forms. External interference is caused by disturbance power flows or by other forms of direct contamination. Highlighting the various sources of contaminating inputs provides a clear view of the limits on the ultimate resolution of a sensor in executing its primary function. In the case of sensor systems, the resource output is also the information output. It is the influence effects that make good design difficult to achieve.

2 SENSORS, TRANSDUCERS, AND MODIFIERS – TERMINOLOGY AND DEFINITIONS

Through the study of the various blocks used in routine practice, it has become clear that two prime kinds of energy

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

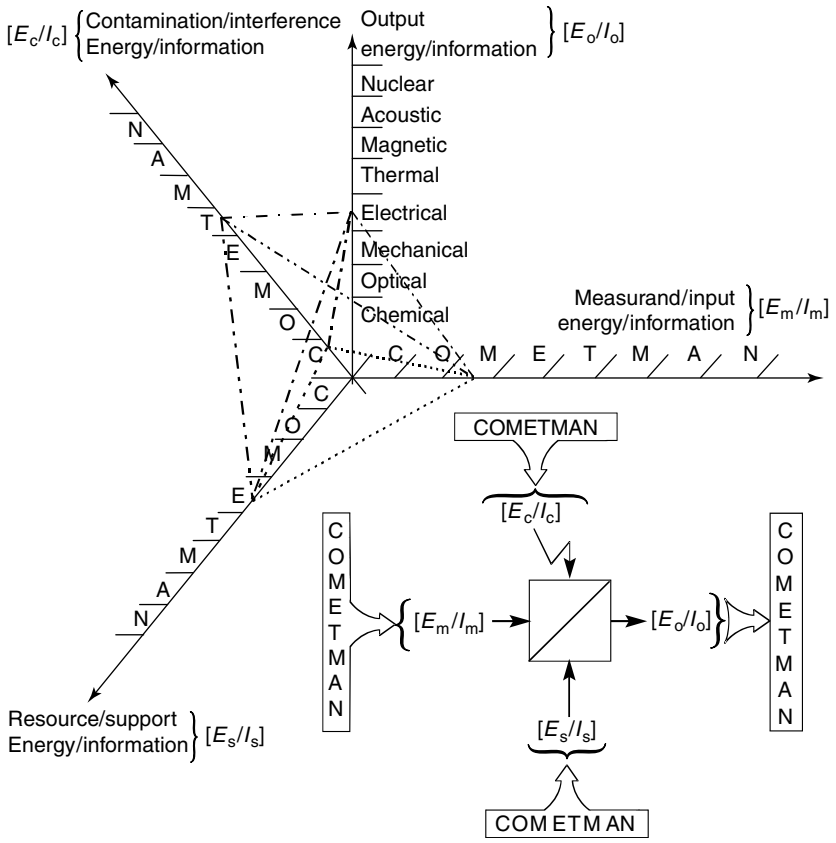

Figure 1. Boundary perspective of a sensor system and its influencing effects.

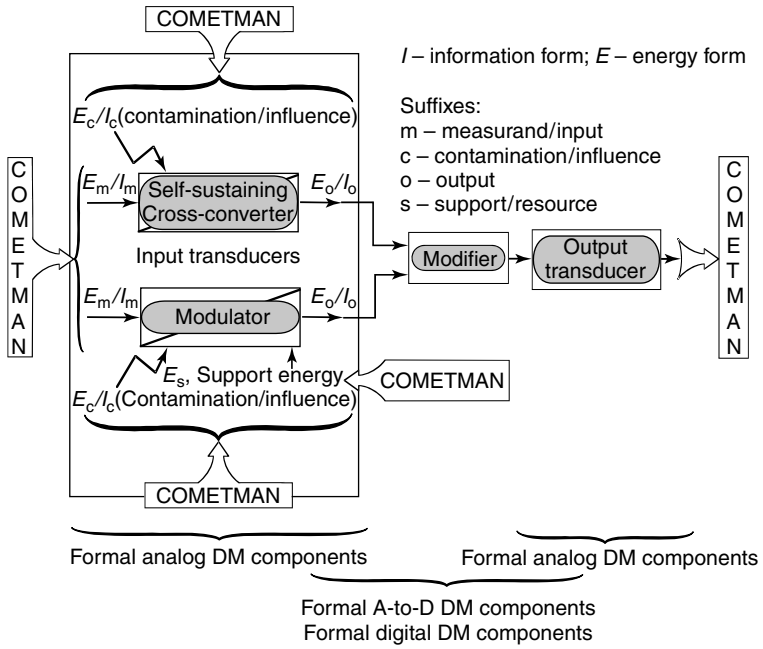

Figure 2. Functional block diagram of a basic instrumentation system illustrating modifier elements and input and output transducers.

handling operational structures are evident in instrumentation systems. Figure 2 illustrates the most basic structure of an instrumentation system made up of input and output transducers and modifiers (Middelhoek and Noorlag, 1981; Middelhoek and Hoogerwerf, 1986). The relationship between this structure and Formal Data Measurement Components, or FDMCs, outlined in **Article 14, Hierarchical Aspects of Measurement Systems, Volume 1**, is also given in this figure.

A transducer is a device that transforms the input signal of one energy form into an output of another energy form, doing so in such a way that a prescribed relationship is maintained between the input and the output signal.

A sensor is an input transducer involving the process of measuring those variables that characterize the flow of information and energy.

An example is the mercury-in-glass thermometer in which heat energy is converted into mechanical energy, forcing the mercury to move along the glass as it expands or contracts.

Another example is the bellows pressure sensor, where an increase in pressure causes the bellows to change its length.

The most commonly used sensors and transducers, which are especially suitable for automation and control purposes, use information carrying signals in the electrical energy form.

It is also important to distinguish between those sensors that do not require the supply of energy from any source other than the system under measurement, and those that do. The former are now commonly referred to as *self-generators* while the latter are referred to as *modulators*. They are also misleadingly referred to as *passive* and *active* respectively.

Self-supporting cross-converting transducers are energy converters, which do not require the supply of energy for support or excitation purposes.

Referring to this species of sensor as a self-generator does not really express the completeness of the functional energy transformation, which they perform. Hence, in some respects, calling this group of sensors self-generators could be viewed as incorrect. Strictly speaking, they should be regarded as converters of an input energy form to a different output energy form. For this reason, it would be of benefit if they were referred to by a name with a more incisive description than self-generators. Such a new name, which should preferably be short, should also clearly and unambiguously convey the idea that no auxiliary energy form is required to support the flow of information in the energy transduction process involved. McGhee *et al.* (1999) have proposed such a renaming, which attempts to express a complex phenomenon by a concise linguistic synonym. In making this renaming proposal, previous contributions to sensor modeling have been taken into account. Stein (1969), Middelhoek and Noorlag (1981) and Middelhoek and Hoogerwerf (1986) use the term *self-generators*. In other places, this group is also referred to as *passive* (Fraden, 1997) or *self-sustaining* (Areny and Webster, 1991).

All of these titles share common shortcomings associated with ambiguity and imprecision. To propose a replacement title, which conveys the important aspects previously stated, requires a clear view of the principles of sensing and the effects used in the sensing process.

Operating principles, including sensor effects, which have been described by Ylilammi (1989), Van Duyn and Middelhoek (1990) and Kwaaital (1993), represent a useful way of classifying sensors. From these principles, it is clear that self-supporting cross-converting sensors convert energy from one form at the input of the sensor to another different form at its output without the use of a supporting energy source. For this reason, they may be called *cross-converters*. However, since some types of modulating sensors also act as cross-converters, the use of the term cross-converter to describe a self-generator will lead to ambiguity. For this reason, McGhee *et al.* (1999) proposed that self-generators should be renamed as self-sustaining cross-converting sensors, or as self-sustaining cross-converters for short. It is likely that this description is probably the most concise but still an adequately complete description is possible.

Examples of self-sustaining cross-converters, misleadingly referred to as passive in various places, are

- the thermocouple, which generates a voltage proportional to input temperature;
- the photovoltaic cell, which gives an electrical output when exposed to light;
- the mercury-in-glass thermometer, whose mercury column expands when exposed to increasing temperature.

The other kind of sensor structure, which needs an excitation or auxiliary supply of energy for its operation, is called a *modulating type*. During their operation, the energy flow is modulated by the input measurand. They are also misleadingly classified as active. Examples of the modulating group of sensors are

- all resistance-based sensors, where electrical energy must be applied to allow the resistance to be measured;
- the photodiode, where a bias electrical current is provided by an electrical support energy source;
- the ultrasonic Doppler flow sensor where an acoustical interrogating energy form is modulated by the flow velocity.

It is recommended that the misleading reference to modulating sensors as active and the naming of self-supporting cross-converting sensors as passive should be avoided in sensor nomenclature. This position is adopted to remove any ambiguity that the terms introduce.

In contrast to other kinds of instrument subsystems, modifiers alter, or modify, the input energy form to give an output in the same energy form. They do not convert the energy to another form. An electronic filter, for instance, processes an electrical, or more commonly electronic, energy signal by modifying the distribution of the frequency content of the signal. It still provides an electrical energy output. Other examples of modifiers are electrical transformers, mechanical levers, and gearboxes, hydraulic rams, and heat exchangers.

Since this article is concerned with sensors, the reader is referred elsewhere for descriptions of modifiers and output transducers (Middelhoek and Noorlag, 1981; Middelhoek and Hoogerwerf, 1986).

3 REPRESENTING AN INSTRUMENT STAGE BY SIGNAL/ENERGY NOTATION

Figure 3(a, b) illustrates representative block diagrams for self-supporting cross-converting and modulating types of sensors with their input and output notation.

It is possible to write down the functional relationship between the signal/energy forms of the output, $[S_o/e_o]$, in Figure 3 in terms of the respective forms for the measurand, $[S_m/e_m]$, the support/resource, $[S_s/e_s]$, and the contamination/interference, $[S_c/e_c]$, inputs. Hence, in the case of a modulating sensor, the functional relationship between the output Signal/Energy form and the three inputs as shown in Figure 3 can be written as

$$\left[\frac{S_o}{e_o}\right] = f\left(\left[\frac{S_m}{e_m}\right], \left[\frac{S_s}{e_s}\right], \left[\frac{S_c}{e_c}\right]\right) \qquad (1)$$

In the case of a self-sustaining cross-converter, there is no support energy. Under these conditions, (1) can be rewritten in the form

$$\left[\frac{S_o}{e_o}\right] = f\left(\left[\frac{S_m}{e_m}\right], \left[\frac{O_{S_s}}{O_{e_s}}\right], \left[\frac{S_c}{e_c}\right]\right) \qquad (2)$$

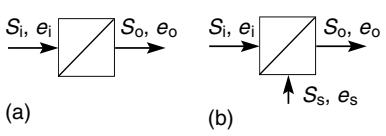

Figure 3. Block diagram and notation for the two types of sensors: (a) self-supporting cross-converting sensors and (b) modulating sensors.

where the term $[O_{S_s}/O_{e_s}]$ indicates that there is no support signal/energy form for self-sustaining cross-converter sensors.

4 CLASSIFICATION OF TRANSDUCERS BY INFORMATION AND ENERGY

Classification in sensing and transduction follows the same general route outlined in **Article 2, Organization of Instrument Science, Volume 1**. This scientific approach to grouping uses the four main orders or problems of classification to assist in the ordering.

In the First Order, known as *Generality or Resemblance*, the question of those relations describing likeness between sensors is considered.

Sensors and transducers must also be grouped on the basis of the Second Problem or Order of taxonomy, which is concerned with their Composition or Collectivity.

While this order is concerned with the relationship of the parts or elements of a sensor system to the whole system and vice versa, the Third Order of classification, called *Hierarchy*, when applied to sensors and transducers, takes account of the relation of rank between the heads or central members of the constituent groups of the elements comprising sensor systems.

These should then be related in the order of composition. In this process, the place occupied by each concrete sensor is assessed in every order relative to other sensors making up both the same order and different orders. Thus, the uniqueness of each sensor in the ordering is distinguished by its similarity with and difference from every other sensor.

Perhaps the most important Fourth Order in the classification of sensors hinges upon the notions of kinship through the relations describing ascent, descent, and collaterality.

As with the orders of Composition and Hierarchy, the last problem of classification just described, which is also known as *Genealogy and Evolution* in the biosciences, is also concerned with the actual sensors to be classified.

These latter orders, when applied for sensor systems, emphasize the importance of a functional and structural hierarchy.

Taxonomy in Sensor Science may thus be regarded as possessing the six main features of its objectives and functions, its materials and activities, together with the methods of discrimination used and hierarchical ordering (**Article 2, Organization of Instrument Science, Volume 1**).

Taxonomy is useful for proving the newness claimed for new sensors. It places a sensing stage into a set position on the basis of its properties. If sensors were so classified, it would show up those that are actually of the same type –

yet appear as a new kind. Too many sensors are constantly being reinvented for lack of knowledge that one already has been reported of the same kind.

5 THE CLASSIFICATION OF ENERGY

Consistent with the previously described orders of classification, it can be seen that the appropriate grouping of sensors must be on the basis of function, structure, information/energy form, and signal output. A good way of grouping transducers uses the transduction principle involved, and the form of the measurand, as shown in Table 1.

Kurt Lion (1969) produced such a classification similar to that in Table 1. In this classification, it is possible to relate the physical effect in the energy domain of the measurand, which allows a transduction into another energy form. Thus, a resistance transducer for measuring displacement is classified as a resistance displacement transducer. Other classification examples are a pressure bellows or a force diaphragm. Notice that all of the diagonal entries in this table correspond to modifiers as defined above.

Questions about energy and information, which are highly relevant in measurement systems, are of fundamental importance and of immediate interest in this article. Energy may be considered on either a macroscopic or microscopic level. There are a number of different, equally valid ways of classifying energy.

To understand the overall classification of energy, it is important to realize that there is a general tendency in physics to represent the largest number of phenomena by the smallest number of models (McGhee *et al*., 1999, 2001).

Physical considerations lead to the classification of gravitation, atomic, magnetic, and electric as possibly being the most representative, irreducible groups.

The energy acronym **GAME**, shown in Table 2, gives a convenient shorthand for these four basic energy forms. Because they lie at the top of the hierarchical grouping of energy domains, they are not very informative from the point of view of either physics or measurement systems.

The GAME energy domains can also be written as the expanded subdomains also given in Table 2. Each of these subdomains is associated with at least one characterizing physical phenomenon. The subdomains of the gravitation and atomic groups of energy forms can be seen to be similar.

Differentiation between both groups is made on the basis of distinguishing potential energy characteristics and kinetic energy manifestations.

Table 1. Examples of transducers and their logical grouping for different input and output signals.

OUT \ IN	Radiation	Mechanical	Thermal	Electrical	Magnetic	Chemical
Radiation	Geometric-optical system filter	Interferometer; Photoelastic transducer	Thermal radiation transducer	Kerr cell; Electro-luminescent transducer, LED	Faraday cell	Transducer based on emission & absorption spectroscopy
Mechanical	Crooke's radiometer; Radiation pressure system	Gravity balance; Ballistic pendulum; Bellows; Gear box	Thermometers; Bimetallic strip; Dilatation thermometer	Electrometer; Electrostrictive transducer; Piezoelectric transducer	Magnetometer; Magnetostriction transducer	Hydrometer; Electrodeposition cell
Thermal	Bolometer	Adiabatic system; Friction calorimeter	Mixing calorimeter; Heat exchanger	Thermal converter	Eddy-current transducer	Combustion calorimeter
Electrical	Photoelectric, Photoresistive & Photogalvanic cells; Photodiode	Resistive; Inductive; Capacitive; Piezo resistor	Thermistor; Thermoelement; Seebeck effect	Transformers; Langmuir probe; Charge collectors; Transistor	Magnetoresistance; Hall-effect transducer	Transducers based on potentiometry, conductimetry, polarography; pH-meter
Magnetic	Curie-effect radiation meter	Magnetoelastic transducer	Paramagnetic transducer device	Electromagnetic transducer; Coil	Magnetic recorder	Magnetic resonance system
Chemical	Photographic emulsion	Ultrasonic chemical transducer	Thermal dye indicators	Electrolytic integrator; Electrical plating	Paramagnetic oxygen analyzer	Chemical system modifiers

Table 2. A conventional classification scheme for energy forms.

Energy forms			
Physics (GAME acronym)	Expanded physical forms	Sensor measurement forms	Characteristic physical phenomenon
Gravitation	Gravitational		Attraction between masses
	Mechanical	Mechanical	Mass in motion has equivalent energy forces, displacements
Atomic	Nuclear	Chemical	Binding energy within nuclei
	Atomic		Binding energy of nuclei and electrons
	Molecular		Bond energy of atoms in molecules
	Thermal	Thermal	Kinetic energy of molecules
Magnetic	Magnetic	Magnetic	Magnetic fields
Electric	Electric	Electrical	Electric fields, potentials and currents
	Electromagnetic radiation	Radiation	Radio waves, through UV to X-, γ-and cosmic rays

The gravitational subgroup is connected with natural forces of attraction between masses.

In a similar way, the bonding energy within nuclei, within atoms and within molecules is also connected with natural forces of attraction but on a microscopic scale. Atomic forces can also be repulsive. This contrasts with the macroscopic scale of gravitational attraction.

Mechanical forces, which are associated with physical motion, cause kinetic energy effects.

The classification of energy using the GAME acronym and its expanded groups may be regarded as the most precise, since the grouping results from the application of the formal principles of taxonomy. It provides an entirely consistent physical view.

Van Dijck (1964) describes another way of grouping energy forms by extracting six from the extended group of nine of the GAME acronym. This abbreviated group of six, which can be identified as being of particular relevance to measurement systems (McGhee *et al*., 1996, 1999, 2001), are called *sensor and measurement energy forms*, in Table 2. These six have been used previously in classifying instrument systems.

This group of six energy forms, used by Kurt Lion (1969) and Middelhoek and coworkers (1981, 1986), are

1. radiant energy,
2. mechanical energy,
3. thermal energy,
4. electrical energy,
5. magnetic energy, and
6. chemical energy.

Gravitational energy, which appears to be unimportant here, is grouped within the mechanical energy form since mechanical variables are more important in measurement.

All of the microscopic potential energy forms are grouped together within the domain of chemical energy. The separation of thermal from the other atomic forms of energy is due to its kinetic energy aspects.

The magnetic form is self explanatory due to its particular manifestation.

Electric circuit variables are distinguished from the entire radiation group.

Although the grouping of energy by the forms in Table 2 is perfectly acceptable, the individual groups are not easily remembered. For this reason, the method used in this article recalls the organization of energy classification given by Peter Stein (1969) in his presentation of the transducer space.

His scheme of energy classification grew from his wide experience as a teacher of measurement and instrumentation. He perceived that the sensor measurement grouping of energy forms given in Table 2, although very close to the central heads of the GAME grouping are not easily remembered. Thus, arose his scheme for classifying energy forms using the memory-aiding (energy acronym COMETMAN, which is summarized in Table 3 (McGhee *et al*., 1999, 2001).

The second column of Table 3 provides the cross-link between it and Table 2. Whereas the previous methods of classification are based upon rigidly linking the energy by similarity, COMETMAN is specifically formulated as a memory aid.

The acronym arises from classifying by Chemical (i.e. molecular), Optical (i.e. radiation), Mechanical (i.e. including gravitation and mass), Electrical (i.e. both electric circuit forms and electromagnetic radiation), Thermal, Magnetic (i.e. including electrical and atomic forms), Acoustic (i.e. correctly speaking within the mechanical group) and Nuclear (i.e. strictly speaking within the atomic group) energy forms.

Once again, the important point to emphasize here is not whether one form of classification is more correct than

Table 3. A classification scheme for energy forms based upon the COMETMAN acronym.

Energy forms			
Modified acronym COMETMAN	Expanded physical forms (GAME acronym)	Physical variables	Human senses
Chemical	Molecular (**A**tomic)	Concentration, reaction rate, redox potential, biological properties, clinical analysis	Smell, Taste
Optical	Electromagnetic radiation (**E**lectric)	Intensity, phase, wavelength, amplitude, transmittance, polarization	Sight
Mechanical	Mechanical (**G**ravitation)	Position, velocity, acceleration, mass, density, force, stress, pressure, moment, torque, shape, roughness, orientation, viscosity	Touch
Electrical	Electric (**E**lectric)	Current, voltage, resistance, inductance, capacitance, permittivity	Pain sensors or nociceptors
Thermal	Thermal (**A**tomic)	Heat flux, temperature, thermal conductivity, thermal capacitance, specific heat, expansion	Touch and sight
Magnetic	Magnetic (**M**agnetic)	Field strength, magnetic moment, permeability, flux density	None
Acoustic	Mechanical (**G**ravitation)	Sound pressure	Hearing
Nuclear	Nuclear, atomic (**A**tomic)		Nociceptors

another. It is the convenience of the most easily remembered grouping that tends to be used, for convenience is an important ingredient in any scheme of classification (Thomson, 1911).

In this classification of energy form, the optical form is extracted from the radiation group, the acoustic from the mechanical group, and the nuclear from the atomic/chemical group, to allow the formation of the acronym.

The inputs of a sensor system then become the energy and information form of the input, the resource energy form, supporting the flow of information, and the energy and information form of the contamination. Thus, the resource and contamination classes have a possible total of eight energy form inputs each.

6 SPATIAL MODELING OF TRANSDUCERS AND SENSORS

Sensor systems have been clearly placed within human–machine supersystems (**Article 5, Humans in the Real World, Volume 1**). This allows sensor systems to be introduced as information machines for measurement (**Article 107, Principles of Sensor Science, Volume 2**) where the importance of sensors in the overall view of measurement was also emphasized. The importance of the boundary view of systems, and consequently of sensor systems, including the concepts of extrinsic and intrinsic sources of interference is highlighted in **Article 68, Setting the System Boundaries, Volume 2**. These sources of interference and their discrimination are essential in fulfilling the primary aim of measurement as stated by Solopchenko (1994). This primary aim is '... taking account of errors, their sources and their quantification ...'. This article describes a spatial tetrahedron method for modeling and for predicting the possible energy sources of interfering effects. Errors are covered in depth in **Article 48, Common Sources of Errors in Measurement Systems, Volume 1**; **Article 49, General Characterization of Systematic and Stochastic Errors, Volume 1**; **Article 50, Errors in Signal Systems, Volume 1**; **Article 51, Errors in Digital Signal Systems, Volume 1**; **Article 52, Error Models, Error Budgets and their Calculation, Volume 1**; **Article 53, Calculation and Treatment of Errors, Volume 1**; **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**; and **Article 55, Uncertainty Determination, Volume 1**.

A complete spatial representation for the boundary inputs and outputs of a generalized sensor system requires a multidimensional space. As the boundary view of human–machine supersystems reveals (**Article 6, Substructure of Human–Machine Systems, Volume 1**; McGhee *et al.*, 1996; Sandquist, 1985), there is a total of three groups of inputs and three groups of outputs. Hence, the representation becomes too complex for graphical illustration on a two-dimensional paper surface. Previously, Kurt Lion (1969), Peter Stein (1969) and Middelhoek and coworkers 1986, 1981) and McGhee *et al*. (1999, 2001) realized this requirement.

Lion formulated the most basic spatial model by concentrating on the input/output relations already outlined

in Table 1. A highly complex space is immediately reduced to a two-dimensional problem.

Although this model does not include either the support energy inputs or the interference inputs, it is still a convenient starting point for focusing upon transduction as an energy transforming operation. Each one of the input and output groups may be specified as information-bearing signals or energy flowing forms.

Stein (1969) extended the two-dimensional representation of Lion to three dimensions using what he called the *transducer space*. This uses a three-space to illustrate sensing and transduction. Adding a third axis to represent the range of possible support energy forms resulted in a three-dimensional Cartesian space. Each of the axes in this space uses the *COMETMAN* energy form classification. Some time later, Middelhoek and coworkers used the sensor measurement forms of energy classification of Table 2 in the three-space sensor effect cube. A detailed description of spatial transducer modeling is given later in this article.

The 3-D transducer space has one significant disadvantage. In this diagram, no account is taken of contaminating inputs. Consequently, the influence of interference from whatever source is not transparent. A spatial representation for the boundary inputs and outputs of a sensor system, in its most general form, requires a multidimensional space. Any spatial representation, which does not take all inputs and outputs into consideration, has serious shortcomings.

As there is a total of three groups of inputs and three groups of outputs, the representation becomes very complex for graphical illustration on paper surfaces. In spite of this, McGhee *et al*. (1999) extended the transducer space using the concept of the sensor effect tetrahedron, which is also described in some detail later in this article. This model is an adaptation of the information and energy tetrahedron used in system modeling (**Article 6, Substructure of Human–Machine Systems, Volume 1**; McGhee *et al*., 1996, 2001).

Other contributors in the field of measurement have also realized the importance of spatial modeling for simplifying the complex problems of classification in sensors such as in the case of optical sensors. Initial attempts which give good basic insight into optical sensor classification, utilized the three-dimensional structure of the transducer space and the sensor effect cube but named the axes of the representation differently. Subsequently, a more rigorous analysis gave an expanded classification called the *Tri-Angular Pyramid Sensor Representation*, or TAPSER, scheme (El-Hami *et al*., 1993).

The sensor effect tetrahedron, which is described below, is an appropriate combination of the transducer space/sensor effect cube, but using the COMETMAN energy classification, and the multifaced objects from the TAPSER space.

7 THE TRANSDUCER SPACE

It is possible to use the COMETMAN classification of energy to visualize the wide range of possible input and output transducers. To develop this approach, it is necessary to realize that any modulating sensor can be represented by the energy/signal notation in the [*x, y, z*] space, where the measurand energy form, x, modulates the support energy form, z, to produce a variation in the output energy form, y, bearing some relationship to the measurand energy form, x. This model is represented mathematically by

$$y = f(x, y) \tag{3}$$

The representation described by (3) can be drawn in a pseudoisometric view on a two-dimensional page as shown in Figure 4.

Each of the axes in this space is labeled along its length with the COMETMAN acronym to give a three-dimensional, or three-space, energy, and/or signal form of the inputs and outputs. In this way, the space can now provide an aid in understanding the interacting relationship between the support energy form and the input and output information carrying signals in their range of possible energy forms. This is now the three-dimensional transducer space, as it was called by Peter Stein, representing the input signal in its energy form along the conventional x-axis, the support energy form along the conventional z-axis and the output energy along the conventional y-axis as shown in Figure 3. Two examples are used to illustrate the use of the transducer space for modeling energy/information flow in sensors and transducers.

Two examples illustrate the application of Figure 4. The first example uses self-supporting cross-converters, called *self-generating transducers* by many other sensor scientists, and modifiers, which operate without an auxiliary energy source. They are represented in the vertical x-y plane.

Consider, for example, the thermocouple. Thermal information flows from the thermal energy input on the x-axis to the information output on the y-axis transduced to the electrical energy form. The appropriate block diagram also appears in Figure 4.

Modulating types of sensors, as the second example, can be shown in the $[x, y, z]$ Cartesian transducer space in Figure 4 depending upon which support energy source is used.

For example, a photoconductance sensor would have its input information at $x =$ Optical, its output at $y =$ Electrical and its support energy at $z =$ Electrical. The radiating optical input energy incident upon the sensor modulates the flow of electrical energy from the support energy port to the output energy port. For this reason,

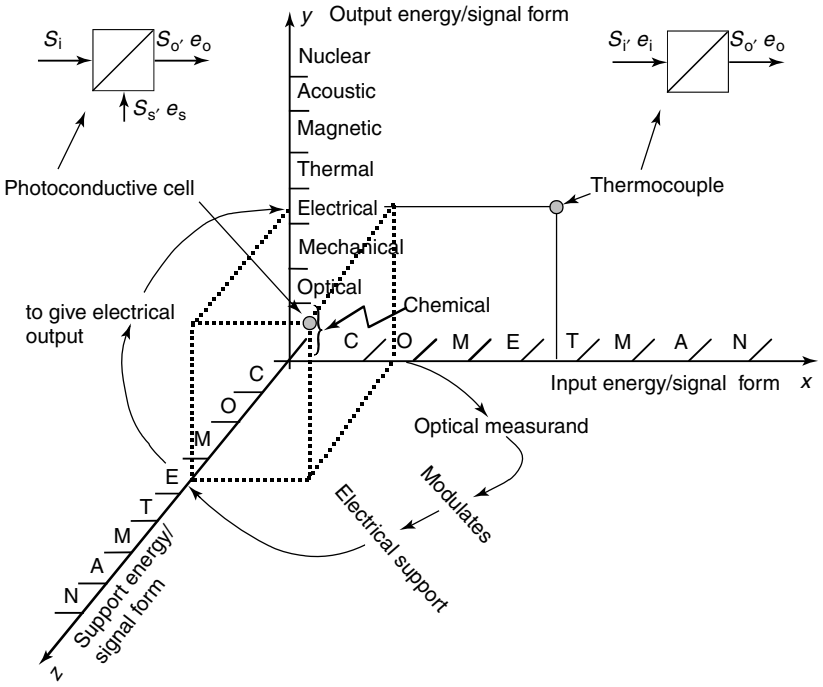

Figure 4. The transducer space – a three-dimensional (three)-space for transducers by energy/information.

modulating sensors of this type bring the advantage of much higher power gain to measurement systems than do self-supporting cross-converters.

The energy/information space diagram, which may also be interpreted as a signal/energy space, allows the prediction or visualization of transducer possibilities. It is clear that there are numerous different possibilities as feasible candidates, when proposing a transduction principle to meet a sensing need. While all known possible combinations of input, output, and support energy forms can be located in this 3-D representation, there are still many positions where practical devices have not been proposed so far.

In accordance with Figure 3, it can be seen from the block diagrams at the top of Figure 4 that any instrument system building block, has three possibilities on inputs and outputs. The self-supporting cross-converting sensor has an input signal, S_m, with its associated input self-supporting or excitation energy, e_m. At the same time its output signal is S_o, and output energy e_o. The difference between the self-supporting and modulating types of cross-converters is a matter of how e_m is supplied to the system as shown in Figure 4.

In self-supporting cross-converting sensors, the system under measurement supports the information flow by supplying energy to the sensor. Modulating sensors, which extract negligible energy from the system under measurement, modulate the support energy input. The energy symbol, e_m, is removed to indicate that negligible energy is drawn from the system under measurement. Inserting the energy symbol, e_S, in the diagram models the effect of modulation of e_S by S_m.

8 THE SENSOR EFFECT TETRAHEDRON FOR MODULATING SENSORS

Starting from the boundary limit viewpoint of a sensor system given in Figures 1, 2 and 3, it is possible to represent a sensor and a transducer effect space, which is more complex than that proposed by either Lion (1969), Stein (1969) or Middelhoek and his coworkers (1981, 1986), but is still useful. In a sensor system, the main output is an information output, which also corresponds to the resource output.

Contamination is also produced at the output. This contamination is the information output when there is cross-coupling into some other information-bearing channel.

It is clear that the output of a sensor system may be regarded as either the resource output, the information output, or even a contaminating source.

Although it is essential to design any system so that the contamination it produces is negligible, this question will not be considered further for the present purposes. Hence, the output energy/information form for a sensor system is given more emphasis in this figure than the contamination produced by the sensor system.

The proposed representation consists of one axis normal to a base plane as shown in Figure 5. Along the base plane of this spatial representation introduce a topological

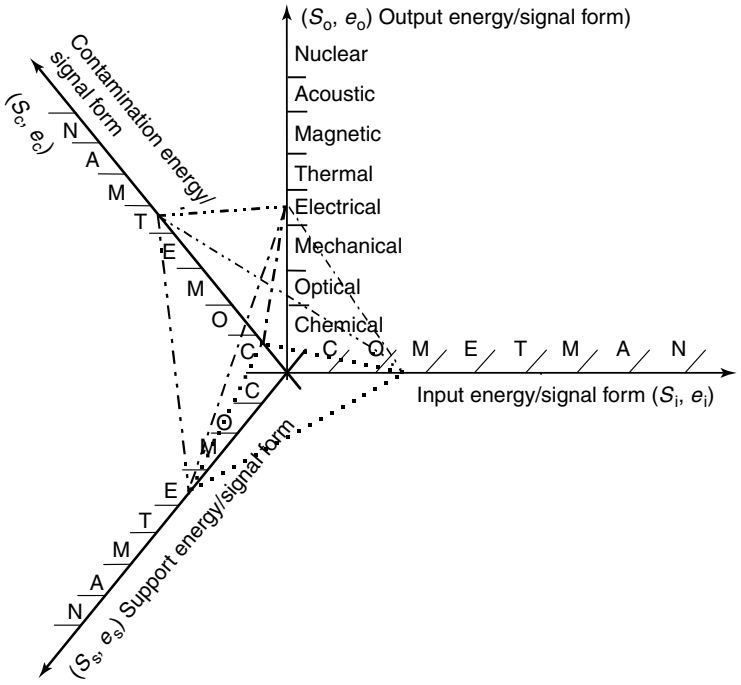

Figure 5. The information and energy tetrahedron for a modulating sensor.

grouping consisting of three axes set mutually at 120° spacing. Each of these axes, taken as representing one of the three input groups with their COMETMAN information or energy classification, clarifies, and justifies the way in which the acronym aids memory. The organization of the three axes on this base plane is a collapsed, two-dimensional representation of the input three-space consisting of the information, resource, and contamination inputs.

This organization of inputs may be regarded further as the input triangle. Such a name is appropriate as illustrated by the input triangle given by the dotted lines in Figure 5. Here, the support energy form is electrical, the contamination energy/information form is chemical, and the measurand energy form is mechanical using a sensor like a resistance strain gauge.

A strain gauge, which measures a mechanical energy domain variable, has been chosen as a typical, but not exclusive, example. It is straightforward to represent resistance transducers for variables in other measurand energy domains. The chemical contamination could be responsible for parasitic electrochemical potentials at the contacts in the electrical circuit.

Each point on the input triangle axes may be joined to an energy/information form on the output axis. When the output is in the form of an information-bearing electrical energy form, the dash-dot line combinations shown in Figure 5 allow the link between all three input forms and the output form to be clearly seen. The geometrical shape, which is outlined by the dotted and the dash-dot lines, has one base plane surface and three inclined surfaces. This represents a tetrahedron or four-faced object. This way of representing the boundary impacts on sensor systems may be called the *information/energy tetrahedron* or the *sensor/transducer effect tetrahedron*.

Illustration of the manner in which the contamination inputs influence the output may be extended to cover contamination from other energy forms. The dot-dot-dash lines in Figure 5 show the case when the contaminating energy form is due to the influence of temperature on the wire of the strain gauge. The deep perception allowed by the sensor/transducer effect tetrahedron given in Figure 5, which is fairly straightforward, is still realistic and comprehensive.

It is quite important to note that the sensor effect tetrahedron extends the transducer space by including the possibility for predicting the energy forms of the various contaminating sources that may be present.

McGhee *et al*. (1999) illustrate the application of the sensor effect tetrahedron to a modulating photodiode, a modulating ultrasonic Doppler flow sensor and self-supporting cross-converting thermocouples.

9 THE SENSOR EFFECT TETRAHEDRON FOR SELF-SUPPORTING CROSS-CONVERTING SENSORS

So far the conditions in Figure 5 correspond to the case of modulating types of sensors and transducers.

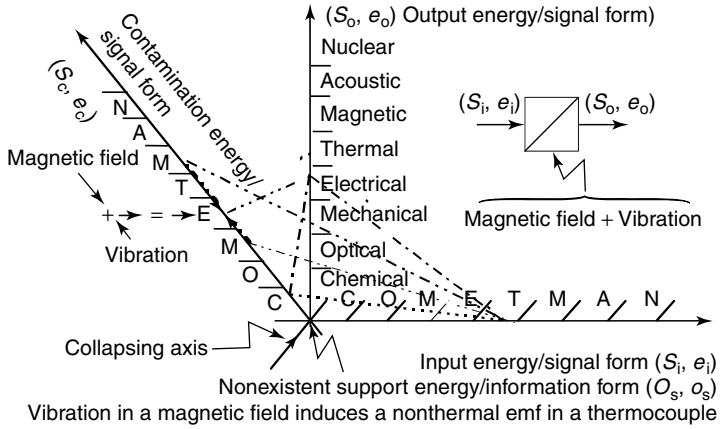

Figure 6. The sensor effect tetrahedron for self-supporting cross-converting sensors using a thermocouple as an example.

Self-supporting cross-converting sensor possibilities may also be represented by the sensor/transducer effect tetrahedron as shown in Figure 6 using a thermocouple for illustrative purposes. In self-supporting cross-converting sensors, there is no support energy form. Consequently, the support energy axis of the input triangle collapses to the origin of the system of axes in the tetrahedron. This origin, usually representing the number *zero* in a numerical space, may be regarded as the point defining the nonexistence of a support information/energy form. Under these conditions, (2) is the mathematical representation for the sensor.

The case for the sensor effect tetrahedron representation of a thermocouple is illustrated in Figure 6 for two types of interference/contamination sources. The chemical interference shown may give rise to a series mode parasitic electrochemical emf in the electrical circuit of the thermocouple as in the previous example for the modulating sensor. A situation illustrating the interaction of different energy forms to produce a propagated contaminating signal is also shown in Figure 6.

If the thermocouple sensor assembly, including its lead wires, are mounted on a structure that is vibrating in an electromagnetic field, the sensor effect tetrahedron allows the possibility of an induced series mode interfering electrical signal to be predicted and visualized. The powerful predictive property of the sensor effect tetrahedron is well illustrated by this example.

The representation of self-supporting cross-converting sensors and transducers shown in Figure 6 may be called the *self-supporting sensor tetrahedron*.

This model of a collapsing four-space may also be viewed as forming a three-space model, when the input and contaminating axes are drawn mutually perpendicular. This is analogous to the effect, which occurs in Stein's transducer space for self-supporting cross-converting sensors given in Figure 4. Whereas this transducer space collapses to a plane, or two-space, from a three-space or 3-D space, in the case of self-supporting cross-converting transducers, the sensor effect tetrahedron collapses to a three-space for the same kind of sensor. The different results of the collapsing are due to the fact that the sensor effect tetrahedron represents the input information/energy groupings using the idea of the input triangle illustrated in Figures 5 and 6 with the added transparency resulting from the inclusion of the interfering energy source forms.

1 PRINCIPLES OF SIGNAL/ENERGY MATRIX MODELING

The basic ideas of classification in sensors and transducers allow a visualization of the diverse possibilities for realizing measuring functions.

Another very important aid in visualizing how the energy and signal are transduced uses the concept of a signal/energy flow matrix (Middelhoek and Noorlag, 1981).

Figure 1 illustrates this for two different kinds of temperature sensors. One of these is a mercury-in-glass thermometer and another is a modern digital thermometer.

The fundamental block diagram representation of input and output sensing/transducing elements and modifying elements, shown in Figure 2 of **Article 109, Structure and Energy in Sensor Systems, Volume 2**, is used to construct the matrix shown in Figure 1. Above this block diagram in Figure 1, is a matrix of rows and columns with the left-hand column indicating the COMETMAN classification scheme for input energy/signal form. The energy domain of the temperature input signal is, of course, the thermal domain.

Consider first when the sensor is a mercury-in-glass thermometer. The input transduction process transforms the thermal energy into mechanical energy, due to the cubic expansion of the mercury in the bulb of the thermometer. This expansion is propagated through the thermometric fluid, the mercury, by modifying the original mechanical cubic expansion into a change in the length of the mercury column. This column length belongs to the group of mechanical variables.

Radiation, which is incident upon the column, is modulated by the reflective, refractive, and absorptive properties of the mercury column so that the human eye perceives the change in length. This perception is by a noncontacting form of sensing through the 108 videceptors in the human sense of seeing, which are mentioned with the other human senses in Figure 2 of **Article 5, Humans in the Real World, Volume 1**.

If the thermometer is a digital electronic unit, the thermal energy is transduced to the electrical domain using a suitable electrical temperature sensor, which could be any one within the contacting group in the classification of temperature sensors. Modification of the electrical energy at the electrical output port of resistive sensors could use a Wheatstone bridge circuit.

Further modification could be performed with an electronic instrumentation amplifier. Subsequently, the analog signal at the output of the instrumentation amplifier is converted to a digital form using an analog-to-digital converter, or ADC. The digital output of the ADC is then encoded and applied to a light emitting diode, or LED. The LED is a photon generator since it transduces its digital electrical input signal to visible radiation at its output.

It is also worthwhile illustrating the application of the signal/energy matrix model of sensors using two other

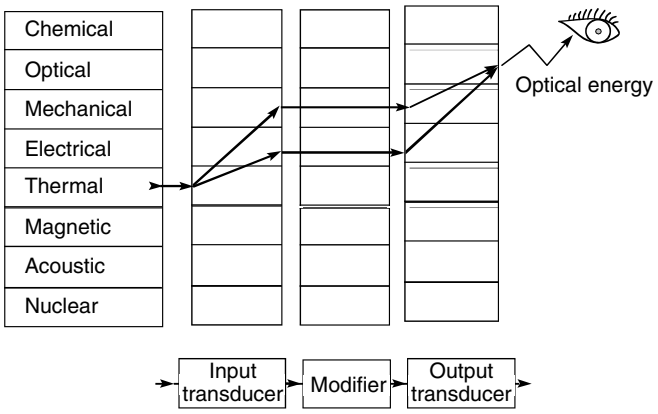

Figure 1. Generalized but simplified energy regime for a mercury-in-glass thermometer and a modern digital thermometer.

examples, which will be presented as case studies. The first example illustrates two methods of measuring mechanical torque, while the second demonstrates two different transduction principles for level measurement.

2 CASE STUDIES IN SIGNAL/MATRIX MODELING OF SENSORS – SHAFT TORQUE MEASUREMENT

The instantaneous value of axial torque on a shaft is to be measured and displayed using an appropriate method. Simultaneously, storage of the measured torque signal is required on a computer diskette or magnetic tape for further analysis and processing. Only two methods of measuring torque will be considered in the proposed design. In the first method, a bonded strain gauge is to be used as the sensor, while in the second an optical method is recommended.

The block diagrams of two torque-measuring instruments are given in Figures 2 and 3. In Figure 2, strain gauges are used to sense changes in applied mechanical force by transducing mechanical force to electrical resistance.

To measure axial torque, a rosette of strain gauges (McGhee *et al*., 1996) should be bonded to the shaft under measurement. Mechanical torque is converted into strain on the shaft surface. The strain gauges bonded to the shaft at angles of 45° to the perpendicular, are under strain. Two of them are under tension and two are under compression. The strain gauges both change their dimension depending upon changes in the forces on the shaft surface.

Dimensional changes are transduced to changes in the resistance of the strain gauges. These resistance variations are then measured, after suitable conditioning, by applying a Wheatstone bridge. The output of the bridge is amplified, converted into a digital signal in an ADC, whose output is fed to a driver for an LED or an LCD display element. The LED operates on the principle of optical photon generation.

In the case of the LCD (liquid crystal display), the electrical input modulates the structure of the liquid crystal whose orientation acts as a modulator of ambient photons. Recording on computer disk or magnetic tape is a transduction from the electrical energy form to the magnetic energy form. The block diagram of the whole instrument is also shown in Figure 2. As an exercise, the reader should write a short description of the energy transductions and signal flows that are shown in Figure 2.

In the optical method of torque measurement represented in Figure 3, the principle of optical modulation is proposed

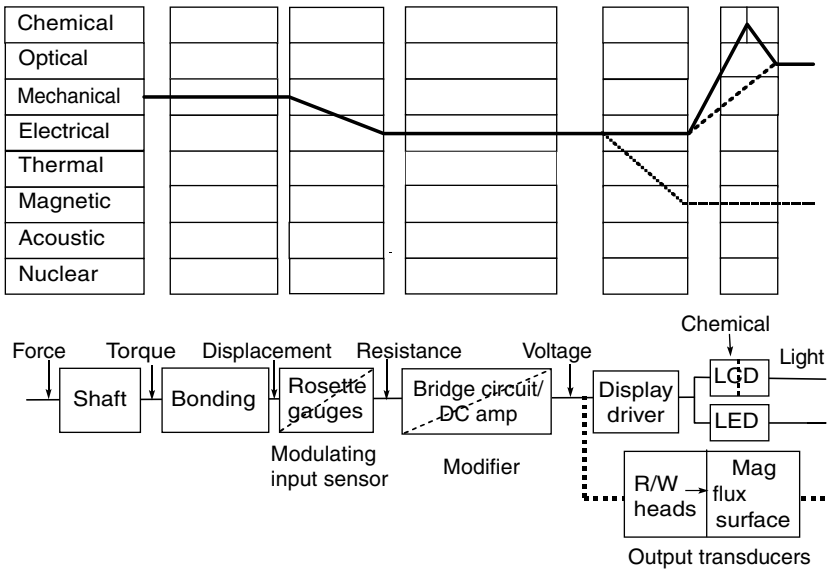

Figure 2. The signal/energy domain matrix and block diagram of a proposed method for axial torque measurement using strain gauges.

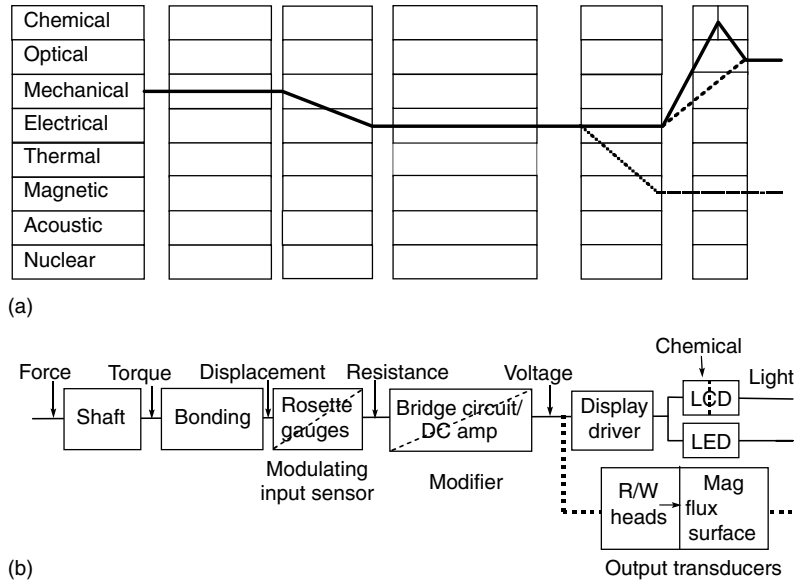

Figure 3. (a) The signal/energy domain matrix and (b) block diagram of a proposed method for axial torque measurement using torque to modulate a light beam.

as a suitable solution. Two rotating circular vanes, each having a regular array of small holes at a fixed radius from their centers, are attached to a shaft with a separation of l mm between them. Light sources are attached adjacent to the outside face of one vane. An array of stationary photodetectors is mounted alongside the outside of the other vane.

The light from the sources passes through the holes in the first vane. If the second vane is aligned properly, there will be a maximum amount of light incident on the photodetectors. When a torque is applied to the shaft, misalignment of the arrays of holes in the vanes will occur. This misalignment causes a reduction in the light that is incident on the photodetectors. The applied shaft torque, a rotary mechanical energy form, modulates the amount of light that is incident upon the photodetectors.

3 CASE STUDIES IN SIGNAL/ENERGY MODELING – LEVEL MEASUREMENT

It is required to measure the level of fluid in a container, to display the measured value, and to record it upon either

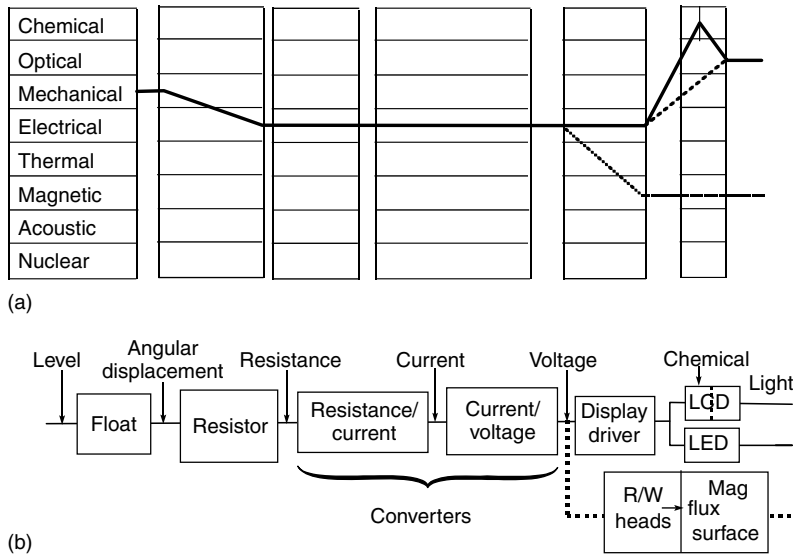

Figure 4. (a) The signal/energy domain matrix and (b) block diagram of a proposed method for level measurement using a float and a rotary potentiometer.

a magnetic diskette or a magnetic tape. The signal/energy domain flow diagrams and block diagrams are shown for each respective system in Figures 4 and 5. Since it is essential to have some primary sensing element to transduce the level, both the proposed methods of level measurement use a float as a primary sensing element. The first also uses a rotary potentiometer and the second uses a linear variable differential transformer (LVDT). As the schematics are quite explanatory, it is left to the reader to complete a written description of both – the matrix and the block diagram.

Further explanations of the method are given in Sydenham, Hancock and Thorn (1992).

1 NEED FOR CLASSIFICATION OF SENSORS

New ideas for sensors are constantly being invented – and reinvented. This is not efficient for in many cases the knowledge on a particular sensor form is already available and is redeveloped instead of being advanced with each new application and experience.

With the existence of hundreds of potential transduction principles, and numerous ways in which they can be implemented, it is possible to form thousands of sensor forms that are often little different to others yet to the new inventor, seem novel and a contribution.

For example, a simple electrical strain gauge mounted on a thin circular diaphragm can be used to measure many variables. Table 1 lists many of the methods used.

What is needed is a universal way to classify sensors as this assists retrieval of information regarding their existence, reveals new combinations, and links potential users to deeper knowledge about them.

In the life sciences, classification and taxonomy has been a key branch of scholarship for centuries. It was needed to assist understanding of the myriad of living objects. With respect to sensors, however, there has not been much attention paid to setting up a serious universal classification schema. This article outlines the main approaches that can be taken – the energy classification that has a universal application but does not cover the form of sensors, and how temperature sensors have been classified as an example of a species taxonomy.

2 CLASSIFICATION RULES IN GENERAL

Classification in sensing and transduction follows the scientific approach for grouping objects using the four main orders of classification to assist in the ordering.

In the First Order, known as Generality or Resemblance, the question of those relations describing likeness between sensors is considered.

Sensors and transducers must also be grouped on the basis of the Second Problem or Order of taxonomy, which is concerned with their Composition or Collectivity.

While this order is concerned with the relationship of the parts or elements of a sensor system to the whole system and vice versa, the Third Order of classification, called *hierarchy*, when applied to sensors and transducers,

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

Table 1. Use of simple instrumented diaphragm to measure different measurands.

Sensor	Method of using the diaphragm
Pressure gauge	Strain gauge on round diaphragm in sealed chamber under pressure
Small deflection meter	Diaphragm used with pin resting on it to deflect diaphragm
Sound pressure meter	Sensitive form of pressure gauge above with large cone connected to the diaphragm
Volume sensor	Chamber with pressure diaphragm at bottom measuring force exerted by height of fluid or solid material
Accelerometer	Flexibility of diaphragm with added mass forms seismic system
Level sensor	Chamber with pressure diaphragm at bottom measuring force exerted by height of fluid or solid material

takes account of the relation of rank between the heads or central members of the constituent groups of the elements comprising sensor systems. These should then be related in the order of composition.

In this process, the place occupied by each concrete sensor is assessed in every order relative to other sensors making up both the same order and different orders. Thus, the uniqueness of each sensor in the ordering is distinguished by its similarity with, and difference from, every other sensor.

Perhaps the most important Fourth Order in the classification of sensors hinges upon the notions of kinship through the relations describing ascent, descent, and collaterality.

As with the orders of Composition and Hierarchy, the last problem of classification just described, which is also known as Genealogy and Evolution, is also concerned with the actual sensors to be classified. These latter orders, when applied for sensor systems, emphasize the importance of a functional and structural hierarchy. Taxonomy in Sensor Science may thus be regarded as possessing the six main features of its objectives and functions, its materials and activities, together with the methods of discrimination used and hierarchical ordering.

3 CLASSIFICATION BY ENERGY

Consistent with these orders of classification, it can be seen that the appropriate universal grouping of sensors must be on the basis of:

- function
- structure
- energy form
- signal output.

Table 2. A scheme of classification for energy forms.

Energy form	Characteristic physical phenomenon
Electromagnetic radiation	Radio waves, through to cosmic rays
Gravitational	Attraction between masses
Mechanical	Lifting, stretching, and movement
Thermal	Kinetic energy of molecules
Electrical	Electric and magnetic fields, currents
Molecular	Bond energy of atoms in molecules
Atomic	Binding energy between nuclei and electrons
Nuclear	Binding energy within nuclei
Mass	Relativistic energy

Energy and signal are of immediate interest. Energy may be considered on either a macroscopic or microscopic level.

Serious consideration of the fundamentals of physics shows that the most basic starting point might be at its four prime forces – electric, magnetic, gravitational, and atomic. These, however, are too much removed from practice to be useful to designers of sensing systems.

There are a number of different, equally valid ways of classifying the energy found in the physical world. For example, a comprehensive but not exclusive grouping of nine various types of existing energy forms is given in Table 2; it stems from experience.

From this group of nine, an abbreviated group of six can be identified as being of general relevance to instrument systems. These six, used by Kurt S. Lion and later by Simon Middelhoek and coworkers, are

1. radiant energy
2. mechanical energy
3. thermal energy
4. electrical energy
5. magnetic energy
6. chemical energy.

Transducers can also be classified according to the transduction principle involved and the form of the measurand. Thus, a resistance transducer for measuring displacement is classified as a resistance displacement transducer. Other classification examples are pressure bellows or a force diaphragm. In the classification, grouping on the basis of transduction principle has been developed by a number of people. Kurt S. Lion once produced such a classification similar to that shown in Table 2. In this classification, it is possible to relate the physical effect in the energy domain of the measurand that allows a transduction into another energy form. The topic is also discussed under the modeling of sensors in **Article 112, Systematic Description of Sensors, Volume 2**.

4 APPLYING THE ENERGY CLASSIFICATION

Although these methods of grouping by energy form are perfectly acceptable, they are not easily remembered in a consistent manner. For this reason, another possibility is organization by energy classification given by Peter K. Stein in his presentation of the transducer space.

In this scheme, the energy forms are classified with the memory-aiding acronym COMETMAN. Whereas the previous methods of classification are based upon a more rigid linking of the energy by similarity, COMETMAN is specifically designed as a memory aid. The acronym comes from classifying by

- **C**hemical (i.e. molecular)
- **O**ptical (i.e. radiation)
- **M**echanical (i.e. including gravitation and mass)
- **E**lectrical
- **T**hermal
- **M**agnetic (i.e. including electrical and atomic forms)
- **A**coustic (i.e. correctly speaking within the mechanical group)
- **N**uclear energy forms.

Once again, the important point to emphasize here is not whether one form of classification is more correct than another. Rather, it is from the convenience of that which is most easily remembered.

5 THREE-SPACE MODELING OF TRANSDUCERS AND SENSORS

It is possible to use this COMETMAN classification of energy to visualize the wide range of possible input and output transducers from two approaches.

The first approach uses a three-dimensional or three-space energy and/or signal form of the inputs and outputs to provide an aid to understanding the interacting relationship between the form of support energy used and the input and output information carrying signals in their range of possible energy forms.

This three-dimensional transducer space represents the input signal in its energy form along the conventional x-axis, the support energy form along the conventional z-axis, and the output energy along the conventional y-axis as shown in Figure 1.

Self-generating transducers and modifiers, which operate without an auxiliary energy source, lie in the vertical x–y plane. Consider, for example, the thermocouple in which thermal information flows from the thermal energy input on the x-axis to information output on the y-axis transduced to the electrical energy form.

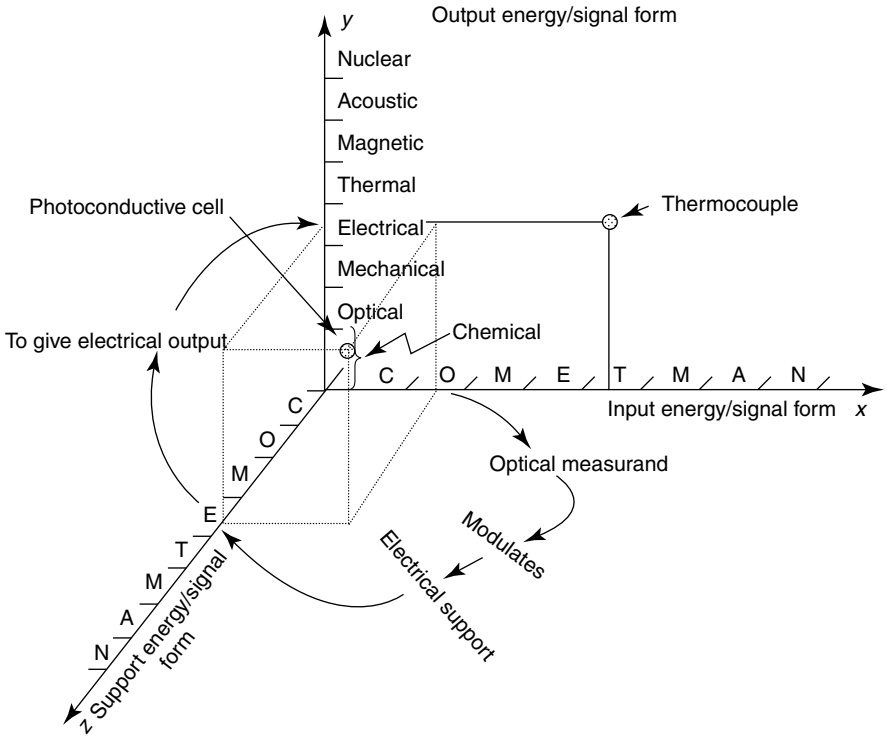

Figure 1. The three-dimensional (three) space for transducers by energy/information.

Table 3. Examples of transducers and their logical grouping for different input and output signals.

OUT \ IN	Radiation	Mechanical	Thermal	Electrical	Magnetic	Chemical
Radiation	Geometric-optical system filter	Interferometer; Photoelastic transducer	Thermal radiation transducer	Kerr cell; Electro-luminescent transducer, LED	Faraday cell	Transducer based on emission & absorption spectroscopy

Magnetic	Curie-effect radiation meter	Magnetoelastic transducer	Paramagnetic transducer device	Electromagnetic transducer; Coil	Magnetic recorder	Magnetic resonance system
Chemical	Photographic emulsion	Ultrasonic chemical transducer	Thermal dye indicators	Electrolytic integrator; Electrical plating	Paramagnetic oxygen analyzer	Chemical system modifiers

Modulating types of sensors can be shown in the [x, y, z] 'transducer space' in Figure 1 according to which support energy source is used. A photo-conductance sensor would have its input information at $x =$ optical, its output at $y =$ electrical, and its support energy at $z =$ electrical. The radiating optical input energy incident upon the sensor modulates the flow of electrical energy from the support energy port to the output energy port. For this reason, modulating sensors of this type bring the advantage of much higher power gain to measurement systems than do self-generators.

The energy/information space diagram allows the prediction or visualization of transducer possibilities. It is clear that there are numerous different possibilities as feasible candidates when proposing a transduction principle to meet a sensing need. While all known possible combinations of input, output, and support energy forms can be located in this three-dimensional representation, there are still many positions where practical devices have not been proposed. Table 3 lists many forms in terms of the energy classification.

An instrument system building block, therefore, has three possibilities for inputs and outputs. The self-generating sensor has an input signal S_i, with its associated input self-generating or excitation energy e_i. At the same time, its output signal is S_o and output energy e_o. The difference between the self-generating and modulating types is a matter of how e_i is supplied to the system as shown in Figure 2.

In self-generating sensors, the system under measurement supports the information flow by supplying energy to the sensor.

Modulating sensors, which extract negligible energy from the system under measurement, modulate the support energy input. The energy symbol e_i is removed to indicate that negligible energy is drawn from the system under measurement. The energy symbol e_s is inserted in the diagram to model the effect of modulation of e_s by S_i.

It is clear that any instrument stage can be represented by the energy/signal notation in the [x, y, z] transducer

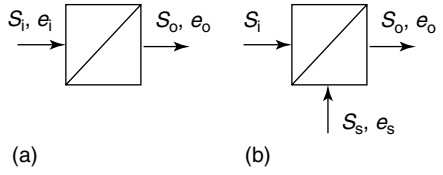

Figure 2. Block diagram and notation for (a) self-generating and (b) modulating sensors.

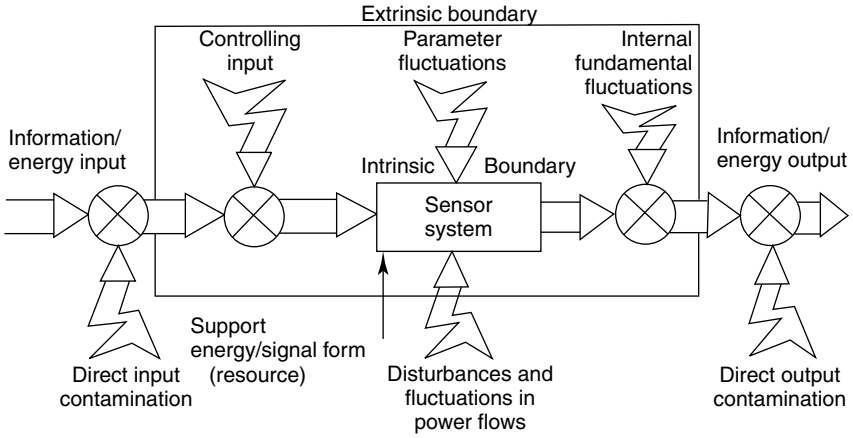

Figure 3. Boundary perspective of a sensor system and its influencing effects.

space, in which the measurand energy form, x, modulates the support energy form, z, to produce a variation in the output energy form, y, bearing some relationship to the measurand energy form, x. These possibilities are all included in Figure 2. The diagonals in the blocks represent the general transduction from one energy form to another. The relationships on Figure 1 and Figure 2 may be written as a mathematical relation with the form

$$y = f(x, y) \tag{1}$$

6 THE SENSOR EFFECT TETRAHEDRON

The three-dimensional transducer space has one significant disadvantage. In this diagram, no account is taken of contaminating inputs. Consequently, the influence of interference from whatever source is influencing the system is not transparent. A spatial representation for the boundary inputs and outputs of a sensor system, in its most general form, requires a multidimensional space. As there is a total of three groups of inputs and three groups of outputs, the representation becomes too complex for graphical illustration.

This situation can be understood by starting from the various perspectives at the boundaries of a sensor system, as are given in Figure 2, Figure 3, and Figure 4. It is possible to represent a sensor and transducer effect space that is more complex than the schemes proposed previously.

In spite of the increased complexity, this sensor effect space is still useful, since it also includes all of the possibilities for contamination inputs.

In a sensor system, the main output is an information output, which also corresponds to the resource output. Although contamination is also produced at the output, it is not necessary to consider it for the present purposes.

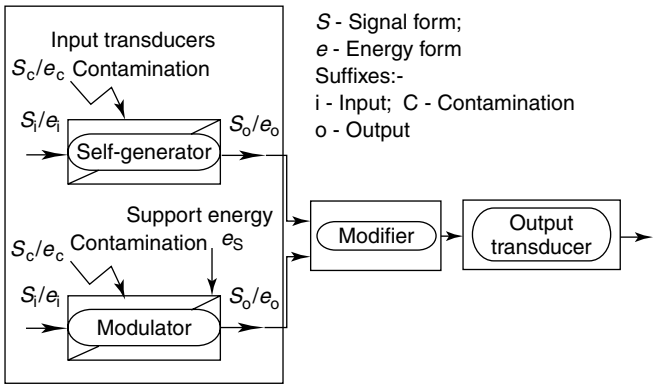

Figure 4. Functional block diagram of a basic instrumentation system illustrating modifier elements and input and output transducers.

Hence, the output energy/signal form for a sensor system is given more emphasis in this figure than the contamination produced by the sensor system at its output.

The proposed representation consists of one axis normal to a base plane as shown in Figure 5. Along the base plane of this spatial representation, introduce a topological grouping consisting of three axes set mutually at 60° spacing. Each of these axes, taken as representing one of the three input groups with their COMETMAN information or energy classification, clarifies and justifies the way in which the acronym aids memory. The organization of the three axes on this base plane is a collapsed, two-dimensional representation of the input three-space consisting of the information, resource, and contamination inputs. This organization of the inputs may be regarded further as the input triangle. Such a name is appropriate as illustrated by the input triangle given by the dotted lines in Figure 5. Here, the support energy form is electrical, the contamination energy/information form is chemical, and the measurand

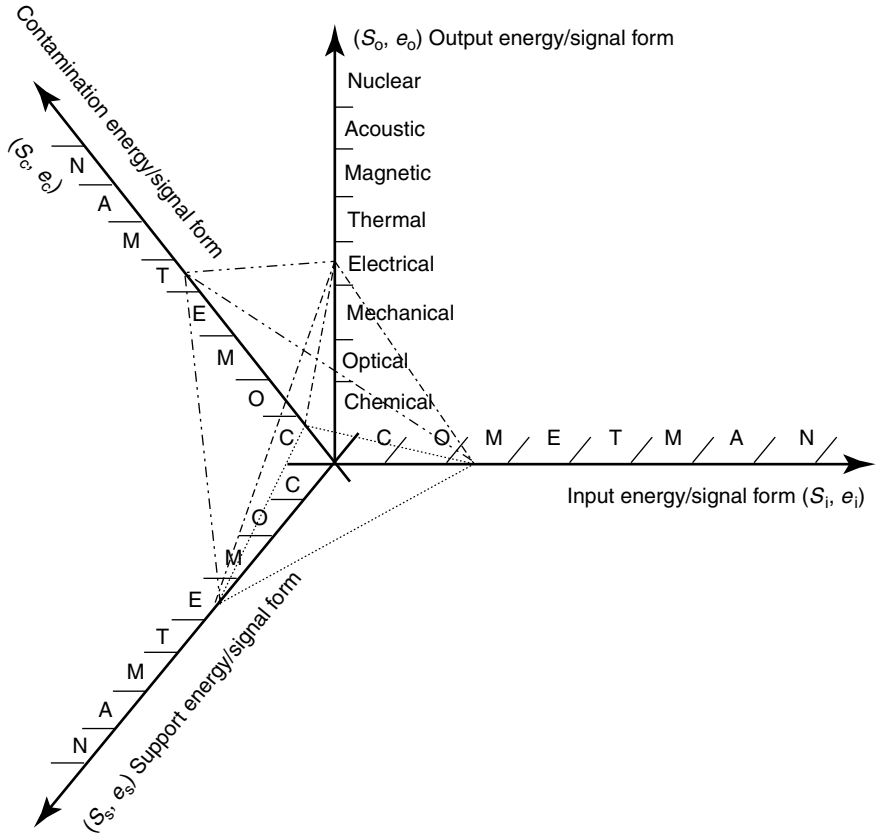

Figure 5. The information and energy tetrahedron for a modulating sensor.

energy form is mechanical, using a sensor such as a resistance strain gauge.

The chemical contamination could be responsible for parasitic electrochemical potentials at the contacts in the electrical circuit. Each point on the input triangle axes may be joined to an energy/information form on the output axis. When the output is in the form of an information bearing electrical signal, the dash-dot line combinations shown in Figure 5 allow the link between all three input forms and the output form to be clearly seen. The geometrical shape, which is outlined by the dotted and the dash-dot lines, has one base plane surface and three inclined surfaces. This represents a tetrahedron or four-faced object. This way of representing the boundary impacts on systems may be called the *information/energy tetrahedron* or the *sensor/transducer effect tetrahedron*.

Illustration of the manner in which the contamination inputs influence the output may be extended to cover contamination from other energy forms. The dot-dot-dash lines in Figure 5 show the case when the contaminating energy form is due to the influence of temperature on the wire of the strain gauge. The deep perception allowed by the information/energy tetrahedron given in Figure 5, which is fairly straightforward, is still realistic and comprehensive.

Extending (1) to include the effects of contamination is easily understood. Hence, the functional relationship between the output energy/signal forms can be written as

$$\left[\frac{S_o}{e_o}\right] = f\left(\left[\frac{S_i}{e_i}\right], \left[\frac{S_s}{e_s}\right]\right), \left[\frac{S_c}{e_c}\right] \tag{2}$$

So far, the conditions in Figure 5 correspond to the case of modulating types of sensors and transducers, which are represented in Figure 2 and Figure 4.

Self-generating sensor possibilities may also be represented by the sensor/transducer effect tetrahedron as shown in Figure 6 using a thermocouple for illustrative purposes.

In self-generating sensors, there is no support energy form. Consequently, the support energy axis of the input triangle collapses to the origin of the system of axes in the tetrahedron. This origin, usually representing the number zero in a numerical space, may be regarded as the point defining the nonexistence of a support information/energy form. Under these conditions, (2) can be rewritten in the form

$$\left[\frac{S_o}{e_o}\right] = f\left(\left[\frac{S_i}{e_i}\right], \left[\frac{O_s}{o_s}\right]\right), \left[\frac{S_c}{e_c}\right] \tag{3}$$

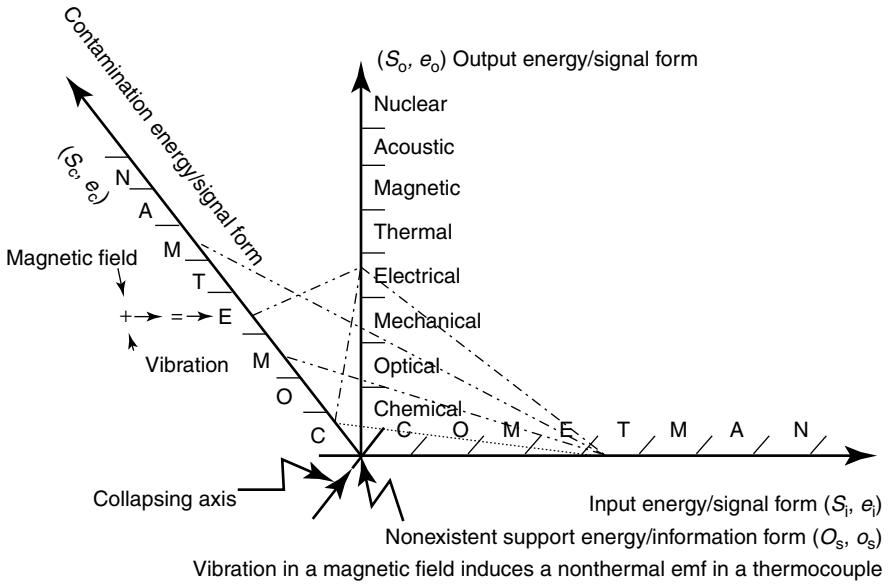

Figure 6. The sensor effect tetrahedron illustrating self-generating sensors and transducers using a thermocouple as an example.

where the term $[O_s/o_s]$ indicates that there is no support signal/energy form for self-generating sensors.

In the case of the thermocouple, illustrated in Figure 4, the measurand energy form is thermal. The chemical interference shown once again may give rise to a series mode parasitic electrochemical emf in the electrical circuit of the thermocouple. A situation, illustrating the interaction of different energy forms to produce a propagated contaminating signal, is also shown in Figure 6. If the thermocouple sensor assemblies, including its lead wires, are mounted on a structure, which is vibrating in an electromagnetic field, the sensor effect tetrahedron allows the possibility of an induced series mode interfering electrical signal to be predicted and visualized. The powerful predictive property of the sensor effect tetrahedron is well illustrated by this example.

The representation of self-generating sensors and transducers shown in Figure 6 may be called the *self-generator tetrahedron*. This model of a collapsing four-space may also be viewed as forming a three-space model, when the input and contaminating axes are drawn mutually perpendicular. This is analogous to the effect that occurs in Stein's transducer space for self-generating sensors given in Figure 1. Whereas this transducer space collapses to a plane, or two-space, from a three-space or three-dimensional space, in the case of self-generating transducers, the sensor effect tetrahedron collapses to a three-space for the same kind of sensor. The different results of the collapsing is due to the fact that the sensor effect tetrahedron represents the input information/energy groupings using the idea of the input triangle illustrated in Figure 5 and Figure 6.

7 SIGNAL/ENERGY MATRIX MODELING OF SENSORS AND TRANSDUCERS

The basic ideas of classification in sensors and transducers allow a visualization of the diverse possibilities for realizing measuring functions. Another very important aid in visualizing how the energy and signal are transduced uses the concept of a signal/energy flow matrix. Figure 7 illustrates this for two different kinds of temperature sensor. One of these is a mercury-in-glass thermometer and another is a modern digital thermometer. The fundamental block diagram representation of input and output sensing/transducing

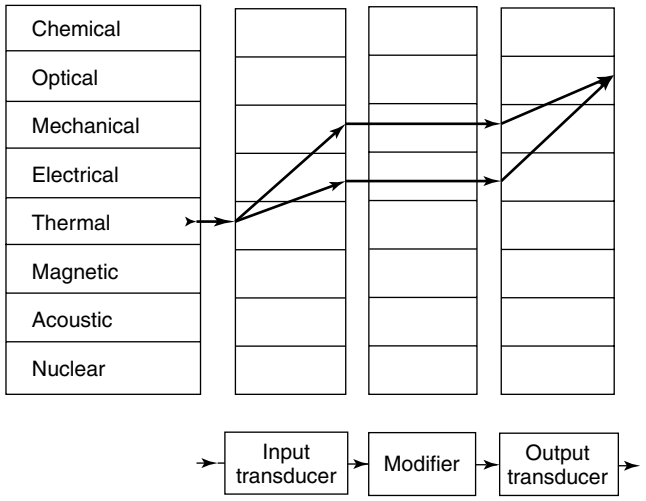

Figure 7. Generalized but simplified energy regime for a mercury-in-glass thermometer and a modern digital thermometer.

elements and modifying elements, shown in Figure 4, is used to construct the matrix shown in Figure 7. Above this block diagram in Figure 7 is a matrix of rows and columns, with the left-hand column indicating the COMETMAN classification scheme for input energy/signal forms. The energy domain of the temperature input signal is of course the thermal domain.

Consider first when the sensor is a mercury-in-glass thermometer. The input transduction process transforms the thermal energy into mechanical energy, because of the cubic expansion of the mercury in the bulb of the thermometer. This expansion is propagated through the thermometric fluid, the mercury, by modifying the original mechanical cubic expansion into a change in the length of the mercury column. This column length belongs to the group of mechanical variables. Radiation, which is incident upon the column, is modulated by the reflective, refractive, and absorptive properties of the mercury column so that the human eye perceives the change in length. This perception is by a noncontacting form of sensing through the 10^8 videceptors in the human sense of seeing.

If the thermometer is a digital electronic unit, the thermal energy is transduced to the electrical domain using a suitable electrical temperature sensor, which could be any one of the contacting group in the classification of temperature sensors given in Figure 8, explained later in Section 8. Modification of the electrical energy at the electrical output port of resistive sensors could use a Wheatstone bridge. Further modification could be performed with an electronic instrumentation amplifier. Subsequently, the analog signal at the output of the instrumentation amplifier is converted to a digital form using an analog-to-digital converter (ADC). The digital output of the ADC is then encoded and applied to an LED (light emitting diode). The LED, which is a photon generator, transduces its digital electrical input signal to visible radiation at its output.

8 GENERAL PRINCIPLES OF TEMPERATURE SENSOR CLASSIFICATION

While little systemic classification work has been contributed for the sensor family as a whole, a significant foundation showing the general rules of classification has been developed for temperature. It provides an example that illustrates the characteristics and scope for other categories.

Elements for measuring temperature extend the human faculties to sense hotness relations between bodies or entities in the real world. This functional extension of the human faculties is held in common with other instruments for measurement, calculation, communication, and control. From the classification perspective, the tree classification diagram of Figure 8 illustrates benefits that the science of taxonomy can bring to the study of temperature sensors. It is obvious from Figure 8 that there are diverse methods for temperature measurement. Only contacting sensors with heat transfer by convection or conduction will be considered in detail. None of the wide variety of noncontacting sensors are considered here.

To provide breadth of perspective, it is essential to introduce some kind of ordering so that similarities between each kind may be identified without in any way diminishing their important differences.

The main function of taxonomy, or classification, is to discover the relationship between different entities that unites them. In the first instance, at the metaphysical, theoretical, or fictitious level, it is necessary to deal with the

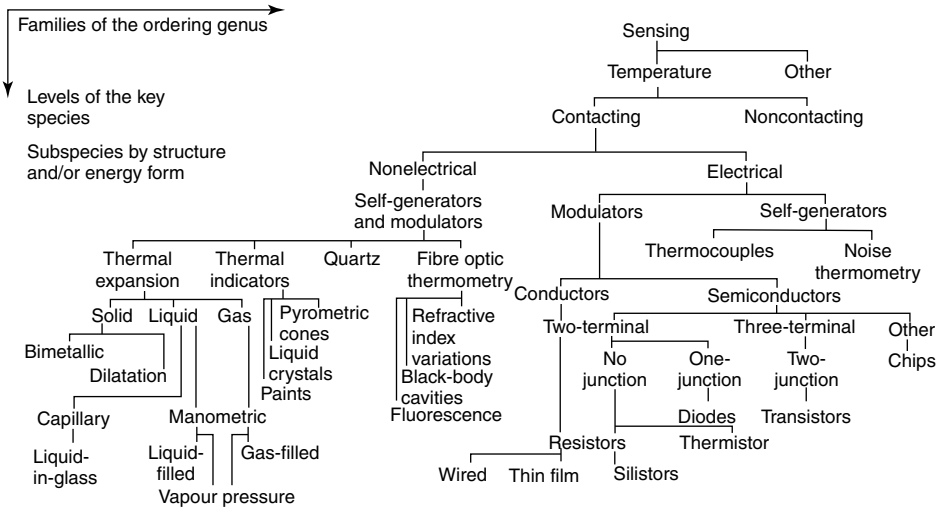

Figure 8. Classification of temperature measuring instruments/sensors by structure and/or energy form.

generality or resemblance of specific methods of temperature measurement. This is concerned with establishing the relationship of likeness.

The second important problem in the classification of temperature sensors should analyze two relationships. The first is that between those similar subspecies of sensing methods. The second is the relationships between one part of a temperature sensor with other parts, which together collectively contribute to the composition of the sensor. It is also necessary to construct a hierarchical ordering based upon the relationship between the heads or central members of groups of sensors.

Composition and collectivity play a role in this ordering, as they relate the places occupied in each order, relative to other sensors of the same order. Another last, but not least, ingredient in ordering temperature sensors is concerned with the *kinship* of one sensor type with another type. The relationships of ascent, descent, and collaterality are the essential factors in this aspect of temperature sensor ordering. Ascending and descending relationships place the sensor by structure and energy form relative to the head or central members of principal groups of sensors. Collaterality is that relationship which one type of sensor has with another at the same hierarchical level in the classification.

Applying the above principles, it can be seen that temperature sensors are a specific genus of sensor within the much wider family of sensors. This is emphasized by the branch that shows that other genus of sensor exist. Also, in accordance with the general classification of sensors by their energy relationships given earlier, temperature sensors may belong to the groups of sensor known as either *self-generators* or *modulators*.

The generality and resemblance level in temperature sensor ordering is best approached by comparison with the functions of the human senses. Humans can detect hotness relations by looking at an object, by approaching it, or by touching it.

Neither looking at nor approaching an object requires physical contact to sense its hotness. Touching an object to sense its hotness requires physical contact. Thus, the senses of touch, by contact, and sight or proximity, with no contact, are those used by humans to sense hotness relations.

It is apparent that temperature sensors may be based upon heat transfer by contacting or noncontacting methods. This grouping at the species level of the hierarchy of temperature sensors, classifies them on the basis of these heat transfer mechanisms. This approach to temperature measurement is recognized as the direct form of measurement in the thermal field.

Other possibilities for the noncontacting species use inferential methods. The principle of this technique applies an external energy as an interrogating medium in the measuring scheme for the purposes of information capture about the abilities of the body under measurement to store, dissipate, transmit, or transform thermal energy.

9 TEMPERATURE MEASURING RANGES OF TEMPERATURE SENSORS

It is also possible to classify temperature sensors on the basis of the temperature range of application. Such a

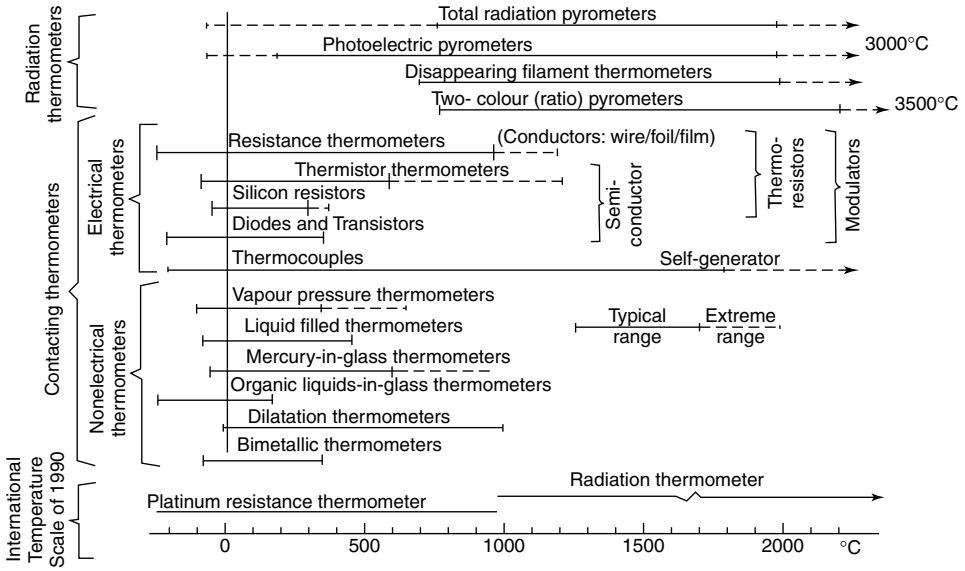

Figure 9. Classification of temperature measuring instruments/sensors by measuring range.

classification is given in Figure 9. An abbreviated form for the temperature ranges of the standard thermometers of ITS-90 is included in this diagram for the purposes of comparison.

A simple classification tree on the various types of elastic flexure used in instruments has been published, Sydenham (1984).

1 PRINCIPLES OF SYSTEMATIC DESCRIPTION OF SENSORS

A sensor performs the exchange of information (thus energy) from one domain to another and therefore it operates on the interface between different physical domains. Several frameworks have been developed for a systematic description of sensors. Basically, they are based on either of two different approaches. The first method follows a categorization on the basis of the various energy domains. However, there is no clear definition of an energy domain, leaving room for different opinions on this description. The other approach is based on a categorization of physical quantities. Although more fundamental, this method also leaves scope for discussions. Obviously, the two approaches are connected to each other, since quantities describe particular phenomena in which energy or conversion of energy is involved.

A common categorization according to physical effects is based on thermodynamic principles. It is the most fundamental, and covers most of the conversion effects that occur in physics. The description is, in particular, useful in the field of material research and optimization of sensor materials. Derived from the thermodynamic approach is the Bond graph notation (Blundell, 1982) with a division of variables into two groups called *effort and flow variables*. This method is not only useful for the description of sensors but has great significance in the design of all kinds of technical systems, irrespective of the domain type.

A further distinguishing property for a subdivision of sensors into just two categories is the need for auxiliary energy (*see* **Article 108, Transducer Fundamentals, Volume 2**). Sensors that need no auxiliary energy for their operation are called *direct sensors* or *self-generating sensors*. Sensors that use an additional energy source for their operation are called *indirect sensors*, *modulating sensors*, or *interrogating sensors*. The names direct and indirect are rather obscure; the name self-generating is misleading: neither the energy nor the information is generated by the sensor for it comes from the measurand.

The terms modulating and interrogating refer to the fact that the measurand affects a specific material property, which in turn is interrogated by an auxiliary quantity. Most sensors belong to this group: all resistive, capacitive, and inductive sensors are based on a parameter change (resistance, capacitance, inductance) caused by the measurand. Likewise, most displacement sensors are of the modulating type: displacement of an object modulates optical or acoustic properties (transmission, reflection, interference), where light or sound is the interrogating quantity. The distinction between these two groups can be useful when considering offset and load errors of sensors **(Article 108, Transducer Fundamentals, Volume 2**). In the last section of this article, a universal model of a sensor is presented that avoids any misinterpretation due to badly chosen names.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

The operation of sensors is governed by

- physical effects,
- material properties, and
- system layout.

Physical effects may either act within one-energy domain or cross domain boundaries. The latter describe the fundamental operation of sensors. Material properties determine the quantitative characteristics of the conversion process, and hence form a guide to the proper material choice for a particular sensor. Finally, with an appropriate sensor layout, the performance of the sensor can further be optimized.

2 SYSTEMATIC DESCRIPTION BASED ON ENERGY DOMAINS

A systematic representation of sensor effects based on energy domains involves a number of aspects. First, the energy domains have to be defined. Next, the energy domains should be allocated to both the sensor input and output. Finally, since many sensors are of the modulating type (**Article 108, Transducer Fundamentals, Volume 2**) also, the domain of the auxiliary quantity should be considered.

From a physical point of view, the nine energy forms that can be distinguished are (Middelhoek and Audet, 1989)

- electromagnetic radiant energy
- gravitational energy
- mechanical energy
- thermal energy
- electrostatic and electromagnetic energy
- molecular energy
- atomic energy
- nuclear energy
- mass energy.

This classification is rather unpractical for the description of sensors. Stein has proposed a system of eight distinct energy forms:

- Chemical
- Optical
- Mechanical
- Electrical
- Thermal
- Magnetic
- Acoustic/fluid
- Nuclear

forming the acronym COMETMAN (Stein, 1963).

Lion reduced this to only six domains, and adopted the term *signal domain* (Lion, 1969). These six domains are

- radiant
- mechanical
- thermal
- magnetic
- chemical and
- electrical.

The number of domains is actually a rather arbitrary choice, so for practical reasons we continue with the system of six domains and remain calling them *energy domains*.

Information contained in each of the six domains can be converted to any other domain. These conversions can be represented in a 6×6 matrix. Figure 1 shows that matrix, including some of the conversion effects. An input transducer or sensor performs the conversion from a non-electrical to the electrical domain (the shaded column), and an output transducer or actuator performs the conversion from the electrical to another domain (the shaded row in Figure 1).

In↓ Out→	**Radiant**	**Thermal**	**Electrical**	**Magnetic**	**Mechanical**	**Chemical**
Radiant	Luminescense	Radiation heating	Photoconductivity	Photomagnetism	Radiation pressure	Photochemical process
Thermal	Incandescense	Thermal conductivity	Seebeck effect; Pyroelectricity	Curie–Weiss law	Thermal expansion	Endothermal reaction
Electrical	Injection luminescense	Peltier effect	PN junction effect; Ohm's law	Ampere's law	Converse piezoelectricity	Electrolysis
Magnetic	Faraday effect	Ettinghausen effect	Hall effect	Magnetic induction	Converse magnetostriction	
Mechanical	Photoelastic effect	Friction heat	Piezoelectricity	Magnetostriction	Gear	Pressure induced reaction
Chemical	Chemoluminescense	Exothermal reaction	Volta effect		Explosive reaction	Chemical reaction

Figure 1. Conversion effects. (Reproduced from 'Physics of Silicon Sensors', Middelhoek *et al*, Copyrigtht (1989), with permission from Elsevier.).

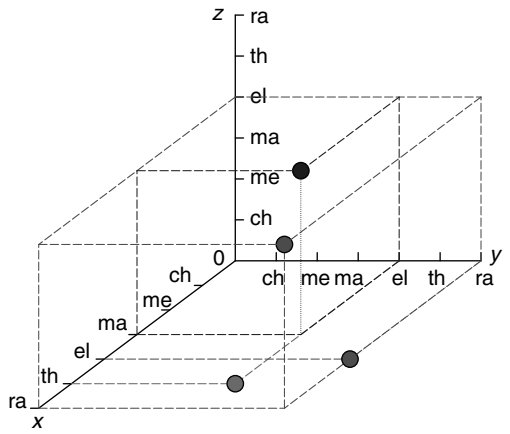

Figure 2. Sensor cube with four transducer types; thermocouple: [th, el, 0], Hall sensor: [ma, el, el], LED: [el, ra. 0] and LCD: [ra, ra, el].

This two-dimensional representation can be extended to three dimensions, when the interrogating energy domain is included. This gives 216 energy-triplets. To get a clear overview of all these possible combinations, they can be represented in a 3D Cartesian space, the sensor cube shown in Figure 2. The three axes refer to the input energy domain, the output energy domain, and the domain of the interrogating input.

Each of the 216 elements of the $6 \times 6 \times 6$ matrix represents one or more conversion effects. When restricting to electrical transducers, we have 5 direct input transducers, 5 direct output transducers, 25 modulating input transducers, and 25 modulating output transducers. To facilitate notation, the transducers can be indicated by indices, like in crystallography, the so-called *Miller indices*: $[x, y, z]$. The x-index is the input domain, the y-index, the output domain and the z-index, the domain of the interrogating quantity. With these three indices, a transducer can be typified according to the energy domains involved. Some examples are

- direct input transducer: thermocouple: [th, el, 0]
- modulating input transducer: Hall sensor; [magn, el, el]
- direct output transducer: LED: [el, rad, 0]
- modulating output transducer: LCD: [rad, rad, el].

These transducers are also visualized in Figure 1. The value of such a representation is rather limited. It may serve as the basis of a categorization for overviews, or as a guide in the process of sensor selection. This also shows why there are so many alternatives for sensing a given variable, and why the uncontrolled generation of so-called new sensors is hard to keep in clear perspective.

3 SYSTEMATIC DESCRIPTION OF PHYSICAL QUANTITIES

Several attempts have been made to set up a consistent framework for quantities and material properties. Most of these descriptions are based on energy considerations, or more precisely, on the first and second law of thermodynamics.

For each energy domain, two variables can be defined in such a way that their product equals the energy (or a derived energy quantity) of the domain type, the conjugate quantities. For instance:

Mechanical:	Tension $\boldsymbol{T}$ (N m^{-2}) and deformation $\boldsymbol{S}$ [−]
	Shear tension τ (N m^{-2}) and shear angle χ [−]
Electrical:	Field strength $\boldsymbol{E}$ (V m^{-1}) and dielectric displacement $\boldsymbol{D}$ (C m^{-2})
	Field strength $\boldsymbol{E}$ (V m^{-1}) and electric polarization $\boldsymbol{P}$ (C m^{-2})
Magnetic:	Magnetic induction $\boldsymbol{B}$ (Wb m^{-2}) and magnetic field $\boldsymbol{H}$ (A m^{-1})
Thermal:	Temperature Θ (K) and entropy σ (J K^{-1} or J Km^{-3}).

The variables ***E, D, B, H, T***, and ***S*** are vector variables, whereas σ and Θ are scalars (so often denoted as $\Delta\sigma$ and $\Delta\Theta$). Note that the dimension of the product of each domain pair is J m^{-3} (energy per unit volume) in all aforementioned cases (note a possible confusion with respect to the thermal domain).

The variables in this list show a remarkable analogy: they belong to either of two classes: through-variables and across-variables. To explain this classification, we first introduce the term *lumped element*. A lumped element symbolizes a particular property of a physical component; that property is thought to be concentrated in that element between its two end points or nodes. Exchange of energy or information only occurs through these terminals.

A *through-variable* is a physical quantity that is the same for both terminals of the lumped element.

An *across-variable* describes the difference with respect to a physical quantity between the terminals. They are also called *intensive variables* and *extensive variables* respectively.

In an electronic system, current is a through-variable, voltage (or potential difference) is an across-variable. Therefore, through-variables are called *generalized I-variables* and across-variables are called *generalized V-variables*. However, this is just a matter of viewpoint. It is perfectly justified to call them *generalized forces* and *displacements*.

In the above groups of variables, ***T, E***, and Θ are across-variables. On the other hand, ***S, D***, and σ are through-variables. They are related to each other through physical material properties or system layout.

For each domain, we can define a pair of *conjugate variables*. In the preceding examples, the product was energy density (J m^{-3}). It is also possible to find other pairs of variables whose product is, for instance, energy or power. A few examples are

mechanical: pressure P (N m^{-2}) and volume V (m^3);
mechanical: force F (N) and distance x (m);
electrical: voltage V (V) and charge Q (C);

all with product energy (J); these pairs are energy conjugate variables.

Other examples are

mechanical: force F (N) and velocity v (m s^{-1});
electrical: voltage V (V) and current I (A = C s^{-1});

both with product power (W); these pairs are power conjugate.

For other domains, such pairs can be defined as well, but with sometimes rather unusual quantities.

From the last examples, we observe regularity in the various domains. Within one domain, we can distinguish state variables and rate variables. They are related as

$$X_{\text{rate}} = \frac{\mathrm{d}}{\mathrm{d}t} X_{\text{state}} = \dot{X}_{\text{state}} \text{ or } X_{\text{state}} = \int X_{\text{rate}}\,\mathrm{d}t \qquad (1)$$

The most obvious cases are

$$I = \frac{\mathrm{d}}{\mathrm{d}t} Q \text{ or } Q = \int I\,\mathrm{d}t \qquad (2)$$

$$v = \frac{\mathrm{d}}{\mathrm{d}t} x \text{ or } x = \int v\,\mathrm{d}t \qquad (3)$$

4 SYSTEMATIC DESCRIPTION BASED ON THERMODYNAMIC LAWS

On the basis of laws on energy conservation, several frameworks for a systematic description of material properties and physical effects and hence for the description of sensors can be built up.

According to the first law of thermodynamics, the energy content of an infinitely small volume of an elastic dielectric material changes by adding or extracting heat $\mathrm{d}Q$ (J) and by work $\mathrm{d}W$ (J) exerted upon it is given by

$$\mathrm{d}U = \mathrm{d}Q + \mathrm{d}W\,(\mathrm{J}) \qquad (4)$$

The work $\mathrm{d}W$ is the sum of the different energy forms involved, for instance, electrical and mechanical energy: $V\,\mathrm{d}Q$ and $F\,\mathrm{d}x$. Since $\mathrm{d}Q = \Theta\,\mathrm{d}\sigma$ (J) (temperature and entropy), we can generalize the energy change as

$$\mathrm{d}U = \sum_i A_i\,\mathrm{d}B_i \text{ (J)} \qquad (5)$$

where A_i is an extensive variable and B_i the conjugated intensive variable. So if we consider only the thermal, electrical, and mechanical domains, the energy change is governed by the equation

$$\mathrm{d}U = \Theta\,\mathrm{d}\sigma + V\,\mathrm{d}Q + F\,\mathrm{d}x \text{ (J)} \qquad (6)$$

When energy per unit of volume is considered, this equation reads as

$$\mathrm{d}U = T\,\mathrm{d}S + E\,\mathrm{d}D + \Theta\,\mathrm{d}\sigma \text{ (J m}^{-3}\text{)} \qquad (7)$$

(Note that for entropy we have used the same symbol but the dimension is now J Km^{-3}.) Apparently, in this equation only through-variables affect the system. If, on the other hand, only across-variables affect the energy state of the system, the equation for the energy change per unit volume is

$$\mathrm{d}G = -S\,\mathrm{d}T - D\,\mathrm{d}E - \sigma\,\mathrm{d}\Theta \text{ (J m}^{-3}\text{)} \qquad (8)$$

where G is the Gibbs potential that can be found from the free energy U by a Legendre transformation. We continue the discussion with the last expression because the resulting parameters are more in agreement with experimental conditions. After all, it is easier to have the across-variables as inputs or independent quantities (temperature; electric field, or voltage; force) and to measure the resulting through-variables or dependent quantities (strain; dielectric displacement or current).

The energetic state of a system can be described by pairs of conjugate variables, the pairs being determined by the energy forms that have to be regarded for a specific situation. However, the system configuration or the material couples the conjugate variables of each pair. Examples within one domain are

$T = c \times S$ (Hooke's law, with c, the mechanical elasticity)

$P = \varepsilon_0 \chi_e E$ (with χ_e, the electrical susceptibility)

$J = \mu_0 \chi_m H$ (with χ_m, the magnetic susceptibility)

In general, the extensive variable, A_i and the intensive variable, B_i within one domain are connected according to

$$A_i = \alpha_i B_i \text{ or } B_i = \beta_i A_i \tag{9}$$

where α_i is a (generalized) modulus and β_i is a (generalized) compliancy. These are the state equations of the system.

As an example, in the mechanical domain, Hooke's law can also be written as

$$T = c \times S \text{ or } S = s \times T \tag{10}$$

where c is the modulus of elasticity (or Young's modulus) and s, the compliance.

Likewise, variables in one domain are linked to variables in another domain, expressing the cross-effects. So

$$A_i = \gamma_{ij} B_j \text{ or } B_j = \gamma_{ji} A_i \tag{11}$$

where γ_{ij} and γ_{ji} represent material properties linking domains i and j.

The aforementioned equations form the basis for a formal description of sensors, since it is now possible to describe physical effects crossing domain boundaries. We illustrate the concept with a system in which only the mechanical, the electrical, and the thermal domains are involved. So the starting point is the equation:

$$\mathrm{d}G = -S\,\mathrm{d}T - D\,\mathrm{d}E - \sigma\,\mathrm{d}\Theta (\mathrm{J\ m^{-3}}) \tag{12}$$

The through-variables S, D and σ in this equation can be written as partial derivatives of the Gibbs potential:

$$\begin{aligned} S(T, E, \Theta) &= \left(\frac{\partial G}{\partial T}\right)_{\Theta,E} \\ D(T, E, \Theta) &= \left(\frac{\partial G}{\partial E}\right)_{T,\Theta} \\ \sigma(T, E, \Theta) &= \left(\frac{\partial G}{\partial \Theta}\right)_{T,E} \end{aligned} \tag{13}$$

From these equations, we can derive the various material and sensor parameters. To that end, the variables S, D, and $\Delta\sigma$ are approximated by linear functions, that is, we take only the first term of the Taylor series expansion in the points $T = 0$, $E = 0$ and $\Theta = \Theta_0$ of the functions $S(T, E, \Theta)$, $D(T, E, \Theta)$, and $\sigma(T, E, \Theta)$:

$$\begin{aligned} \mathrm{d}S &= \left.\frac{\partial S}{\partial T}\right|_{E,\Theta} \mathrm{d}T + \left.\frac{\partial S}{\partial E}\right|_{\Theta} \mathrm{d}E + \left.\frac{\partial S}{\partial \Theta}\right|_{E} \Delta\Theta \\ \mathrm{d}D &= \left.\frac{\partial D}{\partial T}\right|_{E,\Theta} \mathrm{d}T + \left.\frac{\partial D}{\partial E}\right|_{\Theta} \mathrm{d}E + \left.\frac{\partial D}{\partial \Theta}\right|_{E} \Delta\Theta \end{aligned} \tag{14}$$

$$\mathrm{d}\sigma = \left.\frac{\partial \sigma}{\partial T}\right|_{E,\Theta} \mathrm{d}T + \left.\frac{\partial \sigma}{\partial E}\right|_{\Theta} \mathrm{d}E + \left.\frac{\partial \sigma}{\partial \Theta}\right|_{E} \Delta\Theta$$

Combination of (13) and (14) results in

$$\begin{aligned} S &= \left(\frac{\partial^2 G}{\partial T^2}\right)_{\Theta,E} T + \left(\frac{\partial^2 G}{\partial T \partial E}\right)_{\Theta} E + \left(\frac{\partial^2 G}{\partial T \partial \Theta}\right)_{E} \Delta\Theta \\ D &= \left(\frac{\partial^2 G}{\partial E \partial T}\right)_{\Theta} T + \left(\frac{\partial^2 G}{\partial E^2}\right)_{\Theta,T} E + \left(\frac{\partial^2 G}{\partial E \partial \Theta}\right)_{T} \Delta\Theta \\ \Delta\sigma &= \left(\frac{\partial^2 G}{\partial \Theta \partial T}\right)_{E} T + \left(\frac{\partial^2 G}{\partial \Theta \partial E}\right)_{T} E + \left(\frac{\partial^2 G}{\partial \Theta^2}\right)_{E,T} \Delta\Theta \end{aligned} \tag{15}$$

Now we have a set of equations connecting the (dependent) through-variables S, D, and σ with the (independent) across-variables T, E, and Θ. The second-order derivatives represent material properties; they have been given special symbols.

The constant variables are put as superscripts, to make place for the subscripts denoting orientation (applied in nonisotropic materials).

$$\begin{aligned} S &= s^{E,\Theta} T + \mathrm{d}^{\Theta} E + \alpha^{E} \Delta\Theta \\ D &= \mathrm{d}^{\Theta} T + \varepsilon^{\Theta,T} E + p^{T} \Delta\Theta \\ \Delta\sigma &= \alpha^{E} T + p^{T} E + \frac{\rho}{T} c^{E,T} \Delta\Theta \end{aligned} \tag{16}$$

These superscripts denote constancy with respect to the indicated parameters, for instance, $s^{E,\Theta}$ is the compliance at zero electric field E and constant temperature Θ.

The nine associated effects are displayed in Table 1. Table 2 shows the corresponding properties. The parameters for just a single domain are ε, c_p, and s. The other parameters (p, α, and d) denote cross-effects.

Note that direct piezoelectricity and converse piezoelectricity have the same symbol (d) because the dimensions are equal (m $\mathrm{V^{-1}}$ and C $\mathrm{N^{-1}}$). The same holds for the pair pyroelectricity and converse pyroelectricity, as well as for thermal expansion and piezocaloric effect. Further, the second order derivatives in (15) correspond with the parameters γ_{ij} of (11). Since the order of differentiation can be reversed, the parameters γ_{ij} and γ_{ji} are equal.

Table 1. Nine physical effects corresponding to the parameters in (16).

Elasticity	Converse piezoelectricity	Thermal expansion
Direct piezoelectricity	Permittivity	Pyroelectricity
Piezocaloric effect	Electrocaloric effect	Heat capacity

Table 2. Symbols, property names, and units of the effects in Table 1.

Symbol	Property	Unit
s	Compliance, elasticity	m^2N^{-1}
d	Piezoelectric constant	$mV^{-1} = CN^{-1}$
α	Thermal expansion coefficient	K^{-1}
p	Pyroelectric constant	$Cm^{-2}K^{-1}$
ε	Permittivity, dielectric constant	Fm^{-1}
$c^{E,T}$	(Specific) heat capacity	$Jkg^{-1}K^{-1}$

Equations (7) and (8) can be extended just by adding other couples of conjugate quantities, for instance, from the chemical or the magnetic domain. Obviously, this introduces many other material parameters. With three couples we have nine parameters, as listed in Table 1. With 4 couples of intensive and extensive quantities we get 16 parameters, so 7 more (for instance, the magnetocaloric effect, expressed as the partial derivative of entropy to magnetic field strength).

5 A UNIFIED APPROACH TO TRANSDUCER MODELING

As a consequence of the energetic basis for the sensor description in the preceding sections, the information exchange between a sensor (or measuring system) and its environment (input devices, output devices, auxiliary sources, interfering sources) always implies two quantities: an across-variable and an associated through-variable. Energy (and thus information) enters or leaves the system through a pair of terminals making up a port. We distinguish input ports and output ports. A direct sensor can be described by a two-port model or a four-terminal model (Figure 3a). The input port is connected to the measurand and the output port corresponds with the electrical connections of the sensor. Likewise, a modulating sensor can be conceived as a system with three ports: an input port, an output port, and a port through which the auxiliary energy is supplied (Figure 3b).

In these models, the across-variables are denoted by E (effort) and the through-variables by F (flow) respectively. For each domain, the two variables E and F are defined in such a way that their product equals the energy of the domain type or a time or space derivative of energy. The subscripts x, y, and z are chosen in accordance with the sensor cube from Figure 1.

Direct sensors provide the information about the measurand as an output signal, an energetic quantity. Modulating sensors contain the information as the value of material property, or a geometric quantity, not an energetic signal. The information enters the system through the input port,

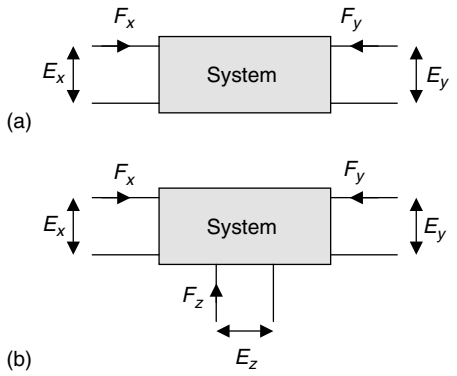

Figure 3. Port models of a sensor: (a) two-port (direct sensor) and (b) three-port (modulating sensor).

where the measurand affects specific material or geometric parameters. To extract the information from such a sensor, it has to be interrogated using an auxiliary signal. The information stored in the sensor is available latently, in the latent information parameters or LIP (Stein, 1992). These parameters are modulated by the input signal, and interrogated by the auxiliary or interrogating input.

At zero input, the LIPs of a modulating sensor have initial values, set by the material and the construction. Generally, the input has only a small effect on these parameters, resulting in relatively small deviations from the initial values.

Note that direct sensors also have LIPs set by materials and construction. They determine the sensitivity and other transfer properties of the sensor. So, the input port of all sensors can be denoted as LIP-input port. As a consequence, any sensor can be described with the three-port model of Figure 3(b). Only the functions of the ports may differ, notably the LIP-input port and the interrogating-input port.

According to the unified transducer model as introduced by Stein, an input port can be controlled either by design (it has a fixed value) or by the environment (the measurand or some unwanted input variable). So we have four different cases (Figure 4).

LIP input \ INT. input	Design controlled	Environment controlled
Design controlled	**Source**	**Direct sensor**
Environment controlled	**Modulating sensor**	**Multiplying devices**

Figure 4. Unified transducers.

The characteristics of these four cases are briefly reviewed.

1. *Design-controlled LIP-input and design-controlled interrogating input*. All inputs are fixed. This type represents a signal or information source, for instance, a standard, or a signal source with a constant or predetermined output. The output is totally determined by the construction and the materials that have been chosen. Any environmental effect on the output is (ideally) excluded.
2. *Design-controlled LIP-input and environment-controlled interrogating input*. Since the latent information parameters are fixed by design, the output only depends on what is connected to the interrogating input. When this is the measurand, the transducer behaves as a direct sensor.
   Examples are as follows:
   - *Thermocouple sensor*: the Seebeck coefficient is fixed by the choice of the materials.
   - *Piezoelectric accelerometer*: the sensitivity is fixed by the seismic mass and the piezoelectric properties of the crystal.
3. *Environment-controlled LIP-input and design-controlled interrogating input.* The measurand affects particular material properties or geometric parameters. These changes are interrogated by a fixed or well defined signal at the interrogating input. The transducer behaves as a modulated sensor.
   Examples are as follows:
   - *Strain gauge bridge*: strain alters the resistance of the strain gauge(s); a bridge voltage converts this resistance change into an output voltage.
   - *LVDT* (*Linear Variable Differential Transformer)*: a displacement of an object connected to the moving core of the LVDT will change the transfer ratio of the differential transformer. An AC signal on the primary coil acts as an interrogating quantity.
   - *Hall sensor*: the measurand is a magnetic induction field that acts on moving charges imposed by a fixed (or known) current applied to the interrogating input.
4. *Environment-controlled LIP-input and environment-controlled interrogating input:* These are multiplying transducers: the output depends on the quantities at both inputs, often in a multiplicative relation. For instance, a Hall sensor could act as such when the interrogating input is not a fixed current (by design) but a current that is related to just another measurand.

It is important to note that any practical transducer shows all four types of responses to varying extents. A strain gauge (a modulating transducer) produces, when interrogated, an output voltage related to the strain-induced change in resistance. But the circuit can also generate spurious voltages caused by capacitively or magnetically induced signals. A thermocouple (a direct transducer) produces an output voltage proportional to the measurand at the interrogating input. If, however, the material parameters change due to (for instance) strain or nuclear radiation (inputs at the LIP port) the measurement is corrupted.

Since just one response is desired, other responses should be minimized by an appropriate design. This universal approach helps identify such interfering sensitivities and their relative importance.

1 FEEDBACK-MEASURING SYSTEM

There are only a few structural schemes employed in the construction of instruments and instrument systems, and one such scheme is the use of a feedback. A feedback system can be thought of as a system that tends to automatically maintain a prescribed relationship of one system variable to another by comparing functions of these variables and using the difference as a means of control. The main characteristic of a feedback system is its closed-loop structure (*see also* **Article 18, Nature and Scope of Closed-loop Systems, Volume 1**). A measuring system in which feedback is the basic structural arrangement is called a *feedback-measuring system*, and a systematic analysis, description, and review of such systems has been undertaken by Jones (1979).

A general block diagram of such a system is shown in Figure 1. Here, the output signal (usually electrical) is converted to a form (usually nonelectrical, e.g. force) suitable for comparison with the quantity to be measured (e.g. force). The resultant error is usually transduced into electrical form and amplified to give the output indication. Normally, a sensor and associated circuit has a nonelectrical input and an electrical output, for example, a thermistor, strain gauge, and photodiode, whereas a so-called inverse transducer or precision actuator has an electrical input and a low-power nonelectrical output: for example, a piezoelectric crystal, translational, and angular moving-coil elements can be used as inverse transducers. The sensor, inverse transducer, and usually the amplifier must be close to the point of measurement, whereas the indicator may be some distance away. The feedback loop must have sufficient negative gain and the system must be stable. The system is driving fairly low-power devices at its output, and the inverse transducer essentially determines the characteristics of the system, although noise connected with the sensor and amplifier input stage may well be important. In practice, the measurand may not be directly connected to the null or balance point, and there may well be one or more primary sensing elements inserted between points X and Y as in Figure 1.

2 GENERAL PROPERTIES OF FEEDBACK SYSTEMS

A measuring system may have many components or elements and it is convenient to consider each such element as a block with its own input–output relationship that is its own transfer function. The blocks representing the various elements of a system are connected to use their functional relationship within the system, thus producing a block diagram for the system.

A generalized block diagram of a simple feedback system is shown in Figure 2. The diagram illustrates negative

feedback, in that the gain around the loop has negative polarity. In this case, the measurand r and the output indication c are in phase, but if in the practical system they are in antiphase, then the amplification A will have a negative sign associated with it and both inputs to the comparator will have positive signs.

In Figure 2 a fraction α of the quantity to be measured (r) is fed in and a fraction β of the output is fed back; α, β and A are transfer functions, while n_1 and n_2 are noise sources at the input and output of the amplifier respectively. Assuming $n_1 = n_2 = 0$, the following equation expresses the situation of Figure 2:

$$\alpha r - \beta c = \frac{c}{A}$$

or

$$\frac{c}{r} = \frac{\alpha}{\beta}\frac{A\beta}{1 + A\beta} \tag{1}$$

The ratio c/r is called the *closed-loop gain*, while $A\beta$ is the *open-loop gain* and both are transfer functions. Provided that $A\beta \gg 1$, $c/r \approx \alpha/\beta$, and c/r is largely independent of A and is simply determined by transfer functions α and β. Thus, the sensitivity of such a system can be changed by altering α or β. In some practical feedback-measuring systems, the feedback also makes α and β well defined. Actually, α and β may alter, but so long as their ratio remains fixed, c/r is well defined.

The main properties of this general system can be summarized as well-defined gain (giving accuracy), wide bandwidth (giving fast response), low or high output impedance (allowing remote indication), reduction in noise effects and extraneous disturbances, and the property of inversion. Negative feedback can be employed to produce instrument high input impedance, and unity-gain feedback often allows noncontact measurement. Measurement devices providing a frequency output usually employ feedback, and feedback can be used to enhance the characteristics of frequency-selective networks.

3 STABILITY CONSIDERATIONS

It is important to investigate the output response of a system, particularly a feedback-measuring system, when the input changes rapidly. This transient response characterizes the stability of the system. A system is defined as stable if its impulse response approaches zero as time approaches infinity. A system is defined as being unstable, if, with zero input, the output increases indefinitely. If the output of a system has continuous oscillation of constant peak-to-peak amplitude, the system is considered to be neutrally stable. Consideration of the degree of stability of a system often provides valuable information about its behavior. Clearly, it is desirable that feedback-measuring systems are stable and respond satisfactorily to rapid changes in the quantity to be measured.

It should be noted that in general for a feedback system, designs for accuracy and stability tend to be incompatible. From (1) accuracy required $|A\beta|$ to be high, while for second- and third-order systems, high $|A\beta|$ produces less damped and unstable systems respectively. In practice, when it is necessary, the open-loop frequency characteristics of a feedback system are tailored such that at quasi-static frequencies, the gain is very high to give the required accuracy at these frequencies, and at frequencies near to unity gain, the loop phase shift is less than -180° to give the required damping characteristics. Feedback-measuring systems often use a combination of mechanical and electrical means of damping. There are a number of useful texts available on the design of systems with control loops, for example, by Jones (1979), and by DiStefano, Stubberud and Williams (1990); *see also* **Article 19, Dynamic Behavior of Closed-loop Systems, Volume 1**.

Systems incorporating feedback involve comparison of two physically similar variables and production of a minimum or null (at point N in Figure 1). In feedback-measuring systems, pervariable (or 'through' variable) balance occurs with force, torque, current, and heat flow, while in the case of transvariables (or 'across' variables), voltage, temperature, and displacement balances are common.

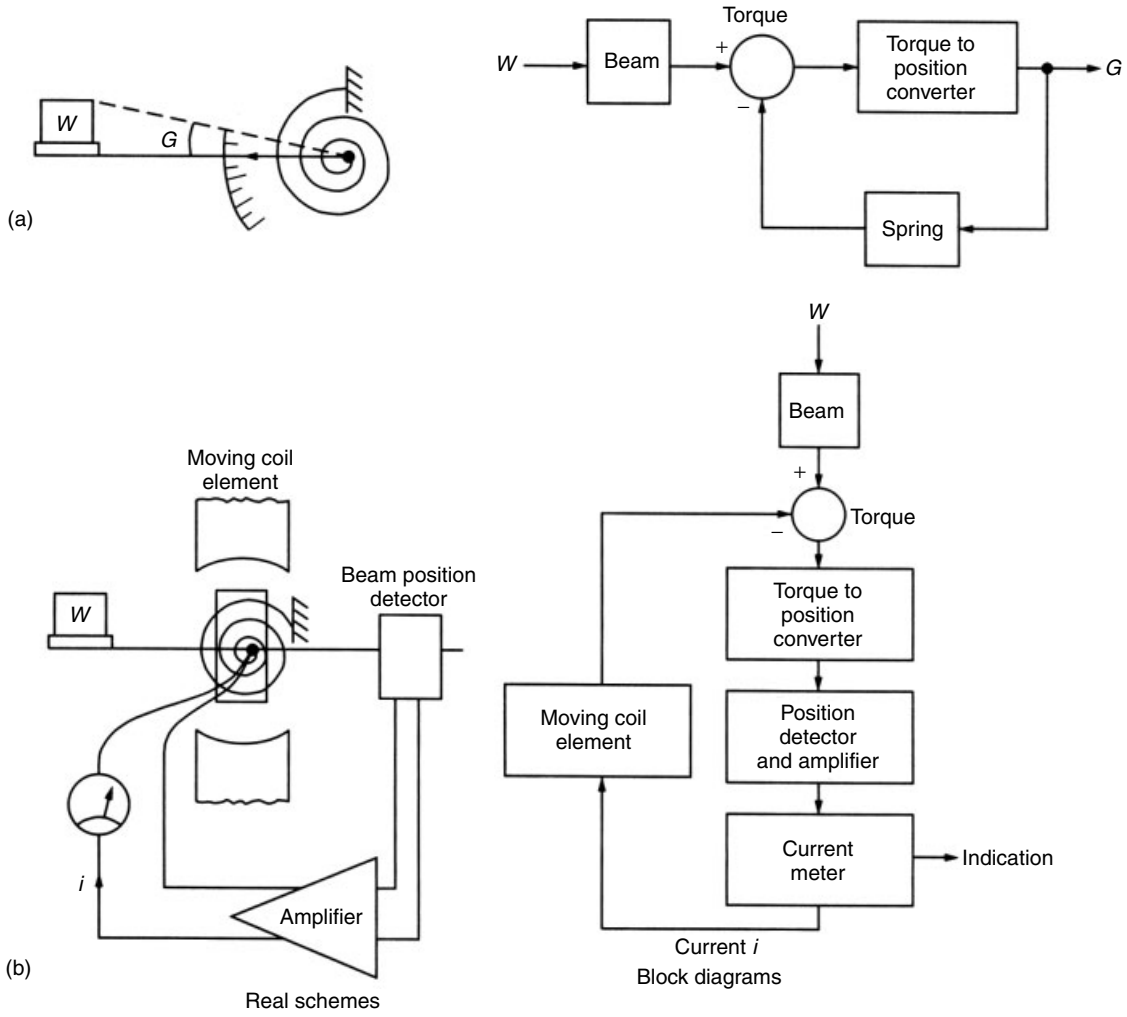

Figure 3. Measurement of small weights: (a) simple system and (b) more complex system. (Reproduced from *Instrument Systems: Functional Architectures from Concise Encyclopedia of Measurement and Instrumentation*, Finkelstein and Grattan, 1994, with permission of Elsevier.)

4 EXAMPLES OF FUNCTIONAL ARCHITECTURE

A simple system for measuring small weights is shown in Figure 3(a). The weights W are placed on a plate fixed to the end of a pivoted beam such as to produce a torque in an anticlockwise direction. A spiral spring fixed about the pivot produces a torque in a clockwise direction proportional to the beam angular deflection G. At some point the torques will balance, and G is an indication of W. The block diagram for this system shows that there is inherent feedback, in that the mechanical indication G produces a torque via the spring constant (feedback path), which subtracts from the torque produced by the weights on the beam (feedin path) to give an error torque. Linearity between G and W is very dependent on the linearity between G and the spring torque.

A torque balance that results in very little beam movement and, therefore, greater accuracy is shown in Figure 3(b). Here, the clockwise torque is produced by the current i in a moving-coil element fixed about the pivot point. Without weights the beam remains stationary and i is zero. When weights are applied, the beam tends to move in an anticlockwise direction, and this movement is detected by sensors, for example, photodiodes, which produce an electrical signal; this is amplified to give current i, which, in turn, produces the counter torque to almost maintain beam balance. As there is little angular movement of the moving-coil element, the current-torque relationship is linear and the electrical output i is proportional to W. The output meter can be some distance from the point of measurement.

Because there is little mechanical movement using this method of measurement, it can be used to measure more rapid changes in W than the fully mechanical scheme of Figure 3(a).

5 FORCE AND TORQUE BALANCE

Force and torque-balance systems are very common and are employed, for example, in precision weighing, for the measurement of acceleration, pressure, flow, level, electrical power, and high voltage. These quantities can be converted to a force or torque; for example, acceleration of a fixed seismic mass produces a force on the mass proportional to acceleration, and a dynamometer movement produces torque on a shaft proportional to electrical power in the movement. The relationship between the quantity to be measured and force may be nonlinear.

The main methods of force and torque balance are shown in Figure 4, where F is the force to be measured and F_f is the balancing or feedback force generated in the particular instrument. For the beam and shaft, F and F_f are converted to torques T and T_f respectively. In each case, the element being used (seismic mass, diaphragm, beam or shaft) is displaced by a small amount in the direction in which F acts before the equilibrium balance $F = F_f$ is achieved. This displacement is the information required by the instrument to generate F_f.

6 BLOCK DIAGRAM AND DAMPING

The block diagram of a basic force (or torque) balance instrument is given in Figure 5(a). The input creates a force (or torque) via, say, a constant K_1, while the output creates the balancing force (or torque) via a precision actuator; if this is of a moving-coil type, it will have the transfer function of a single-order system as shown, where T_1 is the time constant (s is the Laplace complex variable). The mechanical moving element has a second-order transfer function, where m is the mass (or moment of inertia), k is the spring stiffness, and d is the viscous damping (inherent or artificial). K_d is the sensitivity of the displacement sensor and K_a is the gain of an amplifier, while the term $1 + T_a s$ is the transfer function of a (ideal) phase-advance network, providing rate compensation and feedback damping.

In fact this network is likely to be essential to stabilize the system, and this is illustrated by the typical Bode magnitude plots in Figure 5(b). Curve A is the system open-loop gain measured in the region of unity open-loop gain, with $T_a = 0$ *and* $K_a = 1$. The curve has a slope of slightly more than -12 dB/octave at the unity-gain frequency of 10 Hz, and the system is unstable in the closed loop. A suitable phase-advance characteristic is shown as curve P (in practice it is limited as shown by the dotted line), and with this phase-advance in the loop, the system open-loop gain is given by curve B. It is clear that the slope is now less than -12 dB/octave at unity gain and the closed-loop system is stable. A resultant closed-loop step response is shown in Figure 5(c), indicating that the damping is still fairly small. The steady state gain of the instrument or static characteristic $c/r = K_1/K_f$, provided that the open-loop static gain $K_d K_a K_f/k \gg 1$; the accuracy of such instruments is usually better than 1% of full scale. This static gain is chosen to give just sufficient accuracy, because as its value is increased stabilizing the instrument becomes more difficult. Most feedback-measuring instruments incorporate a stability network of some form. Having demonstrated the need and use of such networks, we will not show them in subsequent diagrams. The detailed stability analysis of automatic weight balances has been given by Smirnova

(1960), and Gal'perin and Kolesov (1972). An example of an automatic chemical balance has been given by Smith and Stevens (1959).

7 EXAMPLES OF FORCE-FEEDBACK SENSORS

Various force- and torque-balance instruments are shown schematically in Figure 6, and illustrate the methods of balance, some typical devices used, and the wide application of this form of balance. The arrangement of Figure 6(a) can be used to transmit force information over a long distance. An input movement on a force spring, due to a measurand, creates a torque on a beam with a flexure pivot. Any movement of the beam is detected by the position detector and a current is created in the moving-coil actuator (or force motor) to produce the balancing torque. The output DC is linearly related to the input movement. This two-wire transmitter has a 'live zero' current output, and its sensitivity can be altered by changing the spring stiffness.

A pneumatic pressure transmitter is shown in Figure 6(b). The pressure unit is completely sealed and P_2 could be the pressure at the bottom of a petrol tank, enabling the level of petrol in the tank to be monitored. The output of

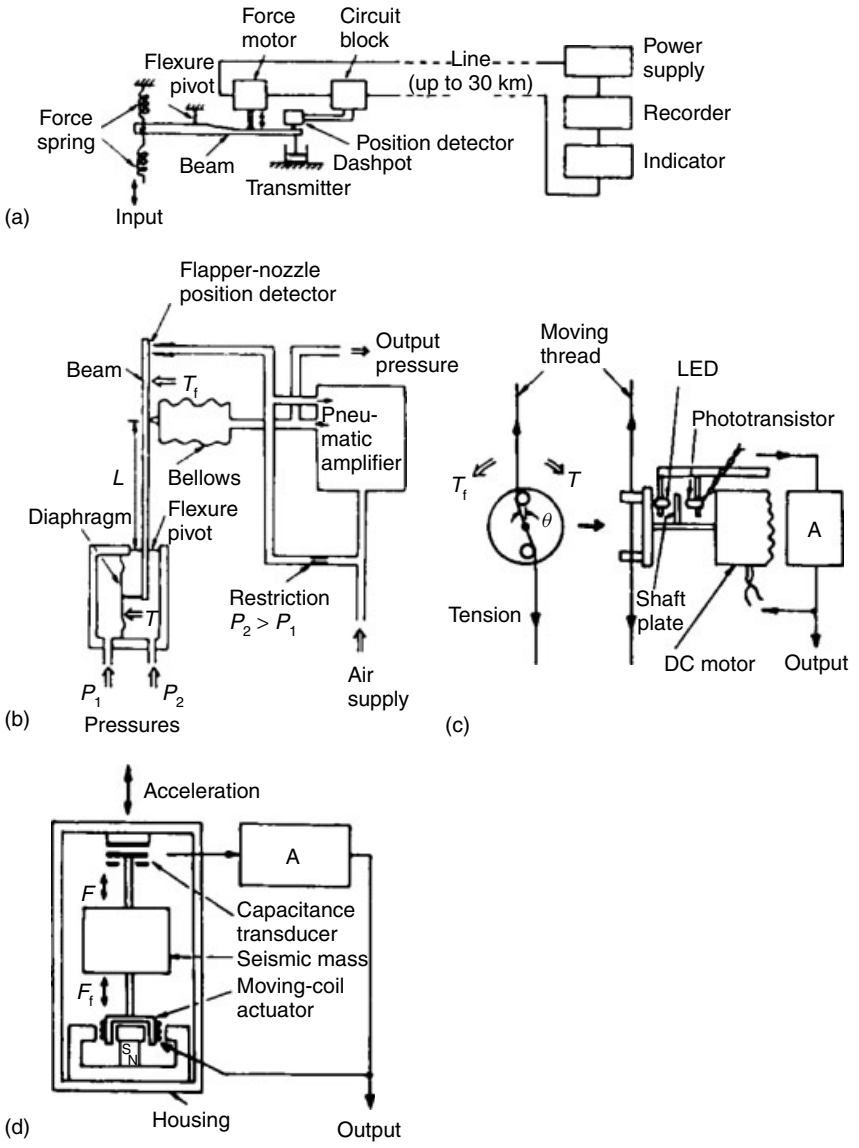

Figure 6. Various force- and torque-balance instruments: (a) two-wire transmitter, (b) pneumatic pressure transmitter, Flexure pivot, $T_1 \Rightarrow T_f$ (c) thread-tension monitor, and (d) seismic-mass accelerometer. (Reproduced from *Feedback in Instruments and its Applications*, Jones, 1979, with permission of Institute of Physics Publishing Ltd.)

this transmitter is air pressure, and the sensitivity of the transmitter is inversely proportional to length L. Various forms of feedback transmitter are used in industry.

The monitor of Figure 6(c) employed in the textile industry uses the torque of a DC motor to balance torque created by tension in the thread; an optical transducer is used to determine the angular position of the motor shaft and the monitor is described by Auckland and Hawke (1978).

In the accelerometer of Figure 6(d), the inertial force derived from the acceleration is balanced by the feedback force created by current in the moving-coil actuator; this has been described by Macdonald (1961).

It should be noted that the moving-coil actuators (both translational and angular) make use of the electromagnetic force created when a current-carrying conductor is at right angles to a magnetic field. The force is at right angles to both the conductor and the field, and is proportional to both the current i_f and field flux density; as a consequence, force-balance instruments employing such actuators usually have linear characteristics with a current as the output. The ratio T_f/i_f may vary from about 0.1 to 50 mN mA^{-1}, while the ratio F_f/i_f may vary from about 0.1 to 20 N A^{-1}.

8 OTHER FEEDBACK-MEASURING SYSTEMS

Feedback is widely used in instruments, and may well be the main structural element of a measuring system, linking the output indication with the measurand. Using feedback, it is possible to improve accuracy and speed of measurement, reduce the effect of interfering and modifying inputs, and allow remote indication and noncontact measurement. The property of inversion assists instrument design, and can assist in provision of digital indication. In general, the main disadvantages are increased complexity, size and cost, but the advent of small cheap integrated circuits has reduced these. The development of transducers and accurate precision actuators seems certain to extend the development and use of feedback-measuring systems.

Besides force and torque balance, other physically similar variables can be balanced in sensory systems: electrical current (and magnetic flux), heat flow, voltage, pressure, temperature, displacement, phase, and radiation, are described by Jones (1979).

Measuring devices where the output is in frequency form usually employ feedback to maintain oscillation. Feedback is used in instruments for control purposes, and the operation of the feedback is similar in both the control and measuring applications; the design for accuracy and stability is basically the same.

1 TYPES OF MODELS AND THEIR CHARACTERISTICS

1.1 Types of models

There are several different types of models for a measurement system interface. The simplest model (Figure 1) is based upon the traditional concept of measurement, which is defined as the comparison of the measurand with some fixed standard unit.

According to the representation scheme, there are physical, linguistic, pictorial, and mathematical models. Mathematical models are by far the most important because of the nature of measurement. In general, a measuring instrument may be described as

$$Z = f(X, Y, W) \tag{1}$$

where Z – output; X – input measurand(s); Y – interference or influence quantities; and W – latent parameters.

According to the level of abstraction, models may be used to represent power flow, signal flow, or information flow. Models may be functional or object oriented, for example, computer-based models implemented in functional or object-oriented programming languages. According to whether the model is based upon the physical attributes and structures or the observed data, functional models may be further classified as data models or physical models.

This section will mainly compare functional and object-oriented models. Other types of models are discussed elsewhere – **Article 13, Signals, Information and Knowledge, and Meaning, Volume 1**; **Article 71, Modeling Methodology, Volume 2**; **Article 104, Models of the Measurement Process, Volume 2**; and **Article 105, Modeling with LabVIEW™, Volume 2**.

1.2 Model characteristics

1.2.1 Functional models

Traditionally, measurement systems are usually modeled with a functional representation. This kind of model typically consists of three basic stages, that is, input stage including a sensor or transducer, signal processing stage and output stage, each of them represented as an input–output functional block, as shown in Figure 2.

Functional representations are well established in measurement and other branches of science. This kind of model is often used as the basis for classification of measuring instruments. They are very useful for determining system static and dynamic characteristics by means of the transfer characteristic and transfer function of each element – *see* **Article 57, Static Considerations of General Instrumentation, Volume 1**.

© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

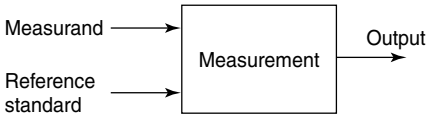

Figure 1. The simplest comparison model.

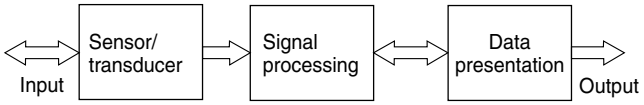

Figure 2. Functional model.

Common to the use of modeling in various problem domains, the intrinsic limitations of a functional model arise from its low level of abstraction. Its reusability is very poor as it is intended for specific systems use. Despite wide use of structural or modular design concepts, it is rather inflexible and often difficult to modify. The size of this kind of model, especially a computer-based one, often increases exponentially with complexity.

As has originated mainly from control engineering, functional models of measurement systems have often failed to address some issues that are of theoretical and practical importance to measurement, for example, operating space of measurement discussed in Stein (1992, 1996). As a result, incomplete descriptions of measuring systems are widely used, and the distinctiveness of measurement science has been seriously obscured. This is probably one of the important reasons measurement science has attracted little theoretical interest when compared with control engineering.

1.2.2 Object-oriented models

The object-oriented approach views a system as a collection of discrete objects that contain both data structure and behavior. The data structures and behavior or operations of an object are defined by a class. An object is an instance of a class. Objects can interact with other objects.

The development of object-oriented methods has been closely associated with computer programming. Use of object orientation first appeared in the development of a discrete event simulation language (Simula) in Norway, Bjørn (1989). As they began to mature in the late 1980s, object-oriented methods have spread to other areas, for example, system analysis and design. Indeed, they have become a general modeling approach in recent years, Rumbaugh (1991).

The power of the object-oriented approach lies largely in its closeness to the natural view of the real world. By raising the level of abstraction from the function to the object level, it focuses on the real-world aspects of a system, providing a better model of the problem space. Its consistence with the real world also provides a unifying platform for all the related activities, for example, analysis, design, and implementation.

Essential characteristics of the object-oriented approach include information hiding or encapsulation, inheritance and piecewise refinement. Objects encapsulate both their data structures and operations and they thus work at a higher level of abstraction. This makes object-oriented models more stable than conventional functional models because changes in operations or functions are decoupled and are localized within objects.

Inheritance comes from the class hierarchy structure, in which a class can have its own data structure and operations, and can also inherit them from its parent class(es). Although the concept originated in artificial intelligence, its inherent existence in class hierarchy structure is unique to object-oriented approach. The reusability of similar objects is one of the most important benefits of object-oriented methods.

The feature of piecewise refinement results from object-orientation and, in particular, its separated external and internal views of an object. Together with encapsulation, it provides a powerful mechanism to achieve high productivity, good maintainability, system integrity, and reliability.

Yang and Butler (1998) have demonstrated the application of object-oriented modeling for a generic measurement system, based upon a generalized measurement concept. A new framework was proposed in Yang and Butler (1997). Depicted in Figure 3 is the architecture of the object-oriented model for measurement systems. It captures important relations in a measurement system and embraces five objects or subsystems, that is, measured object, measuring instrument, human observer, referencing standard, and operating environment. The model represents a measurement system at three system levels: internal (measuring instrument), operational, and environmental.

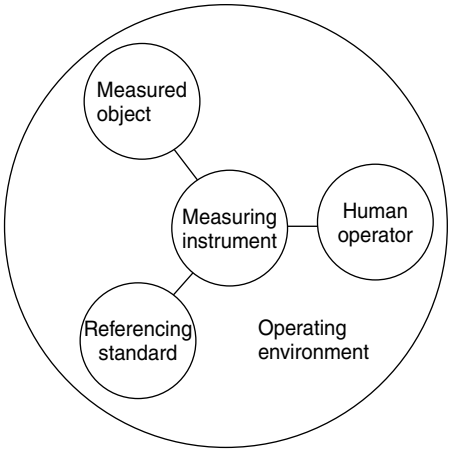

Figure 3. The architecture of an object-oriented model.

2 INFORMATION AND KNOWLEDGE FLOW

A measuring instrument or system may usually be conceptually viewed as a measuring chain, which is defined as a series of elements constituting the path of measurement signal from the input to the output. Sensor interface is the key element of a measuring chain.

The measuring chain can be modeled at different levels of abstraction. At the top level is information and knowledge flow, as the purpose of any measurement is to acquire information and knowledge about the measured system or process. The measuring chain can be viewed as the information path, handling sensing, processing, transmission, storage, and display of information. Although this chain is represented by different terms and blocks, they are invariably of this form.

The information-flow model of a sensor interface represents only the relevant information operation performed by the sensor interface. It typically takes the form of flow or block diagram.

As an information carrier, signal flow always accompanies information flow in a measuring chain. Signal flow is at the intermediate level of abstraction and is commonly used in the analysis, design, and evaluation of measuring instruments. Signal-flow models represent a measuring chain or process as transformed signals in various signal domains, for example, time domain, frequency domain, and time-frequency domain.

Since a signal results from the change or modulation of the energy state, useful signals and unwanted ones (noises) always exist together because of energy interactions. It is thus necessary to apply some form of signal conditioning and signal processing techniques to reduce the effect of noise and to increase the signal-to-noise ratio. Further processing including compensation and correction is also often required. The information is finally decoded or determined with reference to calibration and measurement scale.

Computer tools, both hardware and software, for modeling and processing signals are highly developed. There are many packages commercially available for handling the entire process of signal flows, for example, MATLAB® (http://www.mathworks.com/products/matlab/), and LabVIEW® (http://amp.ni.com/niwc/labview/lv.jsp) – *see* **Article 105, Modeling with LabVIEW™, Volume 2**.

3 ENERGY AND MASS FLOW INTERACTION

At the lowest level of abstraction of the measuring chain is energy or power flow. The system behavior of a measuring instrument and, indeed, a physical system can be modeled on the basis of the energy and power interactions.

One methodology first proposed by Paynter (1961) has been further developed by many researchers. The model is typically presented in a graphic form called a *bond graph* that represents a physical system in terms of power bonds connecting the system elements to so-called *junction structures* that model different types of energy constraints.

The system elements are generally classified into several standard idealized types, namely, storage elements (C-element and I-element), resistor, sources, transformer, and gyrator. There are two types of junction structures, namely, 0- and 1-junctions corresponding to the two generalized Kirchhoff's laws. They are generalized elements and domain-independent, and can describe different systems (e.g., mechanical, electrical, hydraulic, acoustical, thermodynamic, material) in the same way, using analogies in both, their governing mathematical equations and physical concepts.

The bonds, normally labeled and directed, are the energy connections between the two power ports of two interacting elements. Each port represents the physical interaction with other elements or the system environment. The energy flow along each bond or port has a physical dimension of power that can be described with a pair of terminals or variables, flowing in opposite directions.

Such a combination can be found in various physical domains, for example, voltage and current in electrical domain, force and velocity in mechanical domain. One of them may be classified as *effort* variable (e.g., voltage, force), the other as *flow* variable (e.g., current, velocity).

A bond graph has many properties of object-oriented modeling. It can also be easily converted to signal-flow graph and block diagram. An example bond graph for an RLC circuit is shown in Figure 4.

A power-flow model can be used to completely explain the behaviors and characteristics of a physical system such as transducers because it encompasses all the significant energy flows related to the system. System equations governing variables at various ports or elements can be systematically derived from a bond graph. The procedure

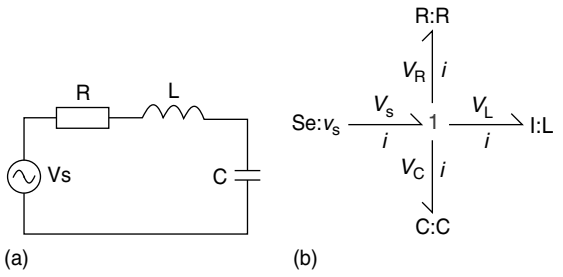

Figure 4. (a) RLC circuit and (b) corresponding bond graph.

may be algorithmized and performed by computer software, for example, ENPORT®, ARCHER®, Camp-G®, and so on.

The modeling of instruments based upon this methodology is given in Finkelstein and Watts (1982). A similar approach was presented in Stein (1992, 1996) as a three-port six-terminal transducer model.

4 SEMIOTIC ISSUES

Semiotics is the study of signs and symbols in various fields, especially language. Its theory explains how the meaning arises during the perception and interpretation of signs or sensory data. Since measurement can be regarded as a symbolic measurement process, there are similar semiotic issues concerned with measurement.

Different models can be used to explain the relationship between signs and their meaning. The most popular one is the triadic model or semiotic triangle developed by Charles Sanders Peirce (1839–1914), as shown in Figure 5.

The semiotic triangle based upon the triadic model consists of three elements:

1. the sign or symbol presented to an observer;
2. the meaning or the concept formed by the observer as the result of the perception of the sign; and
3. the object or referent the sign is referring to.

The meaning of a sign is not only dependent upon the sign itself but also influenced by the observer's experience with the referent. The semiotic model is obviously applicable to an empirical measurement process in which the measurand is the 'object' or 'referent', the measured signal is the 'sign', and the information about the measurand or the measured object can be regarded as the 'meaning' of the signal.

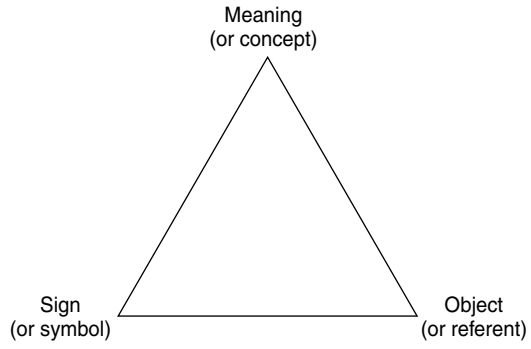

Figure 5. Semiotic triangle.

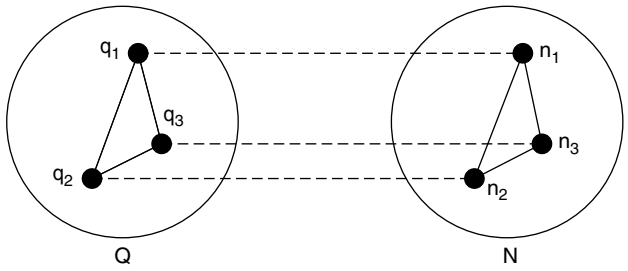

Figure 6. Mapping from observed space to number space.

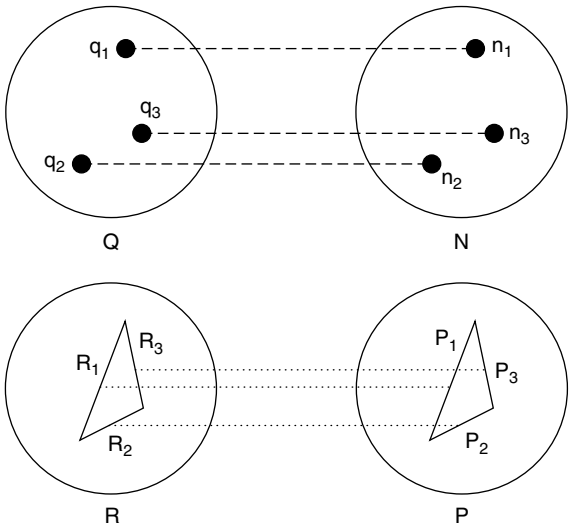

Figure 7. Mapping of individual observation value and the set of empirical relations.

Indeed, the relationship between the human perception and machine perception as shown in the previous block (Figures 6 and 7) is a triadic model, and the 'measurement triangle' in Figure 10 (*see* **Article 13, Signals, Information and Knowledge, and Meaning, Volume 1**) is also a semiotic triangle.

Measurement is primarily concerned with how measurement symbols (signals or data) are related to the observed object(s), whereas semiotics centers on how the symbols are interpreted. They are represented as two sides of the triangle, but they share the common third side, that is, the direct experience of the human observer.

5 SET THEORETICAL EXPRESSION OF INTERFACE CHARACTERISTICS

The nature of a transducer and indeed a measurement process may also be described using the representational

theory of measurement based upon set theory. Measurement may be viewed as a mapping process from an observed space (Q) to a number space (N), as shown in Figure 6.

The possible observation values of the measurand can be represented as a set, for which a set of relations exist. The measurand can thus be regarded as an empirical relational system, including the set of observation values and the set of relations.

According to the representation theory of measurement, as discussed in Pfanzagl (1968), Krantz *et al*. (1971), Narens (1985), and Finkelstein (1982), the nature of measurement is to map the above empirical relational system to a numerical relational system in which there are a set of numbers and a set of relations defined on the set of numbers. There are two mappings involved, one from the set of individual observational values (Q) onto the set of numbers (N), and the other from the set of empirical relations (R) onto the set of numerical relations (P). Together, these sets and mapping define a scale of measurement, Finkelstein (1982). The two mapping processes are also shown in Figure 7.

Given a scale of measurement in addition to the measurement result as numbers, the information or knowledge about the measurands and their relations can be determined.

The above discussions are based upon numerical representation, which can be easily extended to a symbolic representation.

6 ALLOWANCE FOR INFLUENCE EFFECTS

As the sensor interface interacts with other objects including a measured object, reference object, environment, and even possibly a human observer, the energy connections prevailing will undoubtedly influence the behavior and characteristics of the sensor interface. Most models, based upon traditional functional representation, represent well the internal functional aspects of a sensor interface, but are weak in their modeling of the operational and, to some extent, environmental interactions.

In the modeling of measurement systems, functional models tend to be oversimplified, neglecting some important aspects of a measurement system, for example, the coupling interactions between the instrument and the measured object, although some improvement has been made by Finkelstein (1994) and Sydenham *et al*. (1994).

A better approach is object-oriented modeling as it can easily accommodate these external influences. In addition to the conceptual framework, Yang and Butler (1998) have developed an object-oriented model for a generic measurement system. For example, the interactions and influence effects in a measurement system may be modeled as shown in Figure 8.

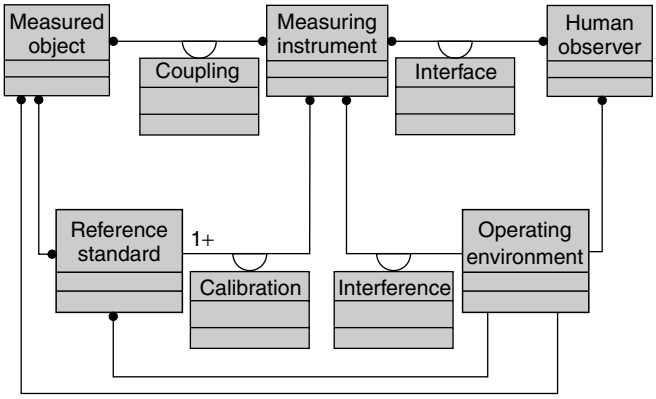

Figure 8. Object-oriented model of measurement systems.

It should be mentioned that the bond-graph model is essentially object oriented, and as such it can also conveniently model the various influence effects.

7 PRACTICAL SENSOR INTERFACE MODELING

A number of practical techniques are available for modeling a sensor interface. They broadly fall into two categories.

The first one is to model the system functions based upon observed or experimental data. It represents the functional relationship between the inputs and outputs of the sensor interface without explicit correspondence between the model parameters and physical attributes.

Traditional techniques of doing the above include regression models, time series models, and system identification. More recently, artificial neural networks are also used for modeling sensor interfaces. It has been proved that a feed-forward artificial neural network with one hidden layer can approximate arbitrary continuous mapping, Cybenko (1989) and Funahashi (1989). An example of three-layered feed-forward artificial neural network is shown in Figure 9.

These traditional techniques and artificial neural networks are normally applied using computer software packages, for example, MATLAB® and its relevant toolboxes.

The second category of modeling techniques is based upon physical modeling, which relates model parameters to physical attributes and structures.

Simple models may be developed manually, but computers have to be employed for more complicated modeling. The models can be developed using general programming languages or special software packages. LabVIEW

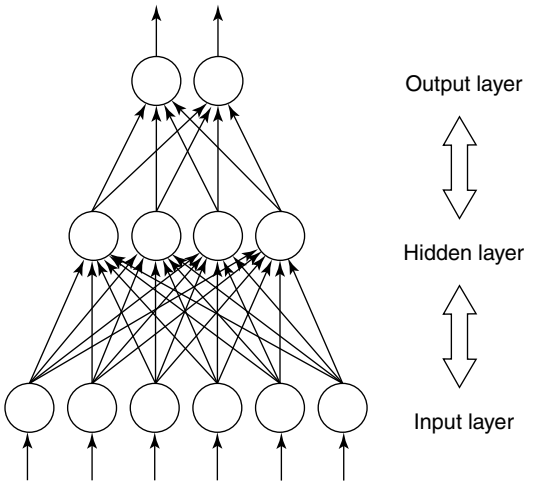

Figure 9. A three-layered feed-forward neural network.

from National Instruments and HP-VEE® (Hewlett-Packard Visual Engineering Environment) are good examples for instrument modeling – *see* **Article 105, Modeling with LabVIEW™, Volume 2**. They are essentially a graphical programming language specially developed for instrumentation and are intended for virtual instrumentation applications.

Another well-established technique is finite element method (FEM) as a mathematical simulation of the actual physical structure. The model is divided into a number of regions known as elements, each of them defined by a pattern of nodes. The method defines an approximation within each element, with appropriate continuity conditions imposed on the interelement boundaries. FEM can be applied to linear and nonlinear structural, thermal, dynamic, electromagnetic, and flow analysis. A number of software packages are commercially available, for example, ANSYS®, EMFlex®, and so on. These make the task relatively easy, for the mathematics is hidden, allowing practitioners to apply the practical inputs needed.

As described in Section 3 here, bond graphs have been successfully applied to build power-flow models. A bond-graph model can be both power and information oriented. There are several software packages for general bond-graph modeling, for example, ENPORT®, ARCHER®, Camp-G®, BondLab®, SYMBOLS®, Modelica®, and so on. One particular package, developed specifically at City University, London for transducer modeling, was MEDIEM (Multi-Energy Domain Interactive Element Modeling).

Further information on the difficulties and shortcomings of modeling of the measurement systems interface is found in the keynote and in other papers of the IMEKO TC-7 Conference held in Krakow, Poland, June, 2002. Key papers are 'in production' with the *Measurement Jnl* at the time of writing.

1 DECIDING THE INPUT AND OUTPUT FORMS OF ENERGY

The information in a transducer is carried and conveyed by signals, which in turn reside in certain power or energy form. Signals can be regarded as the factors of energy or power.

Signals may be classified into various domains according to their energy forms, that is, electrical, mechanical, thermal, radiant, magnetic, and chemical. The above six signal domains, as proposed by Middlehoek and Noorlag (1981), are most commonly used, although it is possible to add additional domains. Some example signals in these six domains are given below.

Electrical: resistance, capacitance, inductance, current, voltage, and so on;
Mechanical: motion and dimensional: displacement, position, strain; length, height, width, thickness, area, volume; velocity; acceleration, vibration, force, load, torque, and so on;
pressure, sound, flow, and so on;
Thermal: temperature, heat, and so on;
Radiant: intensity, phase, frequency (wavelength), polarization, power, and so on;
Magnetic: field intensity, and so on;
Chemical: concentration, crystal structure, aggregation condition, and so on.

A transducer has energy connections with some other elements and the environment. Each connection interface is usually called *power port*. Intrinsically (without considering environmental interactions), a transducer has two or three power ports, that is, input, output, and modulation (or sometimes called *interrogation*), although modulation is not always necessary. Two-port and three-port transducers are shown in Figures 1 and 2.

A two-port transducer is also called *self-generating* or a passive transducer, and a three-port transducer is called *modulating* or active transducer (Sydenham, Hancock and Thorn, 1989; Middlehoek and Noorlag, 1983).

For example, a piezoelectric transducer is a two-port transducer and a strain gauge is a three-port transducer.

Since each power port of a transducer may be in one of the six energy domains, a two-port transducer has $6^2 = 36$ combinations, each as a transducing or conversion mechanism, for example, a piezoelectric transducer has direct conversion from mechanical to electrical.

Similarly, a three-port transducer has $6^3 = 216$ possible conversion mechanisms. For example, a strain gauge connected to a bridge circuit has a conversion from mechanical to electrical, which is modulated by electrical power. With both two-port and three-port transducers combined, there are 252 possible conversion mechanisms.

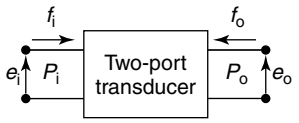

Figure 1. Two-port (self-generating or passive) transducer.

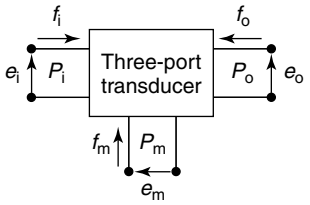

Figure 2. Three-port (modulating or active) transducer.

2 TRANSFORMATION REPRESENTATION METHODOLOGY

The input, output energy, and, if necessary, the modulation energy, together define a conversion mechanism or transduction principle of a transducer.

2.1 3D coordinates and matrix representation

A useful way of classifying transducers and physical effects is to represent the conversion mechanism in 3D space, with the energy form of input, output, and modulation as the three axes (e.g. x, y, and z axes, respectively), and each conversion principle or physical effect can thus be shown as a 'sensor effect cube' (i.e. a cube region in 3D coordinate system), as presented in Middlehoek and Noorlag (1981).

Consequently, each element of a measuring chain may be expressed as 3D coordinates, for example, $[x, y, z]$, where x, y, and z are one of the six energy forms, (Middlehoek and Noorlag, 1981).

On the basis of the 3D classification, Middlehoek and Noorlag (1981) have further proposed a methodology for describing a measuring instrument by joining the 3D coordinates of each stage, with additional lines drawn to show the energy source/flow as well as the signal flow.

Although it is a novel and interesting idea, one has to constantly check to see which element and which coordinate the lines are from, and to which element and which coordinate they go to. With all the coordinates quite similar or the same because only the energy form is given, it is quite difficult to interpret a conversion process.

A simpler approach shows each transducer as a transformation column (Figure 3), with the left and right vertical edges corresponding to the input and output energy form respectively, as presented in Middlehoek and Noorlag (1981) and Sydenham, Hancock and Thorn (1989). A line may be drawn to connect the input and output domains, representing the transformation from one energy to another.

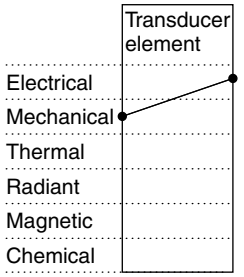

Figure 3. Matrix representation of a transducer. (Reprinted from Sensors and Actuators, Middlehoek, S. and Noorlag, D.J.W., Vol 2, Three-Dimensional Representation of Input and Putput Transducers, page 27, Copyright (1981), with permission from Elsevier.)

All the elements of a measuring chain can be shown as such columns and connected together as a matrix. The conversion lines may be joined together in the transformation matrix of a measuring chain, (Middlehoek and Noorlag, 1981).

For example, assume that a pressure transducer has a mechanical diaphragm to convert the measured pressure to displacement, which is measured by an intensity-modulated transducer. The light intensity is first converted to electrical current by a photodiode and then to a voltage with an amplifier. The corresponding matrix representation is shown in Figure 4.

It is quite straightforward to use this kind of matrix representation to describe conversion processes and energy flows. However, it does not include the modulation input directly, and the representations of energy flow and signal flow are not integrated.

Both the coordinates and matrix approaches proposed are mainly graphic presentations, and, as such, it is neither easy nor efficient to handle these representations using computers. *See also* **Article 109, Structure and Energy in Sensor Systems, Volume 2**.

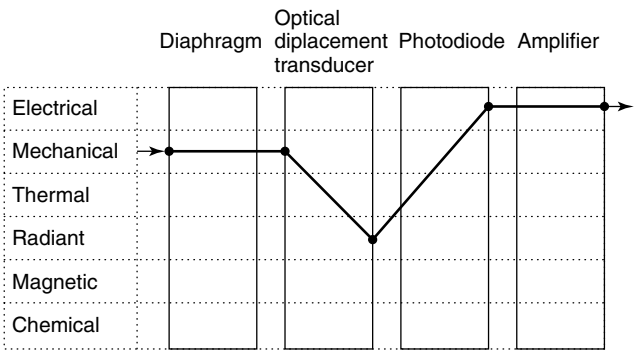

Figure 4. A pressure transducer using matrix representation.

2.2 Transducer conversion logic representation

A better representation is presented here, which combines energy and signal flows. It is compact, highly efficient, and easy to use. It also has a natural link to signal flow diagram and block diagram. This approach may be generally referred to as transducer conversion logic or language.

According to this approach, a two-port (or self-generating) and three-port (or modulating) transducer or element can be represented as

$$x \rightarrow y \tag{1}$$

and

$$x|z \rightarrow y \tag{2}$$

respectively, where x, y, and z are input, output, and modulation of a transducer respectively. They take a form Ds, where s is the signal concerned, D is one of six energy forms, which may be identified with the initials, that is,

E = Electrical

Me = Mechanical

T = Thermal

R = Radiant

Ma = Magnetic

C = Chemical

For example, a piezoelectric transducer has a direct conversion process

$$\mathrm{Me}.F \rightarrow \mathrm{E}.q \tag{3}$$

which converts mechanical force to electrical charge. A strain gauge connected to a bridge circuit can be represented as

$$\mathrm{Me}.\varepsilon \rightarrow \mathrm{E}.R|\mathrm{E}.S_v \rightarrow \mathrm{E}.v \tag{4}$$

where the strain is converted to electrical resistance, which is then converted to a voltage output with voltage modulation.

Of course, longer names can also be used for signals, if necessary. But as the signal domain is specified, it is quite easy to understand standard symbols for variables or signals that are commonly used. In fact, the same symbol, but in different domains, can be easily resolved. This makes the representation more powerful.

The above conversion expression for a three-port or modulating transducer can be expanded to model a more complicated process in which the modulation itself is converted from another source, that is,

$$x|z \rightarrow y \tag{5}$$

where $z = x_1 \rightarrow z_1$ or $z = x_1|y_1 \rightarrow z_1$.

The combined conversion can be expressed as

$$x|(z \leftarrow x_1) \rightarrow y \tag{6}$$

or

$$x|(z \leftarrow x_1|z_1) \rightarrow y \tag{7}$$

Take the above strain gauge connected to a bridge circuit for example; assume the voltage supply is converted from an optical light source, which in turn is controlled by an electric current source, then the process can be expanded as

$$\mathrm{Me}.\varepsilon \rightarrow \mathrm{E}.R|(\mathrm{E}.S_v \leftarrow \mathrm{R}.I|\mathrm{E}.S_i) \rightarrow \mathrm{E}.v \tag{8}$$

where R.I is the light intensity in radiant (R) domain, E.S_v is the voltage source, and E.S_i is the current source.

3 SPECIFYING THE SYSTEM PARAMETERS

The best way to specify the system parameters for a measurement system is to follow a systematic approach, given by Bosman (1978) and the framework proposed by Yang and Butler (1997, 1998). The latter is based upon systems approach and object-oriented modeling.

Figure 5 shows the general model architecture. It captures several important aspects of a measurement system. It encompasses five subsystems: measuring instrument,

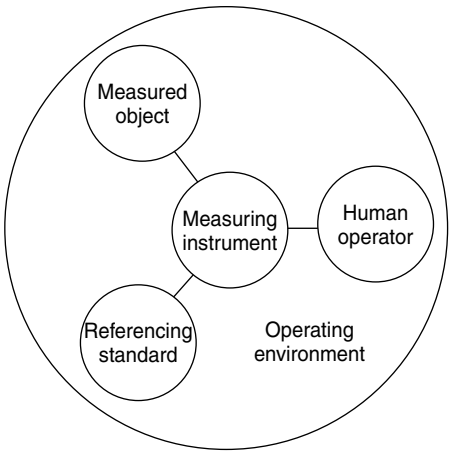

Figure 5. Object-oriented model for system specification.

Table 1. Quality matrix for system specification.

	Internal	Operational	Environmental
Features	Size Weight Principle Material	Data format Coupling method Calibration method Human interface	Power supply Operating environment
Capability	Measurand(s) No. of channels Intelligence	Networking interface	Temperature compensation
Performance	Resolution Measuring range Dynamic range Repeatability Uncertainty Frequency response Drift	Flexibility (object dependence) User friendliness Calibration frequency	Cross sensitivity EMC

measured object (measurand), referencing standard, human operator, and operating environment. The measurement results can be affected by all the five subsystems, with the instrument as the most important one. The system may be considered at three different system levels, that is, internal, operational, and environmental. At each level, important attributes, capability, and performance can be specified. The specification may be presented as a quality matrix as shown in Table 1, which was first used by Yang (1995).

4 PROGRESSIVE DEVELOPMENT USING THE TRANSDUCER CONVERSION LOGIC

The transducer conversion logic or language presented in Section 2 has the key features of object-orientation, such as hierarchy and inheritance, piecewise refinement, and information hiding. Thus, it is essentially an object-oriented approach to description and modeling of a measuring chain and conversion processes.

Since the transducer conversion logic has a very simple syntax and consists of only texts, it can be easily handled and processed by computers. For many transducers, typical conversion mechanisms can be used as default or options, which makes it much easier to automate analysis and design of transducers or instruments.

In addition, the representation can be easily converted to a signal flow or block diagram. The use of the transducer conversion logic can be further demonstrated, taking the above pressure transducer, for example.

The measured pressure is applied to a mechanical diaphragm, whose deformation is sensed by an intensity-modulated optical fiber sensor. The light intensity is then converted to electrical current by a photodiode and finally converted to a voltage with a transimpedance amplifier. The measuring chain may be first represented as

$$\mathrm{Me}.p \rightarrow \mathrm{Me}.\varepsilon \rightarrow \mathrm{R}.I \rightarrow \mathrm{E}.i \rightarrow \mathrm{E}.v \tag{9}$$

where p is the measured pressure; ε is the diaphragm deformation; I is the output light intensity from the optical fiber sensor; i is the current output from the photodiode; and v is the amplifier voltage output.

More details about the light intensity modulation can be added as follows:

$$\mathrm{Me}.\varepsilon|\mathrm{R}.S_I \rightarrow \mathrm{R}.I \tag{10}$$

where S_I is the light source, and

$$\mathrm{Me}.\varepsilon|(\mathrm{R}.S_I \leftarrow \mathrm{E}.S_i) \rightarrow \mathrm{R}.I \tag{11}$$

where S_i is the current source.

The latter expression shows that the mechanical deformation is converted to light intensity, with the light source powered by an electric current source. Note that more details can be simply added without affecting the structure.

Assume the photo detector is voltage biased, then we have

$$\mathrm{R}.I|(\mathrm{E}.v = \mathrm{const}) \rightarrow \mathrm{E}.i \tag{12}$$

The expanded chain can thus be expressed as

$$\mathrm{Me}.p \rightarrow \mathrm{Me}.\varepsilon|(\mathrm{R}.S_I \leftarrow \mathrm{E}.S_i) \rightarrow \mathrm{R}.I|\mathrm{E}.S_v \rightarrow \mathrm{E}.i \rightarrow \mathrm{E}.v \tag{13}$$

In fact, this expression may be easily converted to a block diagram as shown in Figure 6.

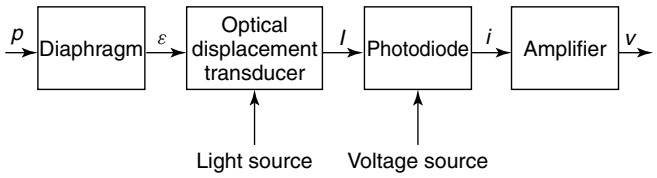

Figure 6. Block diagram of the pressure transducer.

5 USE OF TOOLS TO SUPPORT SENSOR INTERFACE DEVELOPMENT

The complete process of sensor interface development starting from requirement and specification encompasses several important stages, namely, design (including modeling, simulation, optimization), construction, test, and evaluation. Various tools and methods, especially computer-aided tools, are needed during the development process.

Computer-aided design (CAD) is widely used in engineering design, and there are many commercial packages, for example, AutoCAD®, Pro/ENGINEER®, SolidWorks®. There are also software packages for both design and manufacturing, that is, CAD/CAM (computer aided manufacturing) tools. In addition, CAD packages are also available for electronic or optical design.

Modeling and simulation have become increasingly important in product development. As discussed in the previous article, mathematical modeling may be carried out using some software packages, for example, MATLAB®, LabView®, and so on. These models may be implemented as traditional procedural algorithms or as the more recent object-oriented programs – *see also* **Article 105, Modeling with LabVIEW™, Volume 2** and **Article 71, Modeling Methodology, Volume 2**.

The finite element method (FEM) is a very powerful tool and can be applied to linear and nonlinear structural, thermal, dynamic, electromagnetic, and flow analysis. A number of software packages are commercially available, for example, ANSYS®, EMFlex®, and so on.

The modeling can also be based upon the use of bond graphs. A number of software packages have been developed for this kind of modeling, namely, ENPORT®, ARCHER®, Camp-G®, BondLab®, SYMBOLS®, Modelica®, and so on. One special package developed specifically for transducer modeling is the MEDIEM (multi-energy domain interactive element modeling, Sydenham, Hancock and Thorn, 1989).

Once the transducer models are created, simulation and optimization can be further performed. The criteria for optimization need to be clearly identified and defined, and optimization generally involves analysis of a number of different design configurations and/or parameters. The process can be quite computing intensive and time consuming.

Alternatively, it may be easier to follow the design of experiment methodology (DOE) to experimentally model and optimize the design. One popular methodology is the robust design developed by Taguchi (1986), consisting of system design, parameter design, and tolerance design. There are also software tools available for the use of design of experiment. The design of an experiment may be used together with the above theoretical modeling.

1 THE DESIGN PROCESS

The design of a technical system involves making choices on the basis of criteria (from a list of requirements), availability of parts and materials, financial resources, and time. These aspects play a significant role when designing a measurement system.

Blanchard and Fabrycky (1998) distinguish six major phases of the design process: (a) conceptual design; (b) preliminary design; (c) detail design and development; (d) production/construction; (e) operational use/maintenance; (f) retirement – see also (Sydenham, 2004). Thus, sensor selection is a crucial activity in the systems design process, as it will make a great impact on the production of the measurement instrument and the performance during its entire lifetime and may even have consequences related to disposal.

Design methods have evolved over time, from purely intuitive (as in art) to formal (managerial). The process of sensor selection is somewhere in between: it is an act of engineering, in which the design is supported by advanced tools for simulating system behavior based on scientific knowledge. The basic attitude is (still) the use of know-how contained in the minds of people and acquired through experience.

2 THE REQUIREMENTS

Sensor selection means meeting requirements. Unfortunately, these requirements are often not known precisely or in detail, in particular when the designer and the user are different persons. The first task of the designer is to get as much information as possible about the future applications of the measurement instrument, all possible conditions of operation, the environmental factors, and the specifications with respect to quality, physical dimensions, and costs.

The list of demands should be exhaustive. Even when not all items are relevant, they must be indicated as such. This will leave more room to the designer, and will minimize the risk of being forced to start all over again at a later date. Rework is an expensive process and should be avoided where possible by reducing errors as early as possible in the systems engineering life cycle process. The requirements list should be made in such a way as to enable unambiguous comparison with the final specifications of the designed instrument. Once the designer has a complete idea about the future use of the instrument, the phase of the conceptual design can start.

Before thinking about sensors, the measurement principle has to be considered first. For the instrumentation of each measurement principle, the designer has a multitude of sensing methods at his or her disposal. For realization of a particular sensor method, the designer has to choose the optimal sensor type out of a vast collection of sensors offered by numerous sensor manufacturers.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

3 SELECTING THE MEASUREMENT PRINCIPLE

The design process is illustrated by using an example of a measurement for a single, static quantity: the amount of fluid in a container. The first question to be answered in this case is in what units the amount should be expressed – volume or mass. It is important to have a sound understanding of the physics involved and the circumstances of the situation. These may influence the final selection of the sensor.

Figure 1 shows the various measurement principles that could be used in this case:

A: the tank placed on a balance, to measure its total weight;
B: a pressure gauge on the bottom of the tank;
C: a gauging-rule from top to bottom with electronic readout;
D: level detector on the bottom, measuring the column height;
E: level detector from the top of the tank, measuring the height of the empty part.

Obviously, many more principles can be used to measure a quantity that is related to the amount of fluid in the tank.

In the conceptive phase of the design, as many principles as possible should be considered, even unusual or unorthodox ones. On the basis of the list of demands and not as a 'hunch', it should be possible to find a suitable candidate principle from this list, or at least delete many of the principles, on the basis of arguments.

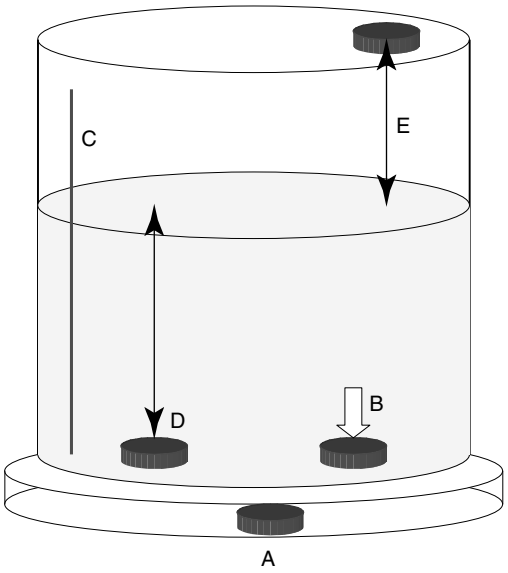

Figure 1. Measurement principles for the amount of fluid in a reservoir.

For instance, where the fluid must remain in the tank during measurement, principles based on volume or mass flow are excluded. If the tank contains a chemically aggressive fluid, a noncontact measurement principle is preferred, placing principles B, C, and D lower on the list, and so on.

Also, method A can possibly be eliminated because of its high costs for large containers.

In this way, the conceptual design ends up with a set of principles having related pros and cons, ranked according to the prospects of success.

4 SELECTING THE SENSING METHOD

After having specified a list of candidate principles, the next step is to find a suitable sensing method for each of them. In the example in Figure 1, we will further investigate principle E, a level detector placed at the top of the tank. Again, a list of the various possible sensor methods is made. This may be

1. a float, connected to an electronic readout system;
2. an optical time-of-flight measurement;
3. an optical range measurement;
4. an electromagnetic distance measurement (radar);
5. an acoustic time-of-flight (ToF) measurement; and so on.

As in the conceptual phase, these methods are evaluated using the list of demands, so not only the characteristics of the sensing method but also the properties of the measurement object (liquid level) and the environment should be taken into account. For the tank system, the acoustic ToF method could have an excellent chance because of being contact-free; or just the contrary, for instance, because of possible high temperatures. In this phase, it is also important to consider methods to reduce such environmental factors (*see* **Article 16, Reduction of Influence Factors, Volume 1**). Anyhow, this phase ends up with a list of candidate sensing methods with merits and demerits with respect to the requirements.

5 SENSOR SELECTION

The final step is the selection of the components that make up the sensing system. Here, a decision has to be made between a commercially available system and the development of a dedicated system. The major criteria are costs and time: both are often underestimated when a new development is considered.

In this phase of the selection process, sensor specifications become important. Sensor providers publish specifications in data sheets or on the Internet. However, the accessibility of such data is still poor, making this phase of the selection process critical and time consuming, in particular for nonspecialists in the sensor field.

Computer-aided sensor selection programs are under development and are partly realized, but up to now their use has been limited. A prerequisite for a general, successful tool facilitating sensor selection is the continuous availability of sensor data on the Internet, in a more standard format, and regularly updated. A good start is www.globalspec.com.

Obviously, the example of the level sensor is greatly simplified here. Usually, the selection process is not that straightforward. Since the sensor is often just one element in the design of a complex technical system, close and frequent interaction with other design disciplines is necessary.

More detail is given on the systems engineering process in **Article 63, Outline of Systems Thinking, Volume 2**; **Article 64, Executing A Measuring System Design, Volume 2**; **Article 66, Phases of System Life Cycle, Volume 2**; **Article 67, Principle of Concept of Operations (ConOps), Volume 2**; **Article 68, Setting the System Boundaries, Volume 2**; **Article 69, Requirements Allocation, Volume 2**; **Article 65, Life Cycle Concept, Volume 2**; and **Article 70, Measuring System Design Methodologies, Volume 2**.

1 ROLE OF MATERIALS IN SENSOR CONSTRUCTION

A report of the Fellowship of Engineering, RFE (1983), classified materials as having two main roles.

In their active role, they are 'hosts of potentially useful scientific phenomena, and always bring about a conversion of energy (or information) from one form to another'. They can provide this conversion using a gas (such as in a filled thermometer), fluid (liquid crystals in a display), or a solid (piezo-electric material in an accelerometer).

In the sensors of measuring systems, energy conversions are concerned with the provision of information about the physically existing world; modulation of an energy link carries the required information from the system being studied to the observer.

In their passive role, materials provide the capability to support, connect, control, contain, or display the sensing phenomenon provided by the active components of a constructed object.

All passive materials are active to some degree in that they respond to one or more forms of external energy. They are not, however, regarded as transducer materials unless the active transduction action is deliberately enhanced and controlled. For example, normal passive structural steel has mechanical hysteresis that varies far more than it does in the active instrumentation alloys processed to make precision springs and load cells.

Another characteristic often exhibited in a sensor material is reversibility of the transducer action. For example, piezoelectric material will produce electric charge when its shape is deformed; conversely, when an electric charge is supplied to it, the shape changes. Not all materials exhibit this.

Sensor materials ideally provide a linear, or at least reproducible, energy transformation. Efficiency of the energy transformation is usually less important than its all-important fidelity.

The concern of technology for producing sensor materials is to enhance the efficiency of the information transformation action. A requirement is also that the transduction action remains constant regardless of time and the in-service level of influencing variables and operational signals.

Some sensors rely on loss of some of their mass to produce signals. Examples include many chemical sensors where intimately related mass/energy transformations take place; and special, electrically resistive, tape used to monitor the abrasive level of magnetic recording tapes, whose resistance rises as the tape is worn away. In these cases, the design aim is to prolong the useful sensing life, usually

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

by increasing the sensing sensitivity, thereby requiring less mass consumption per unit time.

By the traditional design methodology, a sensor is created from a selected mixture of different active and passive materials, their integration chosen to enhance the sensing effect while attenuating undesirable internal and external influence effects.

In contrast, the modern integrated microelectronic form of sensor makes use of a common base material that is modified to enhance the sensing parameters while adequately controlling the nonsensing ones. In this microelectronic sensor form, highly pure silicon is doped, with a range of materials, at minute levels of impurity to make it sensitive to one of a wide range of measurands in certain positions in its bulk. By use of masks and other processing techniques – *see* **Article 162, Principles of MEMS, Volume 3**; **Article 163, Uses and Benefits of MEMS, Volume 3**; **Article 164, Principles of MEMS Actuators, Volume 3** – the doping and etching can be made to produce both active and passive areas in the two-dimensional and three-dimensional geometry of a single chip of the host material. Here, the technology is required to also control the passive properties.

Another class of integrated sensor is the fiberoptic sensor, wherein a basic element – the optical fiber – is modified by a range of methods to form many different sensors.

Many transduction principles in use today were discovered as physical and chemical effects in the nineteenth century (Sydenham, 1979). The twentieth century has been a period of enhancement of the passive and active uses of materials; their use in sensing systems requires extensive interdisciplinary understanding.

Three main groupings of material types that find application in measuring systems are

- metals
- ceramics, including semiconductors here for convenience
- plastics.

Depending on composition, processing, or application arrangement, these variously form either active or passive components.

Optical materials are covered in **Article 210, Optical Transducers for Chemical Measurements, Volume 3**; **Article 89, Optical Materials, Volume 2**; and **Article 91, Light Sources and Detectors, Volume 2**.

Brief mention is also needed of the many natural materials that were once commonly used, such as wood, leather, bone, ivory, mother of pearl, tortoiseshell, and the like. In general, these are rarely used now because of their relatively high cost, problems of supply, legal restrictions on species protection, and lack of uniformity of properties of the materials.

2 METALS

This group comprises the common, relatively inexpensive, base metals and alloys such as steel, brass, aluminum, and copper. Also used are special metal alloys such as Invar™, Ni-Span C™, Nichrome™, and others sold under proprietary names.

Literature on the common metals is widely available, especially on those used for structural purposes. Information on properties of the specialist metals, however, must usually be obtained directly from the alloy makers.

The common metals have found time-honored acceptance as passive engineering constructional materials due to their ease of working, wide temperature operating range, general availability, well-known history of performance, and range of useful structural properties.

The engineering use of metals is covered extensively in terms of analysis of their upper working load limits. Their use in measuring systems, however, is often more concerned with allowable deflection and stiffness under a working load.

Table 1 is a representative list of the metals used in instrument construction. Typical applications are given to indicate, not prescribe, which to use.

3 CERAMICS

The ceramic group of materials (glasses and semiconducting materials are included here but are not strictly defined as such) provide for such functions as thermal insulation or conduction, high-temperature mountings, and can provide very useful transduction processes for use as both sensors and actuators. While the use of ceramics is less common in instruments, they can be vital because they augment metals and plastics by providing properties the latter two cannot (Ichinose, 1987). Table 2 lists representative ceramics used in instrument construction along with some typical applications.

Silicon semiconductor material is the key to the advance of many miniature sensors and actuators, *see* **Article 162, Principles of MEMS, Volume 3**; **Article 163, Uses and Benefits of MEMS, Volume 3**; and **Article 164, Principles of MEMS Actuators, Volume 3**.

More information is provided on the ultrasonic use of ceramics in **Article 118, Ultrasonic Sensors, Volume 2**; **Article 119, Ultrasonic Instrumentation Principles, Volume 2**; and **Article 120, Ultrasonic Instrumentation Design, Volume 2**.

Table 1. Metals commonly used in instrument construction.

Metal	Application
Commonly available passive metals (often alloyed)	
Aluminum	Panels, mountings, leads, fittings
Brasses (copper–zinc alloys)	Diaphragms, mounts, contacts, springs
Bright steel (often hardened)	Frame, panels, shafts, gears, machined parts, pins, clips, springs, cams, knife-edges, pulleys, chains, flexure strips
Bronzes	Cast frames, cast mechanisms, bearings, gears, cams
Copper	Leads, printed circuit connections, connectors contacts, heat sinks, heat conductors, shielding
Iron	Castings, temperature compensation
Nickel	Corrosion resistant needs, temperature match with glasses
Platinum, Silver, and Gold	Contacts, electrodes, corrosion resistant layers
Solders (silver, tin–lead)	Connections, contact materials
Stainless steel	Springs, support frames, panels, shafts, flexure strips
Special passive alloy groups	
Beryllium–copper and phosphor–bronze (copper–tin)	Springs, sealing diaphragms
Copper–nickel, such as Monel	Corrosion resistance
Copper–nickel–chromium, such as Mu-Metal	Magnetic shielding
Nickel–iron, such as invar, and Ni Span-C	Temperature stable parts Minimal mechanical hysteresis
Nickel–chromium–iron, such as Hastellow C	Diaphragms, springs
Nickel–chromium, such as Nichrome	Electrical heaters
Silicon–iron	Transformer laminations
Active metals for sensing applications	
Bimetal strips	Temperature actuators and detectors
Electrical resistance alloys	Stable resistors, strain gauge foils
Load cell materials	Diaphragms, load cell structures
Magnetic alloys	Thermomagnetic effects, magnetic detectors
Nickel alloys	Magnetostriction
Thermally sensitive electrical resistance alloys and thermocouple alloys	Temperature sensors

Table 2. Some ceramic materials used in instrument construction (From Ichinose, 1987).

Ceramic type	Application
Passive constructional roles	
Alumina	• Heat resistance support
Beryllia	• Heat conducting support
Fused silicas	• Low TEMPCO parts
Graphite	• Heat resistant support, colloidal lubricant
Hydroxyl apatite	• Artificial bones and tooth root replacement
Manganese oxide	• Insulators, IC substrates
Silicon carbide	• Cutting tools, low-wear surfaces
Zirconia	• High-temperature mechanisms.
Active sensing roles	
Alumina	• Sodium batteries
Barium titanate (a PZT)	• Piezoelectric sensing and actuation
Ferrites	• Recording heads, RF transformer cores
Silicon dioxide	• Optical fibers
Stable zirconia	• Oxygen detection
Tin oxide	• Gas sensor
Zinc oxide–beryllium oxide	• Voltage-dependent resistor.

Source: Reproduced from *Introduction to Fine Ceramics: Applications in Engineering*, Ichinoise (1987) © John Wiley & Sons Limted.

A useful introductory text on fine ceramic materials is Ichinose (1987) from which much of this explanation is extracted. More detailed data must be sought from the makers because ceramics, like plastics, are materials with very complex formulae; numerous controlled production factors decide the final performance.

Some instrument ceramics are made with reasonably straightforward, specialized processes that convert natural materials such as sand and clays into the final form. Examples here include the manufacture of fused silica (needing electric arc refining of special sands) and insulating porcelains (liquid pug is cast in molds, followed by drying, and then high-temperature firing).

The advanced materials, so-called hi-tech forms, are much more complex to manufacture. These fine ceramics require to be manufactured using highly refined raw materials, rigorously controlled composition, and strictly regulated forming and sintering.

Production of ceramic powder, the starting material of many fine ceramics, is made with several processes, each being complex and needing expensive plant investment. The powder is formed into the required shape by one of five main sintering processes such as

- die casting
- rubber mold pressing
- extrusion molding
- slip casting
- injection molding

The item is then sintered to bring about the minimum system energy through densification of the powder. These processes require high temperatures (1400–1800 °C) to be present while the pressing action is in place. Final mechanical properties are decided by some twenty major parameters, each needing strict control of several parameters.

To illustrate the complex productions involved, consider making silicon 'chip' sensors. This is a long, many-stage process that requires a plant that is so expensive that many countries cannot afford to have such facilities. The process starts by pulling a pure silicon crystal, followed by zone refining it by sweeping it with heat. This is vital to obtain the highest purity material.

The quite large crystal is then sliced and polished to form thin wafers of pure silicon. These are subjected to several similar cycles of masking, doping, and developing to form the miniature electronic and mechanical components within the silicon. Vacuum deposition is then used to add the metal connections.

The silicon die is then tested and mounted on a support package, electrical leads being bonded from the die to the connection pins.

Finally the product is tested, packaged, and labeled.

Most silicon microelectronic manufacturing plants are built to make electronic circuits and, as such, are not always capable of providing the processes needed for certain sensor manufacturing needs – micromachining needed in MEMs forms, for example, requires special additional processes.

Once a ceramic or semiconductor item is made, it cannot be easily remanufactured, so these components must be ready formed and processed for specific applications. The high costs of manufacturing plant must be supported by large-volume production; the designer of small-runs of sensors has to make use of stock proprietary forms.

4 PLASTICS

Plastics have steadily displaced metals in many instrument application areas, such as in frames, in cases, and in many precision mechanisms. Caren (1988) summarizes their place well.

Plastics permit a greater amount of structural design freedom than any other material. Plastic parts can be large or small, simple or complex, rigid or flexible, solid or hollow, tough or brittle, transparent, opaque or virtually any color, chemical resistant or biodegradable, and materials can be blended to achieve any desired property, or combination of properties. The maximum temperature of operation of selected plastics is constantly being raised, being now well over the boiling point of water.

However, success in their use is very much affected by the part's design and processing. The designer's knowledge of all of these variables can profoundly affect the ultimate success or failure of a consumer or industrial product.

Plastics fall into two major groupings

- thermoplastics, which can be melted and reused;
- thermosets, which are chemically changed by the manufacturing process and cannot be remelted

Typically, thermoplastics are shaped by melting, forcing the (often highly viscous) liquid into the desired shape, and allowing it to freeze. Injection molding (for bulk material) and thermoforming (sheet material) are processes of this type.

Thermosets are compressed into a mold and heated, the heating process changing the chemical structure and forming the molding shape. However, these simplistic divisions are blurred, and injection-moldable thermosets are available. The heating required to set off the thermoset is also often aided by catalysts (as in dough molding) and the chemical change can be brought about by catalysis alone with no external heat as in composite lay-up (for example, fiberglass) construction.

Crystalline thermoplastics are generally stronger, more chemically resistant, and often self-lubricating. Examples are polyethylene, nylon, polypropylene, and acetal. Amorphous thermoplastics such as polystyrene vinyl (PVC), acrylic, and polycarbonate are more easily formed, decorated, and fastened and can be transparent.

Many plastic materials can be formed as foams with closed or open cell structure. Polystyrene foam is familiar as a rigid, yet light and strong, packaging material. Polyurethane foams can be rigid though soft for applications like cushioning material in instrument carry cases. Materials can also be made to foam during molding, forming a solid external skin with a foam core. This provides structural benefits (high strength to weight) and material savings as well as molding benefits from a reduced cycle time.

Individual plastic materials are supplied with a wide range of properties affected by the molecular weight of the bulk material, additives for modification of production performance and final product properties, and coloring agents. Suppliers have ranges of product to suit different processes and provide specialty blends for specific requirements.

An important subset of thermoplastics is the elastomer group. These are plastics with rubber-like elastic properties. SBR (styrene butadiene rubber) is used for protective boots,

Table 3. Plastics used in instrument construction. (Compiled from industry catalogs – a guide only – manufacturers must be consulted in making a detailed choice).

Common plastic name	Application
Passive constructional roles	
ABS	• Telephone handsets, high-quality cabinets, PCB plugs, transparent covers – is platable
Acetals	• Gears, pawls, links, cams, cranks – is platable
Acrylics	• Optical lenses and covers
Cellulosics	• Blister packaging, poor durability
Epoxys	• Circuit boards, hard surfaces
Fluoroplastics (includes PTFE)	• Electrical insulation, bearings, valves, linings, implants
Nylons	• Gears, snap-on parts, hinges, guide rolls, cams, plug connectors, brush holders, print wheels, hot-water valve bodies, switches, coil formers press buttons, bearings
Polycarbonates	• Tough, transparent structures, lenses, safety enclosures, cases
Phonelics	• Low-cost molded parts
Polyimids	• High temperature, low-creep, instrument parts
Polyesters	• Resin for glass, carbon and aramid fiber-based composites, containers, films
Polyethylenes	• Nozzles, containers, cable clamps, cases, cable insulation
Polystyrenes	• Lamp shades, diffusers, instrument frames, panels, video cassette parts, foam thermal insulation and packaging
Polypropylenes	• Appliance housings, cable sleeves, sterilizable parts
Polyurethane	• Cushion soft to glass hard needs, fascias, tubing, cords
Poly (vinyl chloride)	• Cable ducts, pipes insulation on cables switch covers, medical parts
Silicones	• Flexible seals, protective covers, molded seals *Active sensing roles*
Polyvinylidene fluoride (PVDF)	• Piezo electric
Polyacetylene (and others)	• Electrical conduction

shock-absorbing mounts, and grommets. Polyurethane (a thermoset) can be made in hardness ranging from glass hard to soft and rubbery. It is prepared by mixing two liquids and finds applications in cast-in-place elastic elements. Silicone rubbers provide rubbery consistency with excellent chemical resistance, although if used in contact with sensitive items (such as foil strain gauges), a grade should be chosen which does not emit acetic acid on setting.

Some combinations of polymers can also be mixed together to form copolymers (where the chains of the different materials cross-link) or alloys in which the ingredients remain discrete. ABS is a typical terpolymer (a copolymer of three ingredients) while PC/PVC is an alloy.

While the range of plastic materials available presents a large spectrum of opportunity for the designer, the possibilities added by additives, fillers, and reinforcers increase this enormously. These can modify finished part strength, impact resistance, density, and color. The performance of the material in production can also be affected. Materials can be added to plastics in bulk, during molding or by hand lay-up.

In general, the measuring instrument and sensor designer need only be aware of the possibilities arising from the use of additives, leaving detailed recipes to the plastics supplier and manufacturer. Such additives as biocides, fungicides, heat and light stabilizers, and antistatic agents can be quite vital to the success of a product, especially those that relate to dimensional stability and to life.

Fillers are mainly inorganic materials such as talc, kaolinite, feldspar, and glass microspheres. They can improve processability, reduce shrinkage, increase stiffness, and reduce cost.

Reinforcers are fibrous materials including various glass fibers, aramid, carbon, and more exotic materials. Their major use is increasing strength and stiffness, often anisotropically, providing finished products, which, on a strength-to-weight basis, are often comparable with high-strength steels.

All additives can affect surface finish and subsequent decorative processes, those added for physical property improvement frequently adversely affecting the finish.

The selection of plastics is a highly skilled task. Plastics manufacturers, however, provide extensive data and design services including electronic forms of adviser, Endura (2004) and Rapra (2004) being examples of guides. Kroschwitz (1990), Rubin (1988) provide greater and more generic detail.

Table 3 is provided as a first guide to the type of plastics commonly used for the construction of various instrument parts.

5 INFLUENCE EFFECT ON MATERIALS

As explained elsewhere – *see* **Article 16, Reduction of Influence Factors, Volume 1** – all materials respond, to some degree, to a range of external influence effects.

Table 4. Physical effects give rise to unexpected activity in materials.

Term describing effect of	Input variable on (most are reversible)	Output variable
Gas law effect (at constant volume)	Pressure	Temperature
Electrochemical effect	Electric current	Material decomposition
Electromagnetic effect	Electric current	Force
Electrostatic effect	Electric voltage	Force
Faraday effect	Magnetic field	Polarization angle
Hall effect	Magnetic field	Current/voltage
Magnetoresistive effect	Magnetic field	Electrical resistance
Magnetostrictive effect	Magnetic field	Length
Photoelastic effect	Strain	Optical polarization
Piezoelectric effect	Force	Charge
Piezoresistive effect	Force	Electrical resistance
Poisson effect	Longitudinal load	Transverse length
Pyroelectric effect	Heat	Charge
Rectifying effect	Electric current	Flows only one way
Resistance–effect	Strain	Electrical resistance
Self-heating effect	Electrical power	Temperature
Shear modulus effect	Shear load	Length
Temperature velocity effect	Temperature	Velocity of sound
Thermoelastic effect	Temperature	Elasticity
Thermoelectric effect	Temperature	Voltage
Thermoresistive effect	Temperature	Electrical resistance
Young's modulus effect	Tensile load	Length

These can change shapes of passive material support structures and sensitivities of sensing active materials and as such can considerably impact sensor and instrument performance.

Table 4 is provided to assist in identifying likely effects. It lists often-met transduction effects that may give unwanted activity in a material normally regarded as passive or that may alter the active performance. Due attention to such, often unexpected, factors is needed to reach a satisfactory design outcome. Many of the effects are reversible. Generally, only one or two would be expected to be significant in a chosen material but as the system sensitivity is increased more effects become significant.

6 SELECTING A MATERIAL

Metal and ceramic materials tend to be used in instruments to provide design solutions where plastics are unsuited, for instance, where very high temperature and high mechanical stability are needed.

Another factor that dominates the choice of material is the volume of the production run. For small volume runs, tooling costs associated with the often preferred use of plastics are usually very high compared with the cost of computer-controlled machining of metal parts. Ceramics, usually requiring very elaborate manufacturing processes to obtain the forms needed, are often used in stock shapes with minimal machining. Their use is somewhat inhibited by their manufacturing difficulties existing for small volume production.

It might be thought that as materials have been developing since the time of early man, the designer always has at hand materials with the right combination of properties to suit any task. Unfortunately, this is far from the case because the number of well-defined and controlled material properties required is great and each material application will usually involve the need for several particularly stringent properties at the same time. This will be seen in the illustrative case study given in Section 9.

Measuring instruments are made in production volumes ranging from one-off to many thousands but rarely in the numbers seen in consumer electronic goods. Plastic materials, and the production processes required to convert them into products, are generally more suited to high-volume production. For example, injection molding is one of the most widely used processes but the simplest molding dies can cost around $10 000. It is an elegant and versatile process but production runs of less than several thousand inevitably carry a high tool amortization cost per part.

Die-cast metals, once very popular, also can be used but these are falling from favor except where plastics cannot cope because of lack of a key property such as the need to have metal shielding. Even there, however, special electrically resistive, sprayed on and plated coatings can be used to shield the contents of plastic cases.

7 A RATIONALE FOR SELECTING PASSIVE MATERIALS

The first step toward material selection for the passive part of a sensor is to set up the system architecture that will satisfy the operational requirement for the measurement system. This means deciding the functions needed and how they are to be provided as the various needed organic modules.

The module connecting the observed process to the subsequent signal processing and the output actuating device both need an active sensing material, whereas the mountings and following signal processing assembly are made from sufficiently passive materials.

These building blocks, in turn, are made from a combination of parts. This reticulation process eventually identifies the basic components needed, calling for readymade or new parts to be made from appropriate materials.

Crucial in this design process is the simultaneous identification of which salient physical effects, the influence parameters, need to be allowed for.

The passive role of materials in instruments can be found by considering the generalized mechanical restraining purpose of the passive support providing components.

Reuleaux, in 1875, defined a machine as a combination of resistant forces so arranged that by their means the mechanical forces of nature can be compelled to do work accompanied by certain determined motions. As instrument and sensor design is highly interdisciplinary, there are usually many such resistant forces and determined motions to be considered.

In mechanical design, the main system requirement aims to allow movements, in a three-dimensional space, of as many of the six possible degrees of freedom as are needed. These freedoms, for an extended object in space, can occur as three translations and three rotations. A support framework has to hold all six stable so that parts mounted on it are constrained within the required dimensional limits. A slideway allows one degree of translation; a pivot one degree of rotation and so forth.

Two approaches can be used to allow the necessary freedoms in a mechanical system. The first is to make use of materials, selected in shape and type, to form a structure that is effectively nonelastic. This method is known as kinematic mechanical design, *see* **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2**; **Article 81, Principles of Fine Mechanics – Systems Considerations, Volume 2**; **Article 82, Kinematical Regime – Members and Linkages, Volume 2**; **Article 83, Kinematical Regime – Fasteners, Bearings, Volume 2**; and **Article 84, Kinematical Regime – Rotary Motion, Volume 2**. These are formed to allow the needed freedoms and constrain the others. An example is a ball bearing where the rollers and tracks are made to exhibit as little deformation as possible while allowing one-dimensional slide action.

The alternative is to purposefully provide certain parts with elasticity so that movements can occur at intended places. This is known as *elastic mechanical design*, *see* **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 86, Elastic Regime of Design – Spring Systems, Volume 2**; and **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2**. An example is a flexure strip hinge used to allow limited rotation.

In general, kinematic design has the widest applicability but when relatively small movements are needed, its options often cannot compete with the cost-effectiveness and small excursion fidelity of the elastic method.

Once the overall constraint of freedoms strategy is decided, a suitable physical framework is evolved to support the various parts needed to provide the functions. A collection of basic parts set up to provide a particular function is termed a *mechanism*. This, in turn, is formed of members, linkages, joiners, bearings, and parts that provide transfer motion. The classic overview of the detailed design of such parts for fine instruments is given in Trylinski (1971), with a shorter account given in Trylinski (1983).

Parts and roles identified by this top-down design process then allow the choice of material. As can be seen from the abridged list of material properties given in Table 4, the choice of a suitable material can be complex and often impossible to totally satisfy.

8 ALTERING THE ACTIVE AND PASSIVE BEHAVIOR

An often-met difficulty is that the material that must be used is not passive enough to some external influences. Conversely, for sensing use, it may be desirable to increase the activity level. Several methods can be used.

First, unwanted material effects can often be reduced by placing the active part, or the whole unit, in a suitably controlled environment.

Second, some form of compensation can be incorporated. For example, to render a mechanical length formed from a metal bar less variant with temperature, the bar can be mounted end to end with another bar of material that expands in the opposite direction. By use of materials with different TEMPCOs and different lengths, it is possible to set up a system that has closely stable length. In practice, this concept usually needs to apply an opposing parallel action because few materials have negative TEMPCOs.

Another compensation method is to measure the influencing variable and from knowledge of the systematic nature of the activity, change a value in the system at some appropriate place.

The principle of these two compensation methods can be applied to systems in any energy regime. Often, transducers are used to convert energy forms in order to make the comparison and compensatory actuation. An example of this type is the use of a second resistance strain gauge placed in one arm of a Wheatstone bridge interrogation circuit such that its temperature-induced changes cancel out those of the sensing gauge. This second gauge is mounted such that it is not subjected to any strain but is subjected to the same temperature as the sensing gauge. Feedback in instruments is discussed in **Article 113, Force-feedback Sensors, Volume 2**.

There is sometimes a need to increase the effective activity of a material. A commonly used method is to place more than one element in an arrangement that adds or multiplies the effect. An example is the use of a set of series-connected single element thermocouples to form a thermopile. Another example is where the cold junction of a Peltier cooling cell is mounted on a second unit, the temperature difference then being more than one unit alone can provide.

These methods add the effects. A mechanical, hydraulic, pneumatic, or optical lever system can be used to increase a small deflection by simple multiplication.

9 AN EXAMPLE IN MATERIAL SELECTION

As an example of the necessary interplay between the active and passive roles of materials forming a component, consider the materials needed to form a spring and its support framework for a precise and stable weighing balance that is little influenced by its ambient temperature.

The measurement purpose of the spring element (the clearly defined active component) is to produce a reproducible and repeatable elongation proportional to the mass hung on its end.

If the material from which the spring is made changes length with temperature, it will exhibit a displacement error for a fixed load as its ambient temperature changes. This suggests, on first considerations (but see later), that the spring should be made from a material that has a zero thermal coefficient of expansion. Figure 1 illustrates how this coefficient varies in typical instrument materials,

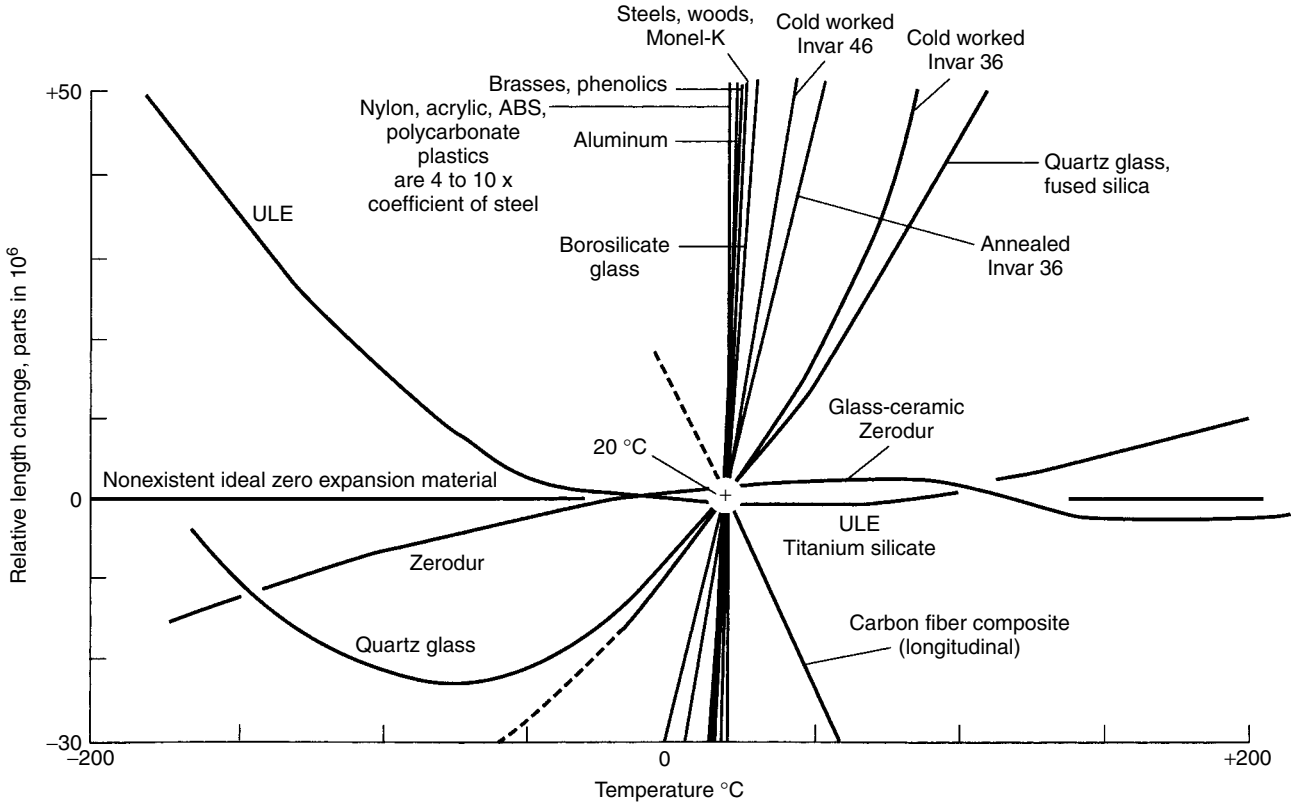

Figure 1. Thermal expansion of selected metals, plastics, and ceramic materials.

showing that some virtually zero coefficient materials are, indeed, available.

However, measurement of spring displacement is made by comparing the length of the spring with a reference support framework that should at first sight be made of a passive material – but again see later.

What is actually required, however, is that the framework and the spring have the same thermal expansion coefficient so that their changes in length track each other as temperature changes. As it is expedient to make a frame from steel, it does appear feasible to use a steel spring, despite its being quite active to temperature effects, because the framework will change length to the same degree as the spring. However, there is another aspect still to be covered.

A vital physical property needed of the measuring spring material is that its modulus of elasticity remains adequately constant with variation of operating temperature – this is expressed as its thermoelastic coefficient or (TEC).

Study of the properties of the steel family shows that its TEC is relatively large. Thus, a steel spring is prone to temperature error in that its weighing sensitivity increases as the temperature rises. For this reason, precision weighing springs made of steel are not suitable unless a temperature correction is applied.

The material needed ideally has a thermal coefficient of expansion similar to structural materials, yet also has a low TEC. No entirely suitable material has yet been developed – a common situation to be faced in instrument design. The nickel–iron–chromium alloys, however, provide some scope. Figure 2 shows how the TEC varies with alloy composition for this family. Note how the alloying ratios are so critical.

Even if the above needs could be met, there is still another important parameter to be considered – the spring should return to the same displacement position when a mass being weighed is removed. This is its mechanical hysteresis. Steels are quite poor in this regard as they obtain some offset with load cycling. Special alloys, such as Ni-Span C™, have been developed that exhibit insignificant mechanical hysteresis, but, unfortunately their TEMPCO and TEC are not at the preferred values.

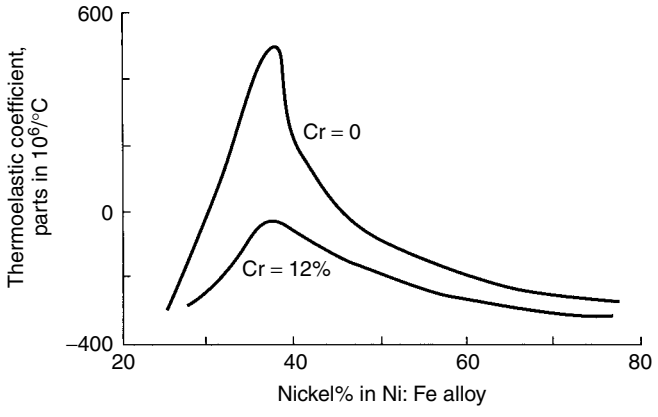

Figure 2. Thermoelastic coefficient variation versus alloying composition for the Ni-Fe-Cr alloys. (Copyright Inco Europe Ltd.)

To make material selection still more complex, the properties mentioned above all may change with history of use, with temperature of operation, and sometimes with level of the present and past history of stress. Additionally, they are usually time-variant, often in nonsystematic ways.

The same considerations apply for the support frame design as that provides the positional reference framework. They are, however, usually of less significance.

In practice, precision springs can be made to only certain performance limits. Use of some form of active or passive compensation can then be used to squeeze a little more sensing performance from the spring. These material limits were gradually met in the evolving design of spring-mass clock movements, finally being replaced by better defined elastic properties of the piezoelectric quartz crystal now commonly used in electronic timekeepers.

The design and operation of highly precise and stable springs is a matter of setting up a system that recognizes the sources of likely error arising from material activity and somehow operates with all of the material restraints in a manner that optimizes the operation. In the case of the spring, this may mean tightly controlling the temperature to keep the spring at its optimum operational condition.

An example of the lengths that are needed is seen in the practical design of a top-performance spring-mass geophysical gravity meter, which is, in effect, an ultrasensitive spring balance that can be carried in the field over rough terrain! To retain the best operational performance, it is necessary to precisely temperature control the spring at all times. The temperature is selected as that where the complex combination of material properties is optimized.

Thus, it is seen that the design of a sensor is not just the procedure of selecting an active material and setting it up within a system of passive supporting and containing materials. To get the best performance sensor design invariably needs complex interaction of material properties with both the active and the passive parts being carefully designed.

The problem of interaction between material properties will be found in any design regime. For example, in optical lens design, obtaining a certain magnification power for a given spectral bandwidth will be a matter of juggling between availability of a few materials having limited ranges of refractive index and varying wavelength dependent transmission losses, *see* **Article 89, Optical**

Materials, Volume 2; and **Article 91, Light Sources and Detectors, Volume 2**.

1 OVERVIEW OF ULTRASONIC TECHNIQUES IN SENSING

Although there are a few different sensing principles for ultrasonic waves, the focus here is on the leading, linear piezoelectric transducers. Individual measurands are represented by the following categories of the transmitted wave parameters:

- propagation or time delay (representing medium flow, wave velocity, range/distance);
- attenuation or complex frequency response (characterizing materials using spectrometry and transmission tomography);
- doppler shift (representing velocity of individual objects);
- resonant frequency (affected by load e.g. deposited mass or fluid level in single frequency and interdigital (IDT) surface acoustic wave sensors (SAW));
- statistical/averaging (e.g. cross-correlation flow measurement, steady state monitoring in alarm/proximity sensors, absorption estimated from reverberation time or scattering, and Doppler or spectral characterization of scatterers such as fish or blood particles).

Influences by other variables are minimized through compensation, numerical correction, noise/drift reduction, and evaluation of methodology. An overview is given by Hauptmann *et al*. (1998).

Piezoelectric transducers are typically highly resonant. Increasing their bandwidth (BW) reduces sensitivity (increasing losses) and is difficult. The upper frequency range is limited by the molecular granularity of physical medium (low-loss ZnO films use GHz range), but common applications use frequencies from 40 kHz to a few MHz. At high frequency f, the wavelength $\lambda = c/f$ is short and the particle velocity high, allowing small transducer size, microelectronic implementation, and use of wave filters and lens for focusing. For typical indicative values of the wave velocity c for several materials, refer to Table 1 in Section 3.

The acousto-optic effect and laser/microwave excitation of piezoelectrics and the glow-discharge effect addressed further, extend measurement principles.

Conversion between the magnetic field and mechanical vibrations is available through the magnetostrictive effect. Unlike Cr-Ni-Co-Fe-based alloys and nickel, it is the new giant magnetostriction of Terfenol (Tb–Fe alloy), rare

earth metals, and some compound semiconductors that offer competitive parameters. Magnetostrictive transducers exhibit significantly larger conversion than traditional piezoceramics, are more robust, heat insensitive, and do not require high voltage, high impedance electric port. Like piezoelectric, the magnetostrictive transducers are reversible (can be used as sensors or actuators). Their ultrasonic applications remain currently in the power area, such as ultrasonic cleaning. Ultrasonic magnetostrictive sensors are likely to emerge soon (http://www.public.iastate.edu/~terfenol/). More detail on ultrasonic methods is given in **Article 119, Ultrasonic Instrumentation Principles, Volume 2** and **Article 120, Ultrasonic Instrumentation Design, Volume 2**.

2 THEORY OF ULTRASOUND

Ultrasonic wave is defined as the vibration of medium particles exceeding the audio frequency (>18 kHz). Field variables (common with the acoustic wave) are particle velocity **v** (vector) and acoustic pressure p in fluids (a scalar) or stress tensor $[T]$, including shear forces in solids or viscous fluids. The ratio $p/|\mathbf{v}|$ or T_{ij}/v_i represents the medium impedance for the relevant vibration mode and the products represent complex power density per unit area (defined for a plane wave).

Ultrasonics in liquids exhibit specific effects, for example, molecular absorption, manifested by a sharp increase of losses in wave propagation at a frequency corresponding to the molecular relaxation time of a fluid (ranging from 30 kHz for carbon dioxide to 10 MHz for hydrogen).

Nonlinear phenomena result from high particle velocities or at high ultrasonic signal frequency or from high pressure level in focused/high energy fields (where either the particle velocity $|\mathbf{v}|$ cannot be regarded as being much smaller than the wave velocity, and the Euler equation governing the wave equation becomes nonlinear, or the flux continuity equation is nonlinear).

They include

- streaming (medium flowing away from transducer's face);
- cavitation (breaking the continuity in a vigorously vibrating liquid and the development of bubbles);
- fog formation (breaking molecules of a liquid medium away from its surface);
- audibility of modulated waves – used in focused beam audio transmission.

3 KEY ULTRASOUND PRINCIPLES USED IN SENSING

The widely used piezoelectric effect offers linear conversion between the stress tensor representing ultrasonic vibration and electric field K received as the output voltage. The mathematical formulation, similar to the one used for electrostatic transducers, represents the class of reciprocal transducers (whereby electromagnetic transducers are antireciprocal). The equivalent circuit uses the dynamic (impedance) type port, (the antireciprocal class uses the mobility type) or else a cumbersome gyrator is required.

The transduction process, best described by single mode relations, can be extended to the tensor form. Detailed, valid-today description of both was given by Mason in the 1940s. For a review of equivalent circuits, refer to Kino (1987). Formulation for magnetostrictive transduction is the same, except for the electric field being replaced by the magnetic field strength H.

Figure 1 presents a single mode transduction (specific orientation of electric and mechanical field) in a thin piezoelectric slice governed by (1a, b).

The voltage E, related to the electric field strength ($\mathrm{K} = E/x$), produces strain ($S = \Delta x/x$) if no external force is applied:

$$\Delta x = Ed \text{ or } \frac{\Delta x}{x} = \mathrm{K}d \tag{1a}$$

The stress in the material ($\mathrm{T} = F/A$) corresponds to free charge Q appearing between the electrodes, manifested as the polarization ($D = Q/A$), if no additional external

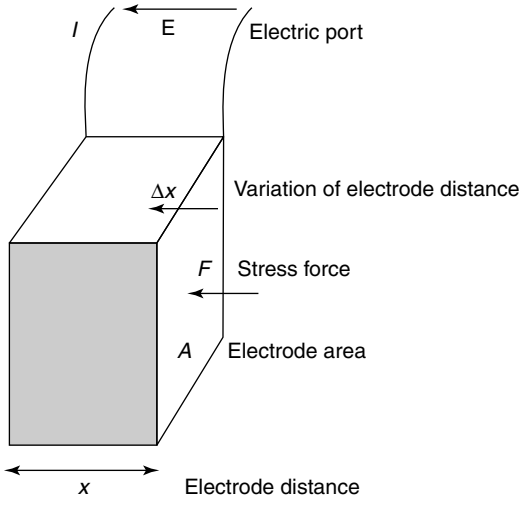

Figure 1. Operation of a piezoelectric transducer: stress F/A causes strain $\Delta x/A$, which produces voltage E (and vice versa).

polarization occurs:

$$Q = Fd \text{ or } \frac{Q}{A} = d\left(\frac{F}{A}\right) \tag{1b}$$

where d denotes the piezoelectric strain coefficient.

Using incremental notation, strain is expressed as the ratio of the material's infinitesimal displacement over the increment of the position along the chosen axis, that is, for a one-dimensional case: $S = \partial u_x/\partial x$. Because the displacement itself is a vector, its variation has to be related to a three-dimensional position – thus, strain is a size 3×3 tensor [S] relating two vectors:

$$\mathrm{d}\mathbf{u} = [S]\,\mathrm{d}\mathbf{w} \text{ where } \mathrm{d}\mathbf{u} = [\mathrm{d}u_x,\ \mathrm{d}u_y,\ \mathrm{d}u_z] \text{ and}$$
$$\mathrm{d}\mathbf{w} = [\mathrm{d}x,\ \mathrm{d}y,\ \mathrm{d}z] \tag{2}$$

Similarly, stress is the variation of the force vector over the infinitesimal spatial grid. For one-dimensional case: $T = \partial F_x/A\partial x$, but for three dimensions, including shear forces, a symmetric 3×3 stress tensor $[T]$ with six independent variables (linearity condition), is used:

$$\mathrm{d}\frac{\mathbf{F}}{A} = [T]\,\mathrm{d}\mathbf{w} \tag{3}$$

The relation between stress and the resulting strain is, in fluids, determined by the elasticity or compliance, but in solids, the elasticity constant $[c]$ is a 6×6 matrix defined by the general Hooke's law: $[c] = \partial[T]/\partial[S]$.

For isotropic solids, $[c]$ contains only three different components, all related to two Lamé constants (μ, λ).

These relations and the equations of motion lead to the wave equation for isotropic materials (4) that can be split into two simpler potential wave equations (5a, b), one for longitudinal (index l) and one for transversal (index t) wave, each propagating along z with a different velocity $c_l \geq c_t\sqrt{2}$.

$$\frac{\partial \mathbf{u}^2}{\partial t^2} = \frac{\lambda + \mu}{\rho}\nabla(\nabla \cdot \mathbf{u}) + \frac{\mu}{\rho}\nabla^2\mathbf{u} \tag{4}$$

$$\frac{1}{c_t^2}\frac{\partial^2 v_t}{\partial t^2} = \frac{\partial^2 v_t}{\partial z^2} \tag{5a}$$

$$\frac{1}{c_l^2}\frac{\partial^2 v_l}{\partial t^2} = \frac{\partial^2 v_l}{\partial z^2} \tag{5b}$$

These two waves, transversal and longitudinal, in piezoelectric materials are interrelated (disturbing one affects the other). To avoid dispersion and linear distortion, only one mode of propagation is facilitated in ultrasonic sensors.

The combined shear-longitudinal motion, in the presence of a boundary, forms waves propagating even slower than c_t – such as Lamb wave (in waveguides) and Rayleigh wave (on a surface) utilized in SAW transducers.

Properties of piezoelectric materials are described by a large number of parameters with significant redundancy (16 basic parameters in 4 pairs of constitutive equations). In the general tensor form, two essential pairs are

$$\left\{\begin{array}{l}[T] = [c^K][S] - [e]'[K] \\ [D] = [e][S] + [\varepsilon^S][K]\end{array}\right\} \tag{6}$$

$$\left\{\begin{array}{l}[S] = [s^K][T] + [d][K] \\ [D] = [d]'[T] + [\varepsilon^T][K]\end{array}\right\} \tag{7}$$

where,

$[c]$ matrix of elastic constants,
$[e]$ matrix of piezoelectric stress coefficients,
$[\varepsilon]$ matrix of dielectric constants,
$[d]$ matrix of piezoelectric strain coefficients,
$[s]$ matrix of compliance constants,

while symbol [..]' denotes the transpose of matrix [..].

Superscript within a matrix denotes that the parameter is measured with invariant voltage, that is, $K = 0$ meaning shorted electric terminals. Similarly, T denotes nulling the variation of internal stress, $T = 0$, whilst superscript S denotes zero displacement condition $S = 0$, that is, rigidly clamped transducer.

Other parameters in use include: piezoelectric stress constant $g = e^{-1}$, transmitting constant $h = e/\varepsilon^S$, transformation ratio $\alpha = d/C_m$ (where mechanical compliance $C_m = \mathrm{d}x/\mathrm{d}F = s.x/A$), and coupling coefficient $k = d(\varepsilon A)^{-1/2}$ that are important in assessing piezoelectric materials since it determines the fraction of the input transmitted between the mechanical and the electric port in an unloaded transducer. Values of k closer to unity are preferred except for such cases where the Q-factor is exceptionally high (Quartz). Note that $k_{33} \neq k_t$, since k_t is defined for transversely clamped operation.

Many transducers have one dominant mode of operation (either longitudinal/thickness '33' or shear/bender '31', '32' mode) but full optimization requires following strict relations in mathematical modeling for secondary effects. Table 1 lists the typical parameters of several piezoelectrics indicating discrepancies between independent measurements.

The piezoelectric stiffening phenomenon where piezoceramics become 'harder' after being poled results from (6, 7). To prove this, calculate $[c]$ or $[s]$ with and without piezoelectric effect, that is, nulling d or e and assuming $D = 0$ (open electric circuit). Consequently, the longitudinal wave velocity in poled materials is increased.

Ultrasonic fundamentals are covered well by Ristic (1983) and Kino (1987).

Improved modeling should avoid using inaccurate material constants – when conditions imposed on a sample's surface cannot be maintained throughout it. Piezoelectric transducer equivalent circuits based on Mason's description have been related to the general linear transducer theory for the general case of distributed parameter devices by Lesniewski and Thorn (1995) leading to a more universal transmission-line circuit.

SPICE simulations by Püttmer *et al.* (1997) using the Mason-based Redwood model, for impedance interferometer 1-MHz piezoceramic transducers showed that incorporating losses, helps reduce simulation error to 10% and in some cases below 0.1%.

The polar pattern of linear transducers in fluids (both sensors and actuators) is determined by the radiation theory of Kirchoff but in practical cases the working integral formula of Rayleigh (8) is used,

$$\Phi_{(x,y,z)} = -\frac{1}{2\prod}\int_{S} v_{n(x,y,0)}\frac{e^{-jkR}}{R}\,dS \qquad (8)$$

where for each frequency component ω (with $k = \omega/c$ being the wave number) of the velocity distribution $v_{n(x,y,0)}$ normal to the transducer's surface S, the resulting acoustic potential Φ is observed in the far field at a distance R from the source.

This formula is valid for flat baffled surfaces but it is often used for slightly curved ones in small enclosures. Resulting inaccuracies are of limited concern because nonuniformity of vibrations in transducers cannot be realistically determined. A better modeling, limited to analysis only, is offered by the finite element method.

4 OVERVIEW OF SENSORS USING ULTRASONIC TECHNIQUE

An ultrasonic wave can be generated in solid dielectrics containing electric dipoles through application of varying electric field (piezoelectricity in piezoceramics and piezocomposites). While crystals and ferroelectrics have natural permanent polarization created by their dipole or domain lattice, dipoles in electrostrictive materials are aligned permanently by applying high electric field (several kV), for example, by corona or contact poling, preferably cooling them down from the Curie point. Piezoceramics manufactured from precalcinated fine powders mixed with binders, dry pressed, baked, and fired, are finally poled and have electrodes deposited. Thin films (0.05–5 μm of $Ba_2Si_2TiO_8$, TeO_2, Si_3N_4, PZT (lead zirconate titanate), or ZnO on silicon) for hair or SAW microsensors are obtained by laser or microwave vacuum sputtering, but also heat only (200–500 °C) bonding of piezosensors on silicon is an inexpensive option since the 1980s.

The fundamental series resonant frequency (Figure 2) is well defined by the electromechanical parameters of the sensor and its load (housing and the medium). The parallel resonance, which involves electric capacitance of the material and connections, is less stable. Minute variations of series resonant frequency relate well to the load impedance (representing fluid density, phase transition, temperature, or deposits on the vibrating surface) and are measurable with reasonable accuracy. A self-resonating PZT sensor with frequency resolution of 0.1 Hz in the MHz range allows reliable measurement of 10–1000 Hz variation caused by mechanical loading such as deposition/growth of biochemical material (refer to Guibault and Luong, 1994).

Narrowband sensors are also suitable in single frequency systems where phase delay of a fixed frequency continuous (CW) or semi continuous signal represents the measurand (e.g. in noncontact surface profiling).

The Q-factor of a sensor (damping), which may be determined at its electric port, is useful in characterization of molecular absorption of solutions. In such measurements, many resonant frequencies (overtones) specific to the sensor's geometry are available, allowing frequency profiling

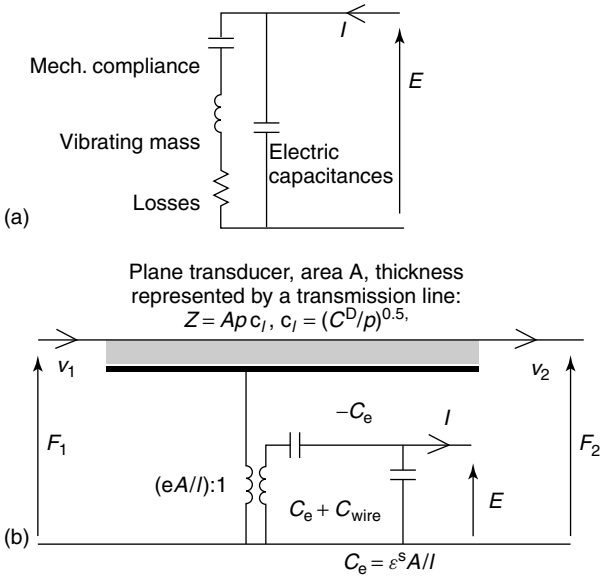

Figure 2. Equivalent circuits of single mode solid-state ultrasonic transducers, (a) simplified lumped network or electric impedance and (b) the exact transmission-line equivalent circuit developed by Mason in 1948 and verified by Redwood in 1956 and 1961.

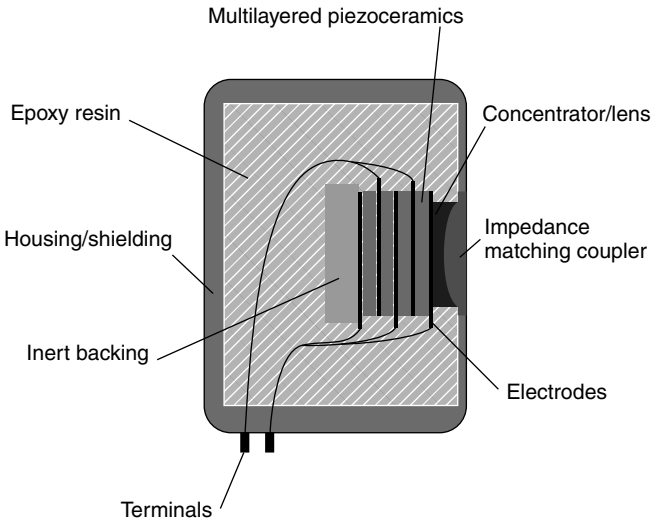

Figure 3. Cross section of a simple bidirectional transducer for NDT or medical imaging, utilizing a concentrator lens for beam focusing and offering an increased efficiency/sensitivity through using multilayer piezoelectric structure with damped housing.

of absorption (relaxation spectroscopy). For a detailed outline, refer to Edmonds (1981, Ch. 2, 3, 4, 8).

Wider BW (see Figure 3) sensors are needed in pulse-echo techniques, where a short transient burst represents either time delay (in ranging systems) and/or signal magnitude (in defectoscopy). The BW representing the difference between the maximum and minimum 3-dB angular cutoff frequency ($\Delta\omega = \omega_{max} - \omega_{min}$, typically ~50% of the center frequency) determines the duration ($t_{min} \cong 1/\Delta\omega$) of the sensor's electrical response to the shortest received transient indicating time delay error (if correlation techniques in signal detection are not used).

The group of broadband (BB) sensors use transient or wideband signals (chirps, modulated, or coded signals) in imaging systems, tomography, holography, and sonar; and requires flat frequency response with minimum distortion. It is possible to compensate/equalize for time-invariant linear distortion using optimized Wiener inverse filter if spectral components of interest have sufficient energy (above the noise level). For an inexpensive way of broadening BW of resonant transducers and references to the practical use of the Wiener filter, refer to Lesniewski and Thorn (2001).

Transducers for imaging applications (sonar, medical) appear as planar or circular arrays with electronic beamforming, but in single low power devices, for example, in nondestructive testing (NDT), lenses/concentrators (of aluminum, epoxy resin, magnesium) offer fixed focus. For details of a 4.5-MHz PZT array for medical imaging, refer to Turnbull and Foster (1992). Bronze, brass, or tungsten are still used for backing piezoceramics but reducing reverberation and cross talk in arrays is better served by lossy resin composites, possibly loaded with tungsten. Composite ceramics offer lower acoustic impedance and losses with good piezoelectric parameters. Refer to Patel and Nicholson (1991) and Richter, Reibold and Molkenstruck (1991) for performance comparison of conventional and composite transducers and to Silk (1984) for backing methods.

The most versatile surface acoustic wave, SAW sensors, developed in the 1970s utilize bulk acoustic wave (BAW) or thickness shear mode (TSM). They are usually microdevices with thin film piezoelectrics, deposited on silicon substrate, operating at frequencies from a few MHz to a few hundred MHz, either band pass or resonating at frequencies relating to IDT structure. Being extremely sensitive to any acoustic loading on the surface, responding to deposited mass, ionic and molar concentrations, temperature, pressure, and humidity, they are suitable as probes for conventional structural tests (http://www.sofratest.com/site/Sales/Catalog/Systems/SAW_Probes/kcu023a.pdf) as well as probes for microsensing (http://www.techtransfer.anl.gov/techtour/sensors.html).

Since they can be excited remotely by microwaves, mixed technology devices are possible. Because of their sensitivity, they require careful compensation against irrelevant variables. For a versatile overview, refer to Drafts (2001).

Piezoelectrics such as SiC and piezopolymers can also be excited by laser beams.

A quality ultrasonic sensor is also a small size capacitance microphone (such as the Bruel&Kjaer 4138 type with BW exceeding 100 kHz) or inexpensive 1/8 inch electret capsules usually offering BW of just over 50 kHz.

5 USE OF ULTRASOUND PRINCIPLES IN SENSING IN SOLIDS

Ultrasonic wall thickness/flaw sizing in metals uses the pulse-echo mode at a few MHz with single transmit–receive piezoceramic transducers (backed by dense lossy resin) and pads of oil, wax, or resin; or else fully immersed in liquid to facilitate coupling. For timber, concrete, and tires, the frequency is reduced by a decade due to higher losses. The actuator is separate from the sensor, although both may remain in one housing. Flaws are assessed according to the delay time of observed reflected pulse and its relative amplitude (refer to Krautkrämer and Krautkrämer, 1990) (http://www.krautkramer.com/).

For monitoring a machining tool (wear, cooling), Nayfeh, Eyada and Duke (1995) employed the pulse-echo methodology and precise measurements of a reflected 10-MHz burst using an ultrasonic transducer mounted within the tool holder. Similarly, Morton, Degertekin and Khuri-Yakub (1999) monitored baked photoresist by relating its temperature and thickness to the reflection coefficient in pulse reflection measurement using a GHz BW, ZnO-on-saphire transducer.

Single transducers for medical imaging tend to employ PZT in epoxy housing, but a copolymer PVDF-TrFE with lossy polymeric backing offers lower acoustic impedance, reducing the mismatch while maintaining a reasonably flat 120 MHz BW.

Research in constructing improved piezoelectric transducers for medical imaging has led to specific profiling of the surface, subdividing the front electrode, and/or graded poling (for state-of-the-art microfabricated transducers, refer to http://www.sensant.com/pro_advDiag.html). This has coincided with new solutions of the acoustic harmonic wave equation from 1987 (following a similar, earlier development in the electromagnetic wave theory), representing a new class of limited diffraction and localized waves (nondiffracting waves, X-waves, Bessel Beams, transient Bessel Bullets), which form very narrow beams, although they decay faster than conventional wave types.

An experimental pulse-echo 2-D imaging system with small limited diffraction beam transducer arrays (48 or 64 elements) has been developed by Lu (1997, 1998) (http://bioe.eng.utoledo.edu/Laboratories/UltrasoundLab/jian_yu_lu_lab.html).

It offered improved images of tissue phantoms up to a depth of 200 mm utilizing a new Fourier transform–based algorithm allowing high frame rate processing. Theoretical analysis of the new waves and an outline of other developments is offered by Salo, Fagerholm and Friberg (2000), a numerical analysis of Bessel Bullets by Stepanishen (1999), and an investigation of finite planar transducers by Chatzipetros *et al*. (1998).

6 USE OF ULTRASOUND PRINCIPLES IN SENSING IN LIQUIDS

Steady coupling and reduced acoustic impedance mismatch between the medium and the immersed transducer offers good interface; thus, solid-state ultrasonic transducers in liquids are readily used. Resonances are damped and the sensor's BW is larger than the BW in gases. The mismatch may be efficiently reduced by using novel composite materials (elastomer based piezorubbers or copolymers) suited for sonar and medical imaging (refer e.g. to Schlaberg and Duffy, 1994).

Sonar transducers are either small arrays of piezoceramic elements or single transducers with focusing concave face and/or lenses embedded in epoxy resin. They are used for bottom profiling or fish location ({echo-sounding}) using pulse-echo principle and narrowband signals (http://www.simrad.com/). A multibeam commercial unit Simrad EM3000 offers depth resolution of 1 cm within 200-m range at 300-kHz operating frequency (for minimum attenuation in seawater).

Other applications include velocimetry, where a measurand that uniquely influences ultrasonic wave velocity in a given liquid is found through time of flight (ToF) of an ultrasonic transient traveling over known distance. Measurement of fluid composition, its temperature, density, or concentration (water–air, water–alcohol, oils/fats, alcohols, molecules in a solution) using the above approaches has been reviewed by Povey (1997). The variation of wave velocity tends to be as high as 10% (e.g. for temperature variation of 30 °C), but effects on wave attenuation by a liquid medium, although under 1% and strongly influenced by frequency, are also measured (refer e.g. to examples by Harker and Temple, 1991). The use of ultrasonic sensors in velocity measurements is straightforward (using edge triggered timer with transient signal amplitude detection) as long as the sensor's low linear distortion allows it to maintain undistorted transient and good definition of the arrival time. If distortion is significant, then a reference transient propagating in a known reference liquid can be used and two distorted transients correlated to establish the time delay.

Imperfect sensors can still be used in velocimetry based on interferometry utilizing the superposition of continuous, sinusoidal signal with its delayed version (through a known length of transmission in an unknown fluid). This interference is manifested by resonances affecting the resulting frequency response of such systems where the wave velocity c can be found from the location of resonant frequencies: $f_n = n(c/l)$, or notch frequencies (antiresonances): $f_n = (2n + 1)(c/l)$, $n = 1, 2, 3, 4, 5$ and so on.

With a single transmit–receive transducer (where T and S1 would become the same transducer in Figure 4), the reflected wave travels twice the length of the fluid-filled tube terminated by a reflecting/rigid end. Examples of acoustic interferometers are given by Trusler (1991) and review of measurement approaches is given by McClements (1995). Errors in this method are caused by imprecise location of the resonance frequencies, which results from multipath transmission in the fluid tested. The transducer cannot radiate a perfect plane wave with

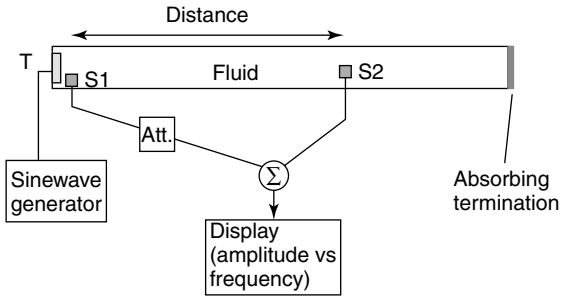

Figure 4. Principle of an ultrasonic interferometer with two independent sensing points (*Note*: (i) The sensor S1 may be omitted and the signal taken directly from the transmitter T. (ii) Only one transmit–receive transducer is used and the tube termination is fully reflecting in a single transducer system).

a constant phase over its body – therefore, the wave reaching the sensor may be interpreted as a sum of beams, some reflected at the tube walls and having different phases, and yet reaching the sensor with different phases.

Acousto-optic effects, such as diffraction of light, variation of refractive index or scattering, and frequency shifting by nonuniform medium density (and by surface waves in solids) created by a perpendicular ultrasonic standing wave are used for nonacoustic sensing of high-frequency ultrasonic waves. The deformed light beams are sensed by photodetectors or interferometers (the most popular commercial sensors being the Bragg Cells) (http://www.goochandhousego.com/page/home.html). Review of relevant sensing techniques is offered by Scruby and Drain (1990). Chiang, Chan and Gardner (1990) have outlined an improved sensor that can be used for detection of ultrasonic wave up to the MHz range (sufficient for medical applications) based on birefringence in optical fiber (ultrasonic field varying the refractive index and causing dispersion of differently polarized light beams).

7 USE OF ULTRASOUND PRINCIPLES IN SENSING IN GASES

Because of the low wave velocity in gases, ultrasonic sensors find application in flow velocity (v) measurement, by sensing the time delay, $t_d = \text{distance}/(c \pm v)$, between two transmission points along the gas flow. A two-path system with simultaneous transmission along and against the flow allows elimination of the wave velocity c by offering two such equations (Figure 5). A commercial five-path gas flowmeter has an error less than 0.5% within the range of 0.4 to 20 ms^{-1} – Fluenta, FMU700 (http://www.fmckongsbergsubsea.com/).

The delay time used for ranging/positioning (in robotics) and level control allows sensing distance to reflecting objects (locally flat, of size larger than signal wavelength with an abrupt change of acoustic impedance). Often 40-kHz center frequency, narrowband piezoceramic sensors with aluminum horn/scatterer are used to reduce impedance mismatch else polyvinylidene fluoride (PVDF) sensors are used – for an overview refer to Manthey, Kroemer and Magori (1992). The impulse response is of irregular ringing form having autocorrelation function with many lobes. Therefore, the limiting error reaches several microns and yet the wave velocity has to be determined. In simpler systems (Vargas *et al*., 1997), the sensed amplitude envelope of the signal leads to a pulse duration of some 100 μs with relative error reaching 3%. Another robotic system developed by Munro *et al*. (1990), with conventional 50-kHz transducers offered 10-m sensing range.

For the state-of-the-art selection, refer to: http://www.hexamite.com/.

Reduction of errors limiting ultrasonic ranging and/or imaging can be obtained through integrating results from a system producing uncorrelated errors.

In a robotic collision avoidance system, Chou and Wykes (1999) combined four-element 100 kHz cf^{-1} ultrasonic linear array (giving poor angular, but good range resolution, reaching 1.7 mm at a distance of some 140 mm) with a charge-coupled device (CCD) optical imager having different characteristics/limitations.

Abreu *et al*. (1999) combined electromagnetic an ultrasonic positioning 3-D system with one transmitter (pulse source: an electric spark) and three remote receivers (conventional resonant 40-kHz transducers) obtaining a resolution of 1 mm within a range of 5 m.

Combining a conventional 40-kHz ultrasonic CW Doppler system (utilizing 5-Hz frequency resolution) with a microwave motion detector unit has improved the elimination of false alarms in an intruder alarm system described by Ruser and Magori (1998).

An efficient transducer, developed for operation in air by Kielczynski, Pajewski and Szajewski (1990), comprised one or more axially vibrating PZT rings embedded in low impedance resin, transmitting vibrations to the air. The resulting device had a narrow beamwidth ($<4^\circ$) and bandwidth of 100–200 kHz (larger than the rings alone), although containing several resonances.

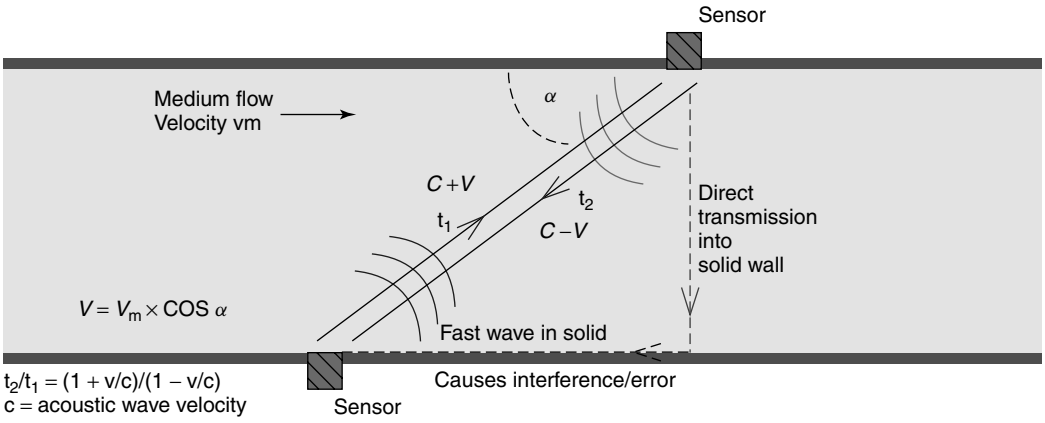

Figure 5. The principle of operation of a two-path ultrasonic flow velocity measurement (*Note*: the dotted path identifies the cross-talk transmission, interfering with the measured transient and causing errors).

An option that may prove successful is the use of sensors where glow-discharge is modulated by acoustic pressure – refer to Kocis and Figura (1996).

8 LIMITATIONS OF ULTRASONIC METHODS OF SENSING

General limitations are gradually lifted with the steady progress in technology (frequency range, automation) and material processing (material purity, profiling accuracy) but the following fundamental limitations remain.

8.1 Impedance mismatch

Affects any method involving transmission in gases, where the huge impedance ratio (7000:1 or worse) between a solid-state transducer and the medium introduces signal loss. In actuators, the peak signal level may be increased to some 100 dB at 1 m by reaching the maximum operating voltage of the piezoelectric material (electric breakdown or linearity limit), but in sensors impedance transformation is necessary. Wave filters offer any transformation but over a narrow frequency range, while horns increase the level/sensitivity by some 30 dB at the expense of reduced frequency range and a likely dispersive transmission (for horn theory refer to Ensminger, 1988 and for modeling, to Lesniewski, 1995). In the case of small size sensors with reduced source capacitance (as low as 10 pF), even a short connecting cable affects the response, thus, sensor-amplifier hybrids increase sensitivity by more than 10 dB (Zheng *et al.*, 1997). Contact between solid-state transducer and tissue in medical imaging is also a source of signal attenuation that cannot be avoided due to impedance discontinuity/instability.

8.2 Delay time

The usual assumption in signal transmission is that signal travels through a homogeneous and time-invariant medium. In fact, a flowing medium is unsteady and nonuniform, with bubbles or multiple phase, yet there are also reflected signals from instrument housing – leading to significant uncontrollable distortion of the received signal. This limits the accuracy of the delay measurement and therefore ultrasonic transducer needs only the BW sufficient to generate a test signal whose autocorrelation has a width comparable with the above error. Narrowing beamwidth may be justified in tomographic reconstruction where many sensors are used.

In signal reflection, narrow beam and wide, BW of transducers is most important, while limitations come from interfering reflections and imprecise determination of the wave velocity (a differential method with reference path is useful).

8.3 Polar and spatial response

A narrow response is useful in isolating interfering signals but it is costly and it negatively affects frequency response and sensitivity. If lenses or special techniques (digitally equalized/filtered arrays) are not used, then the main lobe is frequency dependent and sidelobes are created. Finally,

severely distorted interfering signals may be more difficult to handle (e.g. spikes turning into longer ringing).

1 ACTIVE AND PASSIVE TRANSDUCERS

Transducers for launching or detecting ultrasonic waves utilize mechanical, electromagnetic, chemical, pneumatic, fluid dynamic, or thermal phenomena. Transducers for ultrasonic instruments are mainly in the electroacoustic category. Here, electrical energy is converted to acoustic energy, when transmitting; acoustic or mechanical wave energy is converted to an electrical signal, when receiving.

An important concern in the design of ultrasonic transducers and measuring instruments is the optimization of the system with respect to a reliable and accurate determination of the measurand – the parameter whose value is to be inferred or computed on the basis of 'ultrasonic' observations. In an ultrasonic experiment, one may observe transit time, amplitude of the received signal, oscillator frequency, oscillator strength, or other terms related to these. If more than one parameter is varying, say temperature and pressure, it may be necessary to observe more than one characteristic of the generated or received wave to resolve ambiguities. Generally speaking, one can say that each measurand (flow, temperature, pressure, etc.) influences one or more of the following: generation, propagation, and detection of ultrasound. For a fuller account of such influences and their measurement see Asher (1997), Auld (1990), Baker (2000), Brown and Lynnworth (2001), Hunt, Stubbs and Lee (2003), Kleppe (1989), Lynnworth (1989), Lynnworth and Mágori (1999), Youngdahl and Ellingson (1982), and Royer and Dieulesaint (1999).

2 EFFECTS OF MEASURAND ON ULTRASONIC PROPERTIES

Consider Figure 1. Without further study, it is not obvious as to which is the best way to proceed, where, say the object is to measure water temperature. Ultrasonic transducers and instruments have been available commercially for measuring signal characteristics related to temperature. Their operation is based on the temperature dependence of: (i) the transducer frequency; (ii) the speed of sound in water; (iii) the speed of sound in an intrusive sensor or probe; or (iv) the speed of sound in the beaker material.

In discussing the laboratory experiment depicted in Figure 1, the influence of pressure has been disregarded because this effect is relatively minute unless pressure is very high. Actually, the speed of sound depends on pressure in all the media involved. These include the solids (glass or metal beaker; quartz crystal, which we shall imagine to be embedded within the housed transducer assembly), the liquid (water), and the gas (air) that remain after all the water

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

ISBN: 0-470-02143-8.

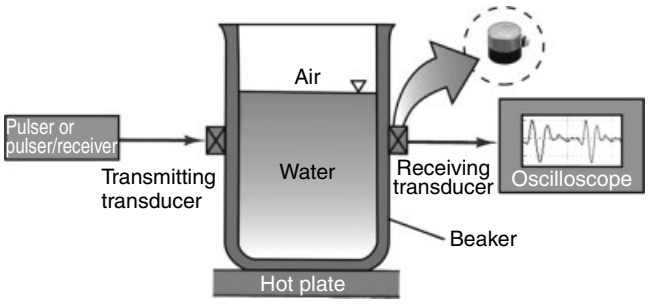

Figure 1. Ultrasonic effects of heating water in a beaker on which a diametrically-opposed pair of resonant piezoelectric (e.g. quartz) transducers are mounted. (Reproduced by permission of Panametrics, Inc.)

has boiled away. One might expect pressure effects to be negligibly small in an 'incompressible' liquid like water, and certainly negligible in a solid such as quartz. But this is not the case. For example, in the particular cut of quartz used by one manufacturer in their quartz pressure gauge, a change of pressure of 69 Pa (0.01 psi) was resolvable as a difference in its resonant frequency. In the case of air, pressure may be calculable if one can utilize the amplitude of the received signal, or the attenuation coefficient, as a measure of air pressure. Once pressure is approximately known, the temperature of dry air (or air of known relative humidity) can be calculated from the speed of sound.

The dependence of the speed of sound on temperature and density in a fluid such as oxygen is given in Figure 2 (Straty and Younglove, 1973). Their data suggests that, over the range studied, the *density* of fluid oxygen could be computed from measurements of speed of sound and temperature. The idea of determining the density of a *known*

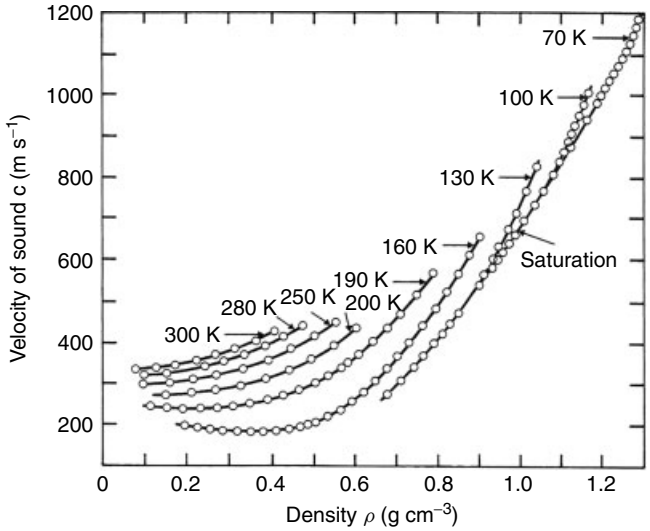

Figure 2. Velocity of sound versus density for saturated liquid and compressed fluid oxygen. (After Straty and Younglove, 1973.)

liquid at an approximately or accurately known pressure is illustrated for several liquids in Matson *et al*. (2002). Figures 3 and 4 suggest methods for determining air pressure or density.

3 TRANSDUCER EFFECTS USED IN ULTRASONIC INSTRUMENTATION

3.1 Piezoelectric, magnetostrictive, electrostatic, and electromagnetic mechanisms

The *piezoelectric* effect discovered by the Curie brothers over a century ago, involves a coupling between elastic

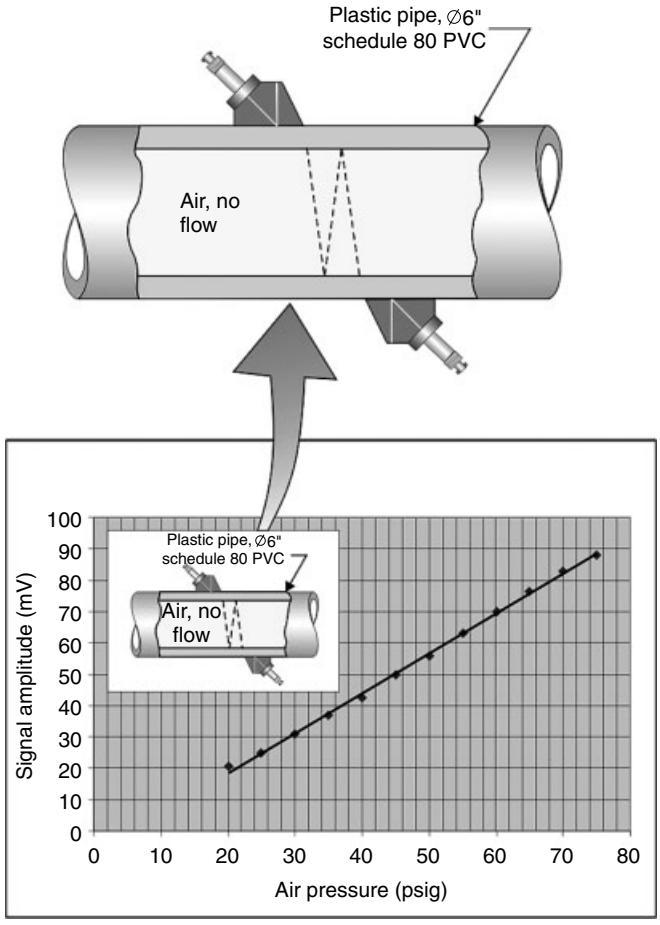

Figure 3. Example of air pressure measured at room temperature, and at no flow with clamp-on ultrasonic transducers. This measurement utilizes the principle that the amplitude of the received signal is proportional to the acoustic impedance of air and therefore, to a good approximation, proportional to the air pressure. Under turbulent flow, signals become jittery. At Mach numbers >0.1, beam drift further complicates the simple relationship depicted in the graph. Changes in temperature or gas composition also influence the pressure/amplitude relationship. (Reproduced by permission of Panametrics, Inc.)

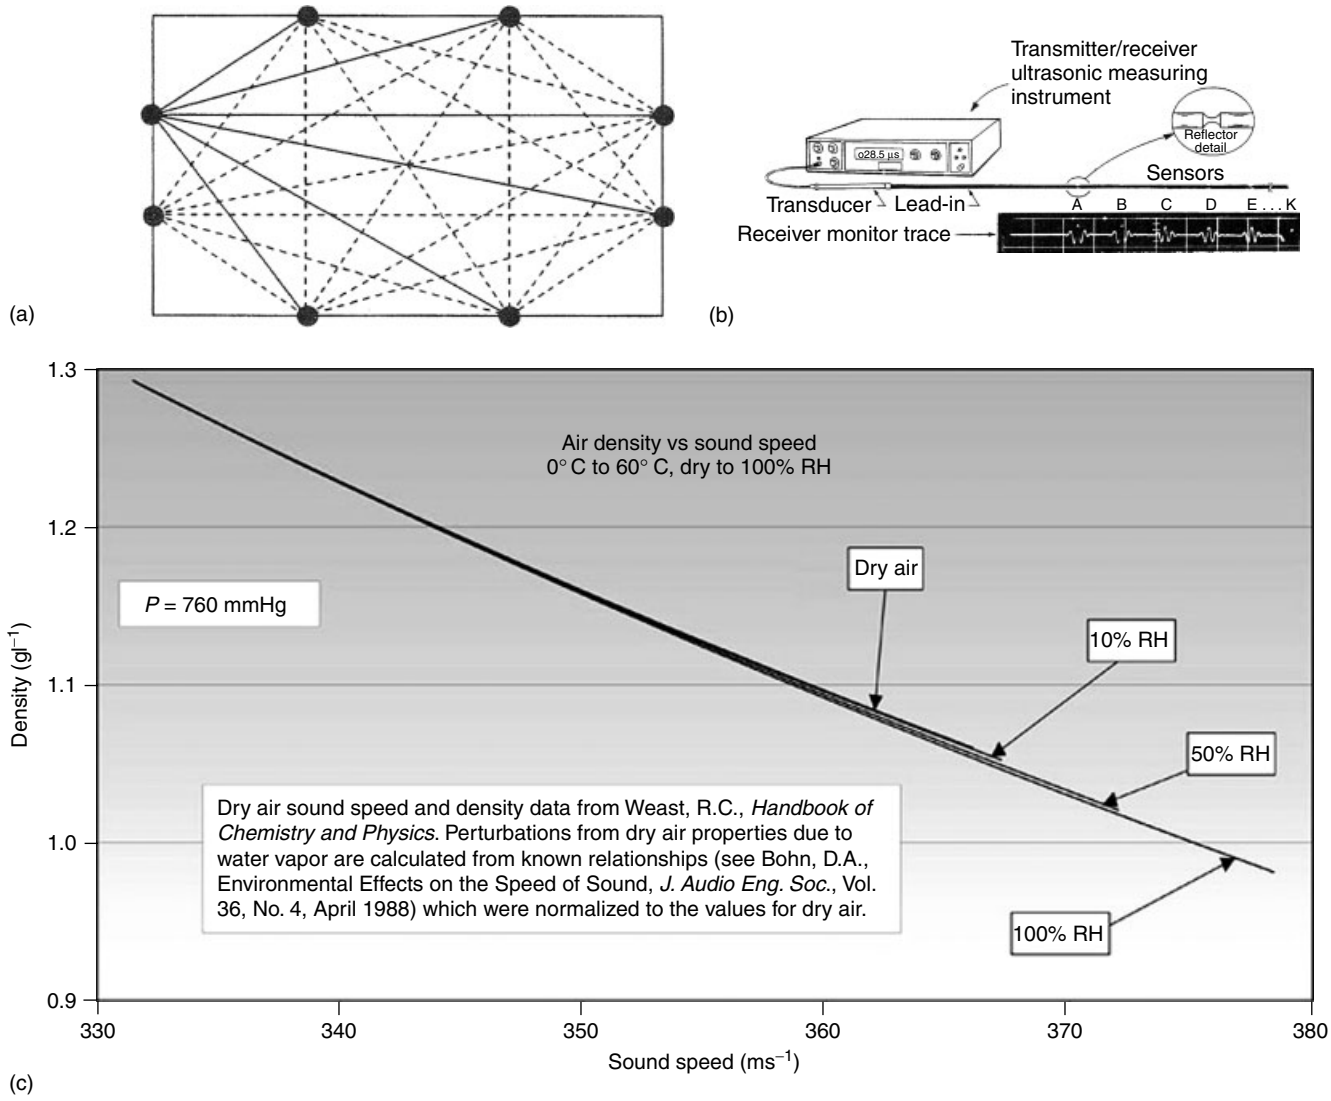

Figure 4. Ultrasonic thermometry using the speed of sound as a multipath indicator of temperature: (a) in the medium itself, (b) in an intrusive waveguide with one or more measuring zones, (c) extending concept (a) to density measurement based on the speed of sound in air. (Reproduced by permission of Panametrics, Inc.)

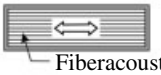
and dielectric phenomena. Piezoelectricity is found only in materials that have no center of symmetry. Quartz, lithium niobate, tourmaline, and other crystals exhibit the effect, but probably most industrial transducers, as used in testing and process measurements today, use poled ceramics as the electroacoustic element. PZT (lead zirconate titanate) and LM (lead metaniobate) are examples of such materials. As a transmitter, piezoelectric (ferroelectric) materials expand (or contract), or exhibit shear, in response to a driving voltage. As a receiver, an electrical signal is generated in response to an incoming pressure or shear wave. These effects can be observed over a wide temperature range, from nearly absolute zero up to the Curie point or the transformation temperature of the element, for example, 573 °C for quartz, and approximately 1200 °C for $LiNbO_3$. The usable frequency range extends down below the ultrasonic band into the audio and infrasonic range, and up to the gigahertz range.

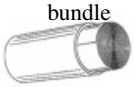
Magnetostrictive devices are usually limited to frequencies below a few hundred kilohertz by the electrical skin effect, although operation into the megahertz range has been reported. Ni, Fe, Co, and their alloys are magnetostrictive, that is, they twist or change their dimensions in response to an applied magnetic field. Conversely, in response to a torsional, tensile, or compressional load, they generate a magnetic field that is typically sensed by a coil surrounding the magnetostrictor. As a compressional stress wave propagates along a magnetostrictive wire, one can imagine a

little bar magnet moving through the wire at the speed of sound. When that magnet passes through an encircling coil, a voltage is induced in that coil.

Electrostatic forces have been used in microphones for a long time. Micromachining has 'modernized' the options, leading to CMUTs (capacitive micromachined transducer). Many of their performance and manufacturability characteristics were summarized by Oralkan *et al.* (2002). Because of the low mass of the radiating membrane, CMUTs have been used in *air* transducers and *immersion* transducers.

Electromagnetic acoustic transducers (EMATs) utilize Lorentz forces in conductors. The Lorentz force is relatively small, but if the conductor is magnetostrictive, the combined effect is large enough to be utilized with essentially standard flaw detectors designed for ordinary piezoelectric transducers. Their chief advantage is the avoidance of any couplant. This can be important if the object under test has a rough surface, for example, a heavily oxidized iron pipe.





4 GUIDING ULTRASONIC WAVES TO SENSE A MEASURAND REMOTELY; BUFFERING AN ULTRASONIC TRANSDUCER

Ultrasonic waves can be guided along elastic structures such as rods, tubes, and plates; and through fluids in pipes or tubes. (In the ocean, acoustic waves can be guided in a sandwiched channel when the water above and below has a sound speed *higher* than that in the channel. But such waveguiding is beyond the scope of this section.) The sensing and buffering purposes of interest here include (i) using propagation in the waveguiding structure to sense one or more characteristics of the waveguide, such as its elastic moduli or its temperature; (ii) to sense a characteristic in the medium adjacent to the waveguide, such as the density or viscosity of the fluid in which the waveguide is immersed; or (iii) to buffer an ultrasonic transducer from a hot fluid into which the buffer radiates in order to measure some characteristic of that fluid, for example, speed of sound, attenuation coefficient, or flow velocity. Waveguides can convey ultrasound to and from a remote region where the transducer, if exposed to the harsh environment of that remote region, might fail because of thermal or chemical attack, or excess nuclear exposure. Another reason for using waveguides is because the specimen size or shape, for example, micrometer-diameter glass fiber, is such that it is awkward to introduce the interrogating energy directly from the transducer to that specimen. In other cases, the waveguide assists in mode-converting from extensional to torsional; from transverse shear to torsion; from extensional to flexural, and so on. Sometimes, multiple purposes are simultaneous goals.

Table 1 illustrates waveguides and buffers investigated by various authors between 1934 and 2003 in monostatic (pulse-echo) and bistatic (through-transmission, or pitch-catch) arrangements.

Figure 5, after Nguyen, Smart and Lynnworth (2004), shows pulse-echo and through-transmission torsional-wave interrogation of a noncircular portion of an otherwise-circular cross-section waveguide, in order to

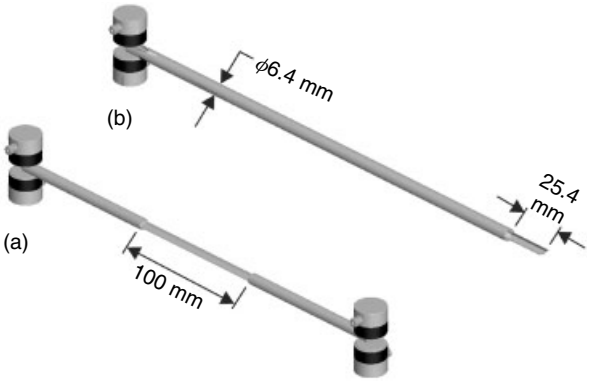

Figure 5. (a) Through-transmission configuration with two pairs of transverse shear transducers, one pair as transmitters and one pair as receivers, at each end of a waveguide. These generate and detect torsional waves by a mode conversion process (Nguyen, Smart and Lynnworth, 2004; Lynnworth, Cohen and Nguyen, 2004). The waveguide with the diamond cross section comprising its center section responds to liquid density (Kim and Bau, 1989; Shepard *et al*., 1999; Lower, Brow and Kurkjian, 2004) and (b) Pulse-echo configuration with one pair of transducers coupled to the circular cross-section end of the waveguide. (Reproduced by permission of Panametrics, Inc.)

sense the density of fluid surrounding the noncircular portion. This technique has a resolution on the order of $1\,\mathrm{mg\,cm^{-3}}$ and, therefore, while sensitive enough for many industrial liquid applications, it is not particularly useful for sensing the density of gases. Air, for example, has a density of $1.29\,\mathrm{mg\,cm^{-3}}$ at ordinary conditions. On the other hand, when the sensor portion is immersed in a low-density gas, it can sense the gas *temperature*, T, nearly independent of gas density or viscosity, especially if the T-sensor is a round rod or tube.

What happens if the sensor is immersed in a high-viscosity liquid? The torsional wave slows down in response to density *and* viscosity, besides being responsive to temperature. In this case, compensation is required to separate the variables of interest. Solutions may include using additional cross-sections and modes such that three independent ultrasonic measurements allow one to sort out the three parameters affecting propagation. If temperature is sensed by a thermocouple, only the two remaining variables need to be sorted out ultrasonically.

5 CONTAINER WALLS AS SENSORS OR WINDOWS FOR NONINVASIVE INTERROGATION

When categorizing ultrasonic instrumentation principles and techniques, it is convenient to organize them according to whether the sensor is the medium itself or an intrusive sensor. Here we use 'sensor' to mean the medium, material, or structure in which the generation, reception, or propagation of ultrasound is measured and in which the said generation, reception, or propagation is influenced by the state, characteristics, or value(s) of measurands in the path.

Referring again to Figure 1, if we think of water as its own sensor ('Propagation' column in Table 2), we must nevertheless acknowledge that the electroacoustic transducers might be legitimately called *sensors*. By designating water as the sensor, we can emphasize that the speed of sound in water is the basis of the way in which we obtain information on the water's temperature. The electroacoustic piezoelectric quartz transducers shown in this particular illustration could be replaced by an external laser generation and detection system, focused on opposite sides of a black beaker, yet the speed of sound in water could still serve as the basis for determining water temperature.

Finally, one must not overlook what might appear to be an intermediate category, that is, using the existing wall used as a sensor. As one example, the acoustic 'ringdown' or echo decay pattern in the wall of a vertical standpipe is often proposed to tell if liquid is present at that level. In the common example of a clamp-on flowmeter, the wall of the pipe provides an acoustically transparent window through which the interrogating beam gains access to the liquid in the pipe. The liquid is its own sensor. The pipe and suitable transducer assemblies make it possible to utilize that sensor

Table 2. Examples of heating effects on the generation, propagation, and detection of ultrasound in water, in the laboratory test of Figure 1.

	Heating effects on:		
Temperature (°C)	Generation	Propagation	Detection
Increase from 20 to 74	Frequency increases	Speed of sound increases; absorption decreases	Signal arrives progressively earlier
75 to 99	Frequency increases	Speed of sound decreases; absorption decreases	Signal arrives progressively later
100	Frequency increases	Propagation is largely blocked by boiling and then by low-impedance air after all the water boils away	Signal weakened by scattering due to boiling and may be undetectable

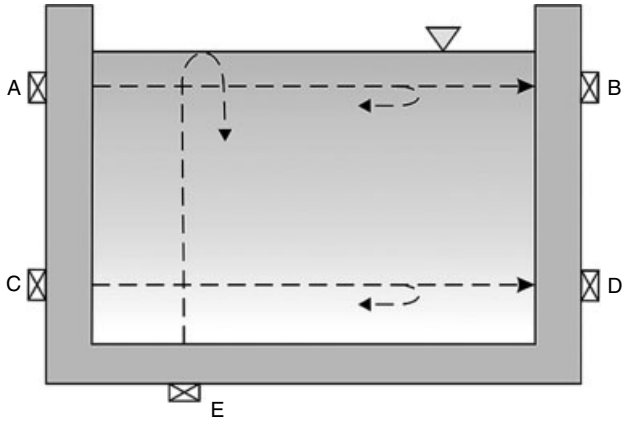

Figure 6. Liquid level obtained noninvasively from an upward-looking pulse-echo transducer, together with four sidewall-mounted through-transmission transducers to compensate for sound speed gradients as well as to have multiple discrete measuring heights (two in this example). Transducers B and D can be deleted if transducers A and C operate in pulse-echo mode, like transducer E. (Reproduced by permission of Panametrics, Inc.)

without invading or physically penetrating the boundaries of the fluid (see Figure 6).

6 LIMITATIONS ON PRECISION AND ACCURACY

6.1 Limitations on coupling, propagation, spatial resolution, and correlations among propagation and measurands

In the field of ultrasonic nondestructive testing (NDT), a variety of couplants – liquids, oils, pastes, gels, and elastomers – are available for transmitting the interrogating wave from the transducer assembly to the part being tested (see Figure 7). The couplant tends to match acoustic impedances as it replaces the low-impedance air gap that would otherwise block most of the transmission between a solid transducer and a solid test object. At temperature extremes, the choice of couplants is greatly diminished. Accordingly, in cryogenic or high-temperature situations, one may resort to pressure coupling (sometimes aided by a compliant film of metal) or to solid bonds of epoxy, solder, or ceramic cements. Coupling to liquid metals is sometimes facilitated by coating the probe so that it is wetted but not dissolved by the liquid metal.

Temperature extremes may be associated with severe sound speed gradients or other inhomogeneous conditions that block propagation. On the one hand, ultrasonic measurements have been made in the laboratory from nearly absolute zero to plasma temperatures of 20 000 K. On the other hand, practical measurements in cryofluids or merely

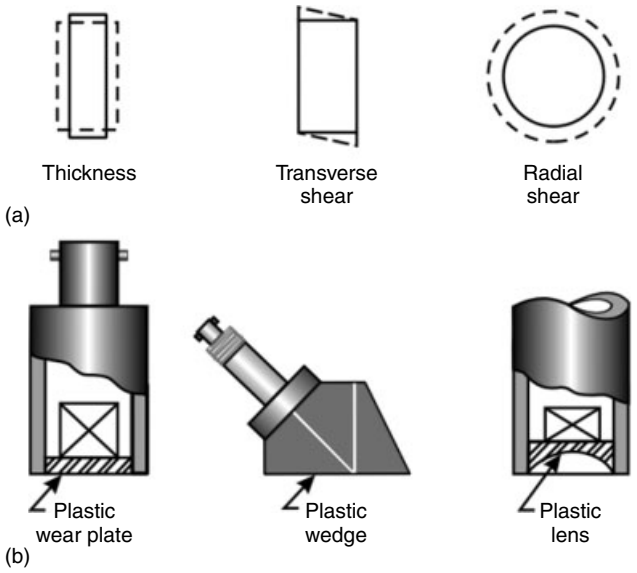

Figure 7. Examples of: (a) thickness mode, transverse shear (often called thickness shear), and radial mode crystals and (b) epoxy-sealed NDT transducers. (Reproduced by permission of Panametrics, Inc.)

in hot water near saturation conditions are often interrupted by 'flashing' or boiling because of the severe mismatch in acoustic impedance between liquid and gas phases.

Another limitation in ultrasonic measuring systems is spatial resolution. Apart from speckle and wavelength-dependent limits, the propagation characteristics of the medium between the transducer and the region under study influence resolution in that region. As in optical systems, diffraction limits the lateral resolution. Depth resolution is usually limited by the time duration of the interrogating pulse, or its bandwidth. Refraction (Snell's law) limits the angle that a beam can be aimed relative to an interface. This means noninvasive interrogations may be unable to examine all areas inside a bounding pipe or vessel.

Yet another limitation applies to the attempts to generalize the correlations between variables such as, say, strength and the speed of sound, molecular weight and the speed of sound, or Young's modulus and the speed of sound. Such correlations may be quite useful when judiciously applied to a limited class of materials, or to specimens of similar alloys of like cross-section. One must be alert, however, to avoid errors introduced by unwanted variables, such as moisture, temperature, pressure, boundary dimensions comparable to wavelength, and dispersion.

1 SELECTION AND INFLUENCE OF NEW ELECTROACOUSTIC MATERIALS, COMPONENTS, AND TECHNIQUES

The pie chart of Figure 1 categorizes ultrasonic measurement or instrumentation applications according to the four principal process control measurands (flow, temperature, pressure, and liquid level). Other slices express explicitly or implicitly, combinations, NDT(nondestructive testing), and analyzer measurands (e.g. gas concentration, relative humidity, etc.). To keep this section of manageable size, let us focus on a specific task.

Consider the task of designing an ultrasonic system to measure without contact, that is, using air-coupled transducers, several characteristics of a fast-moving solid. If the measurement is important, there are likely to be competitors, so the task requires a solution that is better, faster, and cheaper than the competition's. The best solution is likely to be a compromise that nevertheless benefits from the designer's judicious choice of transducer material and mode, methods of data acquisition, signal processing, display features, output functions, and so on. The total ultrasound design task includes many factors (Figure 2). Design principles underlying a diagram of this type are discussed in books such as those by Asher (1997), Auld (1990), Baker (2000), Lynnworth (1989), Royer and Dieulesaint (2000), Rogers (1984), or others. In this section, we deal only with 'air' transducers, admittedly in an overview fashion.

It will be understood that the relatively *low-acoustic impedance of air* (compared to water or common engineering metals) has been a major barrier to ultrasonically testing and measuring materials in air, or even testing air itself, that is, measuring air flow or air temperature. Low-mass membranes and low acoustic–impedance electroacoustic materials are appropriate for ultrasonic measurements of air, gases, or solids tested by air-coupled transducers. NDT 'immersion transducers', developed many years ago for testing solids immersed in water, are sometimes used for biomedical applications in body tissue, technical applications in liquids, and in some gases other than air, as well as air. In other words, sometimes one transducer can be used to test solids, liquids, or gases. Optimizing for a specific application in one state of matter or another, however, may involve selecting or improving the electroacoustic material.

As far as impedance mismatch is concerned, bear in mind that the characteristic acoustic impedance of a gas, Z_{GAS}, equals the product of gas density times sound speed. This means Z_{GAS} increases roughly in proportion to pressure times the square root of gas MW (molecular weight). As a numerical example, the Z for argon at 10 bar is approximately thirty times higher than Z for helium at atmospheric pressure.

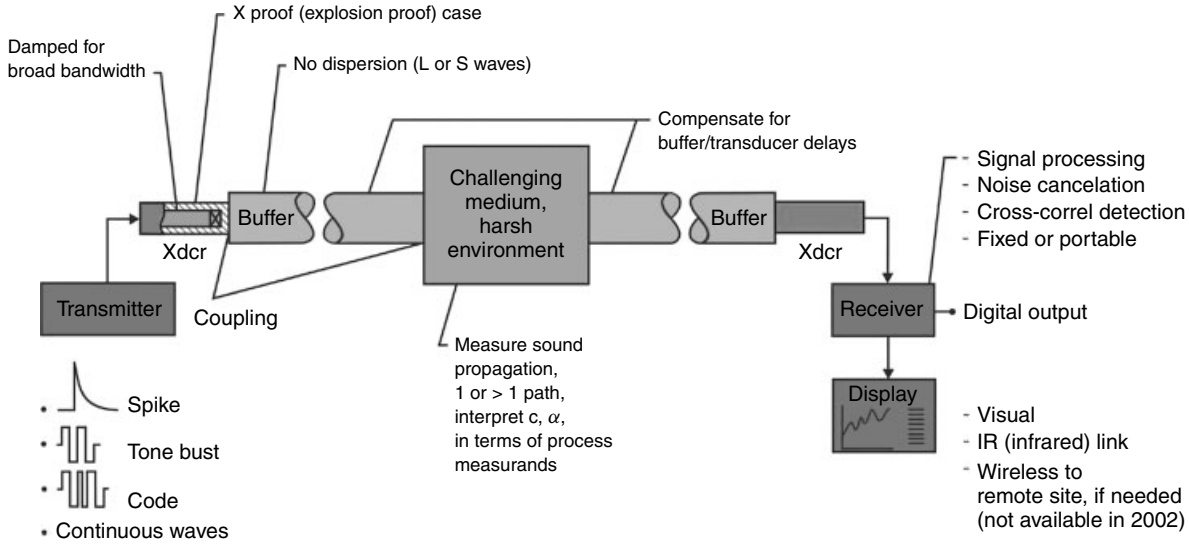

Figure 2. Factors and choices to be considered when designing an ultrasonic measuring system. (Reproduced by permission of Panametrics, Inc.)

New electroacoustic materials, new manufacturing techniques [e.g. layered manufacturing, Safari *et al.* (2002)], piezo polymer composites, CMUTs (capacitive micromachined ultrasonic transducers), polyvinylidene fluoride and copolymer piezoelectric sheet materials, and electrets comprise areas that continue to be dynamic.

2 SPECIAL CONSIDERATIONS FOR TEMPERATURE AND PRESSURE EXTREMES

Temperature extremes can cause failure of transducers in several ways: depolarization when the Curie point is exceeded; chemical reactions when hot; cracking or disbonding due to differential thermal expansion; couplant boils away or becomes embrittled at hot or cold extremes; transducer material becomes electrically conductive when hot; attenuation in the transducer backing or speed of sound in an adjacent wedge changes too much; soldered connections melt. High-purity gas applications may require that during vacuum bakeout the transducer, if wetted, neither outgases nor leaks. For use at high pressure, the transducer must neither deform nor leak. In a downhole tool for exploring geothermal reserves, transducers may be subjected simultaneously to high temperature and high pressure (e.g. $T = 100$ to 350 °C; $P = 20$ to 70 MPa). In testing red-hot steel, buffer rods or momentary contact may be able to isolate the transducer element from the high temperature of the product and the high pressure required for dry coupling. Lasers and emats (electromagnetic acoustic transducers) offer noncontact approaches that avoid couplants. Eventually, such methods may become routine in industry.

3 ULTRASONIC TRANSDUCERS FOR GASES

In contrast to liquids or solids, gases are of low density ρ, low speed of sound c, and consequently of low acoustic–impedance Z – see comparisons in Table 1.

This means that if a *high* acoustic–impedance transducer is used, it is much more difficult to transmit ultrasound into or out of a gas compared to liquids or solids. One generally seeks low-impedance transducers for gases.

Apart from low-mass membrane, ultrasonic transducers and low acoustic–impedance transducers, which are appropriate for air, there are several housed piezoelectric disk designs to be considered. These may be categorized as unmatched and matched. Unmatched designs may encapsulate a resonator (thickness, radial, or flexural mode) in an impervious housing. Matched designs, for which more details have been published, include a single $\lambda/4$ matcher having an impedance as close as practical to the geometric mean of the impedances of the piezoelement and the gas. Two-layer designs also exist (Figure 3). The simpler one-layer design has proved adequate in over a thousand flare gas flowmeters installed in pipelines, refineries, and chemical plants between 1983 and 2003. This design has also been used in high-accuracy flowmeters for natural gas, that is, Hill and Weber (2002).

Acoustic isolation of transmitter from receiver, to prevent cross talk, is often one of the most difficult design aspects of gas transducers used in pairs. Some approaches are illustrated in Lynnworth (1989), or in Lynnworth and Mágori (1999) utilizing transducers mounted on membranes; intentionally alternated impedance mismatches; small contact areas; time delays or damping. If the same transducer is used as transmitter and receiver, ringdown often becomes the key problem as far as coherent noise is concerned. Signals indicative of the measurand cannot be detected until coherent noise generated on transmission has subsided sufficiently or unless it can be subtracted. Some examples of isolating or damping transducers, and damping cross talk or ringing, are shown in Figure 4. In manufacturing broadband NDT transducers, the backing impedance matches that of the piezoelement; it is intentionally attenuative; and may have one or more antireflection surfaces (Papadakis and Fowler, 1972).

4 ULTRASONIC TRANSDUCERS FOR LIQUIDS – WETTED, CLAMP-ON, HYBRID

In this section, we introduce three categories of transducer designs for liquids, Figure 5. Principal characteristics are compared in Table 2.

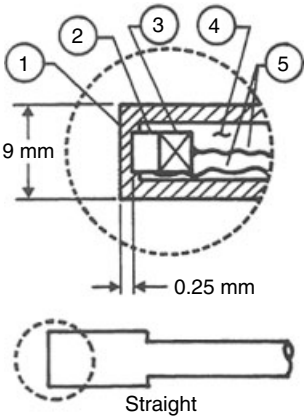
Table 1. Comparison of density and two ultrasonic propagation characteristics of ultrasound for air, water, and stainless steel (longitudinal waves).

Medium (20°C, 10^5 Pa)	Density (ρ) (kg/m^3)	Speed of sound (c) (m/s)	Acoustic impedance (Z) (kg/m^{2}s)	(Mrayls)
Air	1.29	343	450	0.00045
Water	998	1482	1.48×10^6	1.48
Stainless steel 316	7833	5760	45.1×10^6	45.1

Table 2. Categories of transducer designs for liquids.

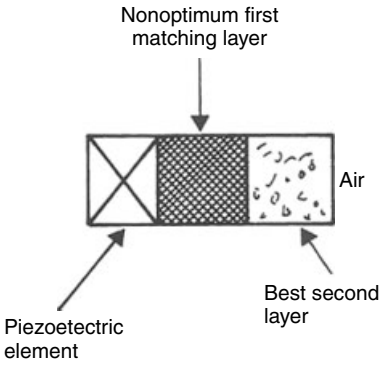
Type	Advantages	Disadvantages
Wetted	Beam path is controllable; used in the most accurate ultrasonic methods; usable over wide frequency range e.g. $0.1 < f < 10$ MHz. May comprise part of replaceable module, e.g. avionic flowmeter.	Requires penetration of pressure boundary; requires isolation valve or empty pipe for installing and removing; cavities distort flow.
Nonwetted clamp-on, strap-on, snap-on, epoxy-on, braze-on, weld-on	Noninvasive, removable unless bonded; easy to retrofit, no cavities. In many cases, it would appear to be the safest way to measure flow in the sense that the pipe integrity is not jeopardized.	Oblique beam path depends on liquid; tendency for acoustic short-circuit noise when conduit wall is thick; usually $f < 2$ MHz. Limited usually to liquids; sometimes usable with gases at high pressure, or gases at atmospheric pressure in special circumstances only.
Hybrid	Combines advantages of wetted and nonwetted approaches. In some cases, the 'window' can be welded, molded, or cast into a valve or pipe fitting to accommodate the occasional or permanent attachment of the transducer.	Requires initial penetration of pressure boundary if window is installed as a retrofit; introduces cavities.

Wetted designs, Figure 5(a), typically employ piezoelements resonant near 0.5, 1, or 2 MHz and may be narrowband or broadband depending on the backing impedance and on the window thickness. Low-impedance backings and thin windows lead to narrowband waveforms. Backings that match the element's impedance and thick metal windows lead to broadband waveforms. But ringing in a thick window can compromise the broadband response. Tapered pipe–threaded housings can be rated up to 20 Mpa (3000 psi). *Flanged* designs, however, are usually preferred for high pressure, depending in part on the fluid and the industry.



Nonwetted external or clamp-on types, Figure 5(b), are designed to fit in standard yokes or tracks. Sometimes they are permanently attached or integral with the spool. Tracks are available with scales so that the axial separation between transducers, as required in contrapropagation or tag flow measurements, can be set easily. For large pipes, magnets or wrap-around straps are commonly used to hold the yokes, tracks, or transducers. For small pipes, below 50-mm inside diameter, one or more transducers may be fixed temporarily or permanently within a given clamp-on or snap-on assembly. Such dual-transducer flowmeter assemblies, for example, became available in the 1980s from Transonic Systems for soft biomedical tubing having internal diameters down to 1 mm, and from Panametrics in 1990 for metal tubing from 10- to 50-mm inside diameter.

The two principal liquid process control uses of external nonwetted transducers have been to measure (i) liquid level, and (ii) flow in pipes. The same or similar transducers can often be used to measure thickness and integrity of pipes and pressure vessels.



Hybrid flowmeter transducers, Figure 5(d, e) evolved first as a convenience for removability and second, and independently, as a remedy to the occasional nuisance and sometimes intolerable errors caused by uncertainty or drifting of the obliquely refracted beam launched in the liquid by a clamp-on angle beam transducer. A hybrid transducer consists of a flat-faced plug that can permanently maintain the pressure boundary while defining one terminus of a known fixed measuring path normal to the wetted face of the plug, and a removable nonwetted transducer that repeatedly mates with the said plug. A hybrid *flowcell* may be taken to mean a spool with transducers that do not comprise part of the pressure boundary. These worked with liquids first and later with gases. A few designs are collected in Figure 6.

In a round conduit of area A, if the flow profile were known precisely, then measurements at a point or along a chord could be readily converted to the area-averaged flow V_{AVG}, from which the volumetric flow rate Q could be calculated as AV_{AVG}. For example, if the flow is steady and *laminar,* the profile is parabolic and a velocity measurement on the axis, V_{AXIS}, would be exactly twice V_{AVG}. Along the midradius chord the chordal average equals V_{AVG}. A measurement along the tilted diameter, V_{DIAM}, is higher than V_{AVG} by 33.3% but is corrected by a meter factor K of value 0.750 in this instance. In other words, $Q = KAV_{\mathrm{DIAM}} = 0.750AV_{\mathrm{DIAM}}$.

For *turbulent* flow, if pipe relative roughness $\in_R$ is known, models exist for estimating the flow profile as a function of the Reynolds number Re. At $\mathrm{Re} = 10^6$, if the pipe is smooth, the diameter path yields V_{DIAM} about 5% higher than V_{AVG}, which is routinely corrected using $K = 0.95$, in this instance. The correction generally is slightly incorrect because of (i) uncertainty in $\in_R$ and its influence, and (ii) uncertainty in the effective beam diameter. *Multipath* flowmeters typically include two or more

paths off the diameter so that a quadrature integration or other weighting procedure can obtain V_{AVG} substantially independent of the profile. For small pipes, the entire duct area can be insonified, as practiced in methods termed 100% area-averaging. In some Doppler flowmeters, range gating is employed, whereby measurements are obtained as a function of distance from the wall. Then the corresponding annular areas are multiplied by their average velocities and the products are integrated to yield $\mathrm{Q} = AV_{\mathrm{AVG}}$ (Takeda *et al.*, 2000). To enhance the interaction between the interrogating wave and the fluid, and thereby improve performance of Doppler or other scatter-based

Figure 3. Transducers for gases: (a) metallurgically sealed single-layer impedance-matched designs for flare gases according to a patent by Lynnworth, Fowler and Patch (1981); legend: 1 thin window, 2 quarter wave impedance matcher, 3 piezo element, 4 potting/backing material, 5 leadwires, (b) two-layer unencapsulated design for air, after Khuri-Yakub *et al*. (1988), (c) clamp-on air transducer, after Ao (2003); see Ting and Ao (2002), (d) gas flowmeter using quadrature integration of flow data obtained in three parallel planes, courtesy of RMG; see Hill and Weber (2002), (e) gas transducer similar to straight one shown in (a) and usable in air at atmospheric pressure and methane up to 100 bar, and (f) comparison of clamp-on paths. Path angles are calculated assuming a refracted angle θ_2 of 60° for a shear wave in the steel pipe. Refracted angle depends on sound speed c_3 in the fluid. Referring to items (1)–(3) commercial contrapropagation clamp-on flowmeters available since the early 1990s include Panametrics' PT868 and 6068 for measuring the flow of liquids. In *water*, the vee path usually works, and θ_3 is about 25° at room temperature. In *air*, $\theta_{3.\mathrm{AIR}}$ is only about 6° and unless pressure is high, the transducers usually need to be placed on *opposite* sides of the pipe. (5) For *liquid* clamp-on, the vee path (shown in (1)) tends to cancel cross-flow as well as double the sensitivity to flow compared to a single traverse. For *gases*, odd numbers of traverses are preferred, to reduce cross talk. This means, if cross-flow is significant, crossed paths are recommended. The velocities measured along the legs of the *X* should be averaged. Best solution: find a long straight run far from disturbances and joints. For *gases* (diagrams (4) & (5)) the flowmeter instrument (6) is Panametrics' GC868 (Ting and Ao (2002)). Diagram (7), drawn for LOX (liquid oxygen) or LN2 (liquid nitrogen), shows the refracted angle $\theta_3 \approx 16°$, nearly midway between water (25°) and air (6°). (Reproduced by permission of Panametrics, Inc.)

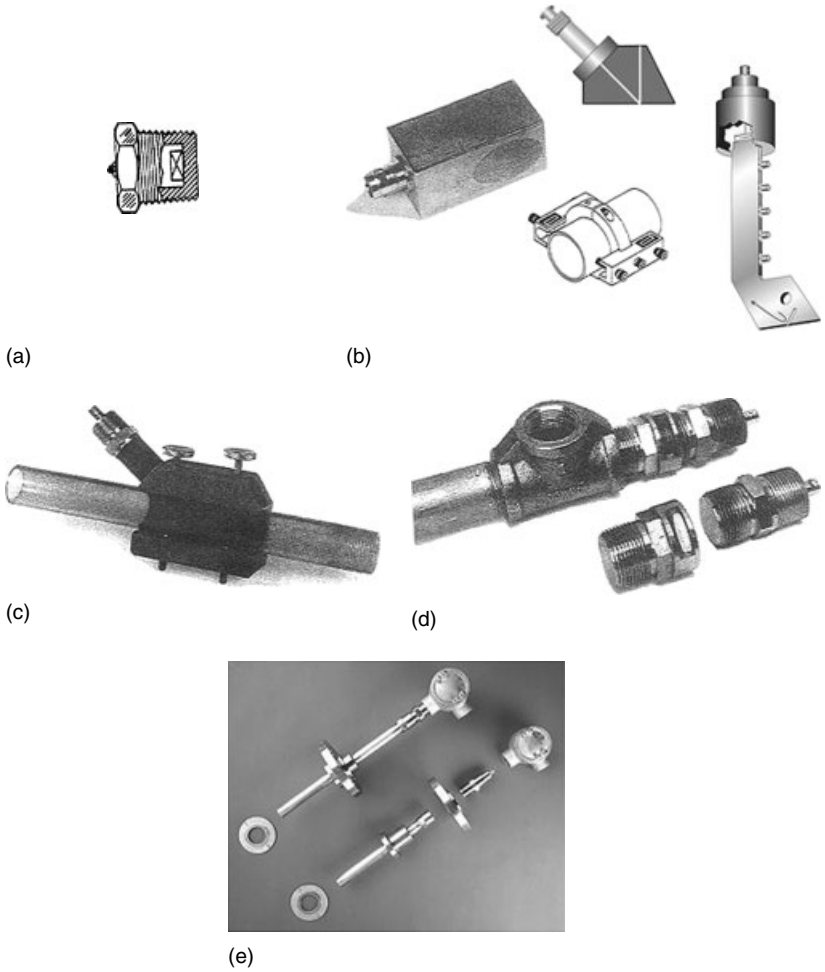

Figure 5. Transducers for liquids: (a) wetted, (b) clamp-on, (c) snap-on, (d) hybrid for ordinary temperature, and (e) hybrid for temperature extremes, using a buffer consisting of a rigid bundle of thin rods within a sealed tube. (Reproduced by permission of Panametrics, Inc.)

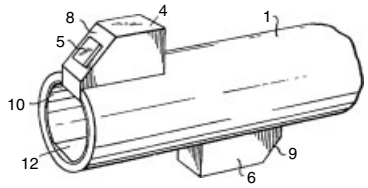
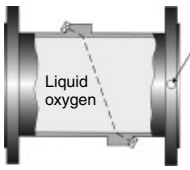


flowmeters in cases in which the fluid does not already contain sufficient scatterers, contrast agents are added. Besides physical contrast agents, investigators sometimes use cavitation bubbles (Takeda *et al.*, 2000). In Lynnworth, Carey and Pedersen (1974), it was suggested that a circumferential external ultrasonic cylindrical transducer, when energized, could generate a hot tag near the axis.

Another way to improve flowmeter performance is to condition the flow to eliminate uncertainty in profile. Flow conditioners (Miller, 1996, Chap. 5; Gallagher, 2002) usually *reduce* cross-flow and swirl, but in principle they could accomplish their purpose of reducing profile uncertainty if they generated a predetermined pattern that includes a known asymmetry and swirl (Hill, 2001). In *small* ducts, flow conditioners have taken the form of static mixers, tube bundles, concentric tubes comprising a Clausius-Mosotti dielectric – constant–based fuel densitometer, or blades (Figure 6).

5 ULTRASONIC TRANSDUCERS FOR NONDESTRUCTIVE TESTING AND EVALUATION OF SOLID MATERIALS



Although the markets and the manufacturers may differ according to one's interpretation of ultrasonic instrumentation (i.e. 'analytic' instrumentation, 'process' instrumentation, 'NDE'(nondestructive evaluation)/NDT instrumentation), one would expect that the physics underlying the wave/measurand interaction would largely determine whether the design of transducers for such applications must differ or could be identical. In practice, many handheld transducers for manual inspection of manufactured parts reflect ergometric design considerations; size, weight, surface contours and finish. Other design considerations include part accessibility, inspectability, transducer wear resistance and longevity. Because of the wide range of materials, geometries, dimensions, microstructures, bonds,

Figure 6. Flowcells and interrogation methods for *liquids*, some of which were later applied or adapted to measuring *gas* flow. Transducers are wetted in some cases and external (not wetted) in others. Flow conditioners were known at least since Turtle (1974); see also, Miller (1996), Chapter 5. A Kenics *static mixer*, not shown, was used as a flow conditioner in 1974 in an R&D (research and development) program and reported by Pedersen, Lynnworth and Bradshaw (1975). (Reproduced by permission of Panametrics, Inc.)

quality levels and a market that has matured over the past half-century, a far greater variety of transducers exists for NDT applications than for any other single process measurand such as flow. Most ultrasonic NDT transducers operate in the 1 to 10-MHz decade. Others are available down to 20 kHz and up to 100 MHz using bondable electroacoustic elements, and up to the gigahertz range using deposited piezoelectrics for acoustic microscopy, see Figure 7.

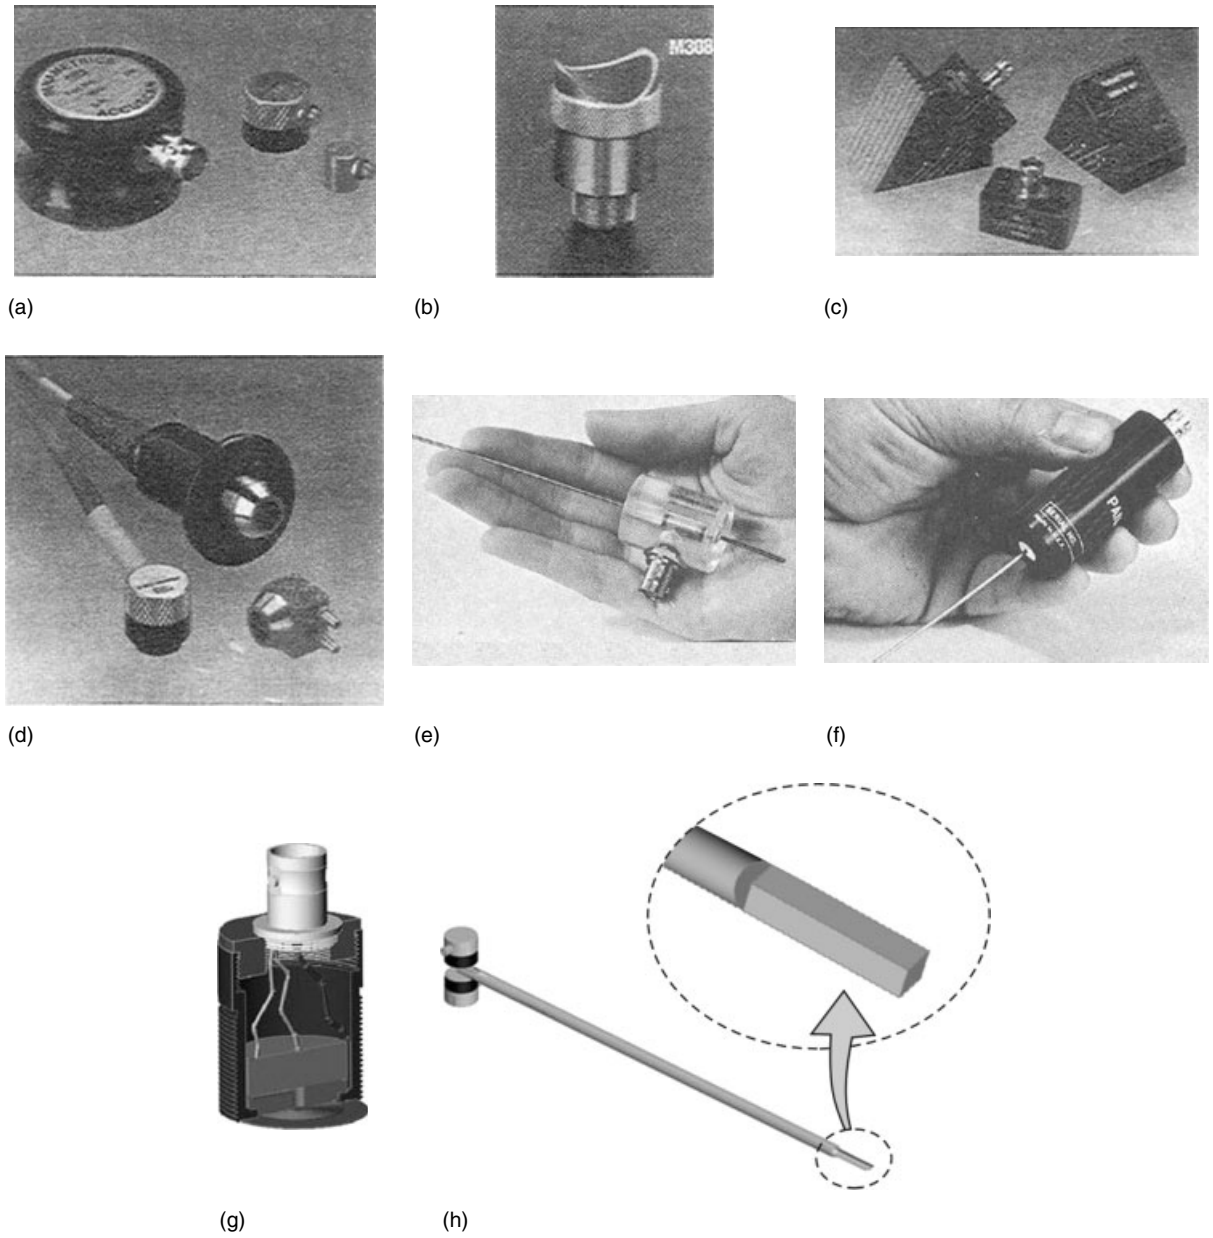

Figure 7. NDT transducers: (a) contact, flat, (b) wetted, focused, (c) angled, (d) dual element for corrosion testing; emat electromagnetic acoustic transducer, (e) slidable magnetostrictive transducer for generating extensional and/or torsional waves, (f) shielded magnetostrictive transducer for generating extensional or torsional waves, (g) emat (electromagnetic acoustic transducer), and (h) shear wave piezo couple used to generate and detect torsional waves by a mode conversion process. The wide range of *sizes and form factors* for 'fixtures' that position NDT transducers is exemplified by comparing (i) a miniature 'clamp-on' transducer that briefly clamps to one's finger; (j) a hand-held transducer in a penlike case versus (k) gantry for robotic ultrasonic scanning system including water squirters for coupling and means to orient transducers normal to an airplane fuselage's contour. Another aspect of *form factor* is the shape or diameter of the specimen. If the specimen is a thin elastic rod, e.g. diameter in the several μm to mm range (l) the methods of Bell (1957) or Fowler (in Lynnworth, Papadakis and Fowler, 1977) may be considered. Post-2000 versions of (l) adapted to moduli measurements and related (derived) characteristics in thin glass fibers are found in Krohn *et al*. (2003). 1 SIGNAL EXTRACTION WHEN NOISE IS PRESENT

A measurement system begins with sensing stages that couple to relevant measurands of the system under study. The power level of the information-bearing signals formed by the sensors is often very low and may be swamped by the unwanted noise signals that are present. Careful attention to sensor and circuit design and assembly, plus use of certain signal processing methods, makes it possible to greatly enhance the original signal-to-noise ratio to usable levels.

This group of articles discusses the various strategies that are available and provides a basis for their use. This is not a widely published topic, the best information probably being available in the literature of companies marketing such products. It is surprising to find that, after well over half a century of signal processing progress, there exist so few full length texts that deal generally with signal recovery and enhancement in general instrumentation applications, see Kester (2002), and the classic work Vainshtein (1985).

It will be found that the techniques, originally conceived for analog methods of signal processing, are often now implemented in digital form, and thus, in many cases provide improved performance at comparable or lower cost. Parts of the systems are, however, necessarily analog and always will be so, since the natural world is not all digital in its structure or form.

2 BASIC METHODS FOR REDUCING NOISE

Recovering or enhancing a signal, or improving a signal-to-noise ratio (SNR) simply means reducing the noise accompanying a signal.

There are two basic ways of doing this:

1. Bandwidth reduction, where the noise is reduced by reducing the system noise bandwidth (B_n). This approach works well if the frequency spectra of the noise and signal do not overlap significantly, so that reducing the noise bandwidth does not affect the signal. With random white noise, the output noise is proportional to $\sqrt{B_n}$. With nonwhite noise, other relationships will apply.
2. Averaging or integrating techniques, where successive samples of the signal are synchronized and added together. The signal will grow as the number (n) of added samples; with random white noise, the noise will grow as $\sqrt{n}$. This is only the case, if the signal characteristics are stationary for the duration of the extraction process.

Sometimes it is useful to combine both techniques. In many applications there is significant overlap between the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

signal and noise spectra and improving a signal-to-noise ratio must be done at the expense of the response time or measurement time (T); with random white noise interference, the output signal-to-noise ratio is proportional to $\sqrt{T}$. The bandwidth reduction technique is best looked at from a frequency-domain point of view; signal averaging and correlation techniques lend themselves to time-domain analysis.

In this set of articles, – **Part 12, Elements: F – Signals and Noise, Volume 3** – mathematics, and theoretical considerations are kept to a minimum and the models presented are basic. Practical best practice requires considerably more processing to precondition signals than is shown here. For further simplicity, it is assumed that all noise processes are stationary and that both signal and noise are ergodic, analog variables; we will not concern ourselves here with digital signals or discrete-time (sampled) signals except where such signals are involved in the enhancement techniques. They are essential in modern application methods but it is the basic ideas that drive the digital methods.

In addition, only signal recovery techniques will be considered. Further processing, such as least-squares polynomial smoothing of a waveform or Fourier transformation to obtain a frequency spectrum, are not considered here.

Discussion is started by reviewing some basic concepts, then moving on to ways of avoiding adding noise (e.g. hum pickup and preamplifier noise) and finally covering the instrumentation techniques used to reduce the remaining noise content. Finally, special considerations involved in recovering pulse signals from photon (light), ion, or electron beams are covered in this section **Part 12, Elements: F – Signals and Noise, Volume 3**.

3 NATURE OF NOISE

Noise is an undesired signal. All systems have it present to some degree. It usually becomes of interest when it obscures a desired signal. Figure 1 shows the power spectral density (power/unit bandwidth) of the most commonly encountered types of noise.

Deterministic noise can range from simple discrete-frequency components such as power-line hum at harmonics of 50 or 60 Hz, to radio frequency interference, RFI, caused by narrow, high-energy pulses from power-line switching spikes, pulsed lasers, radar transmitters, and the like.

Stochastic or random noise is found in most systems both as white noise, where the power spectral density is independent of frequency, and also as $1/f$ or flicker noise, where the power spectral density decreases as frequency increases. Power spectral density is usually measured in mean-squared-volts/Hz or mean-squared-amperes/Hz; for noise, such specifications are usually referred to as *spot*

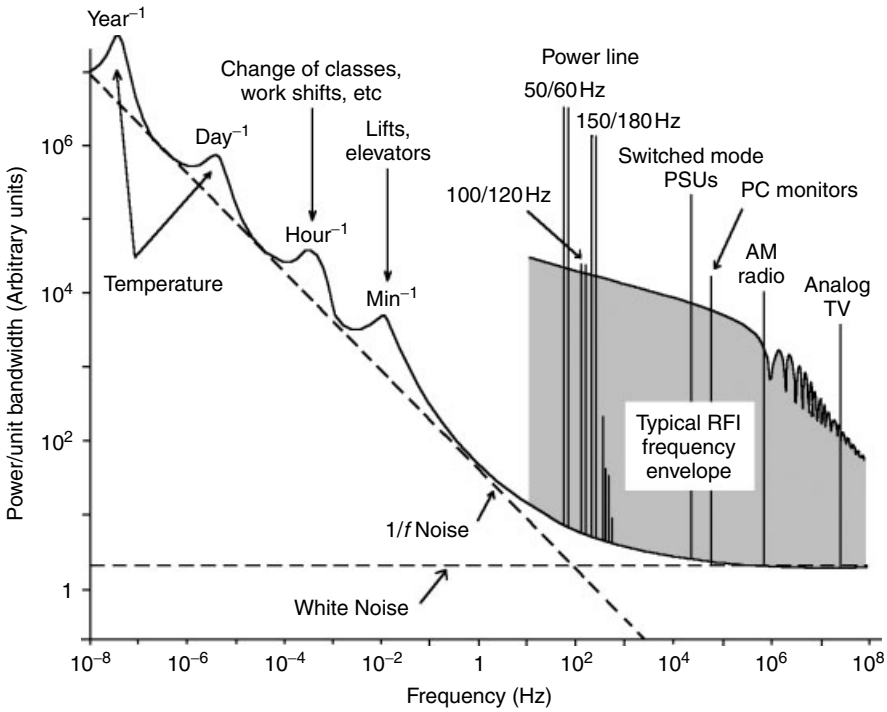

Figure 1. Environmental noise. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

noise data and usually are a function of frequency. Notice that for an rms voltage of v (volts) and a frequency range of Δf (Hz), the power spectral density, S, is given by

$$S = \frac{v^2}{\Delta f} = \left(\frac{v}{\sqrt{(\Delta f)}}\right)^2 \tag{1}$$

The quantity $v/\sqrt{(\Delta f)}$ is usually referred to as *voltage spectral density* and is measured in rms volts/$\sqrt{}$Hz (volts per root hertz). Similarly, we can refer to current spectral density specifications in units of rms amperes/$\sqrt{}$Hz.

4 WHITE NOISE

White noise is usually found in one of two forms: Johnson noise and shot noise. Johnson, or thermal, noise is caused by random motion of thermally agitated electrons in resistive materials, and the mean-square noise voltage is given by

$$v_n^2 = 4kTR\Delta f \tag{2}$$

where k is Boltzmann's constant ($1.381 \times 10^{-23}\,\mathrm{JK}^{-1}$),

T is the absolute temperature (kelvin) and
R is the resistance (ohm).

Alternatively, from Ohm's law, the mean-square noise current is given by

$$i_n^2 = \left(\frac{v_n}{R}\right)^2 = \frac{4kT\Delta f}{R} \tag{3}$$

Shot noise is caused by the random arrival of electrons – *see* **Article 184, Photon Counting, Volume 3** – at, for example, the electrodes of electron tubes or transistor junctions. A DC current, I, will have a noise-current component, i_n, given by

$$i_n^2 = 2AeI\Delta f \tag{4a}$$

where e is the charge of one electron ($\approx 1.6 \times 10^{-19}\,\mathrm{C}$), A is the mean gain experienced by each electron and I is in amperes. In many cases, $A = 1$, so that

$$i_n^2 = 2eI\Delta f \tag{4b}$$

5 FLICKER NOISE

Flicker noise has many different origins and is not clearly understood but exhibits a $1/f^n$ power spectrum with n usually in the range of 0.9 to 1.35. Note that DC drift is a very low frequency form of flicker noise.

What this model represents is that it is increasingly harder to remove noise as the frequency is lowered below 1 Hz or so. This makes practical sense when it is considered that there is a link between noise generation and temperature cycling of mechanical systems. It becomes harder to integrate temperature cycling noise as the cycle time lengthens.

6 IMPORTANCE OF BANDWIDTH

What do we mean by bandwidth? In the simple low-pass filter circuit shown in Figure 2, for example, we usually and somewhat arbitrarily define the signal bandwidth (Figure 3) to be the cutoff frequency, f_c, where $v_o/v_i = 70.7\%$ ($-3\,\mathrm{dB}$) or $v_o^2/v_i^2 = 50\%$ (the half-power point).

7 EQUIVALENT NOISE BANDWIDTH

Notice that frequencies above f_c will obviously pass (although attenuated) through the filter, and therefore are not really cut off. For noise, it is convenient to think in terms of an equivalent noise bandwidth, B_n, defined by the relationship

$$B_n = \frac{1}{G^2}\int_0^\infty |H(j\omega)|^2\,\mathrm{d}f \tag{5}$$

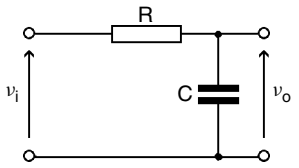

Figure 2. Low-pass filter circuit. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

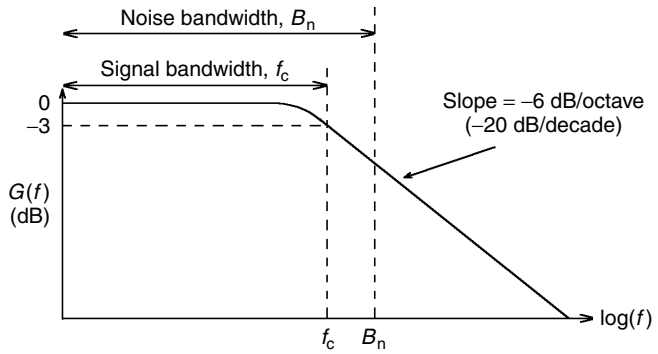

Figure 3. Low-pass filter transfer characteristic. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

where $H(j\omega)$ is the frequency response function of the system and G is a gain parameter suitably chosen to be a measure of the response of the system to some parameter of the signal: for low-pass systems (e.g. Figures 2 and 3), G is usually taken to be the zero-frequency or DC gain. For band-pass responses, G is usually made equal to the maximum gain.

Using the above definition, and taking G to be the zero-frequency gain (i.e. unity), we can readily calculate that for the simple RC filter shown in Figure 2 that

$$B_n = \frac{1}{4}RC \text{ Hz} \tag{6}$$

Noise, of the stochastic form, has been reviewed in relation to instrument systems in a classic paper, Fellgett and Usher (1980).

1 INTRODUCTION TO OPERATIONAL AMPLIFIERS (OP-AMPS)

The voltage levels available from passive sensor conditioners are usually too small to be practically useful; it is necessary to amplify the signal. Since the development of the triode valve by Lee de Forest early in the twentieth century, many other significant developments in amplification have been achieved. Notable milestones were the appearance of the point contact transistor, the bipolar junction transistor (BJT), the field-effect transistor (FET) or junction field-effect transistor (JFET) and the metal oxide semiconductor (MOSFET).

From these developments in semiconductor technology, rapid evolution of solid-state amplifiers has resulted in the integrated circuit operational amplifier, abbreviated to IC op-amp or simply op-amp.

It should also be noted that when the expression op-amp is now used, it usually refers to the IC unit as purchased from a manufacturer. Whenever the word *amplifier* is used, it implies a circuit that employs an op-amp and some other components to constitute the overall amplifier. Amplifiers and the op-amps included in them, which are the basic building blocks of almost all data handling measurement systems, have now reached a very high degree of sophistication. The detailed internal design of op-amps will not be considered here; it is very specialized.

Op-amps are directly coupled amplifiers having, for reasons that will be discussed later, a high gain of the order of $>10^4$. In their own right, they are highly reliable electronic systems. In addition, they bring the benefits of compactness, versatility, and ease of use, which make them essential electronic building blocks. This means they can make a substantial contribution to increasing measuring systems sensitivity while exhibiting versatility in the design of the frequency characteristics of the systems in which they are employed.

In many such industrial systems, the measuring points are fairly remote from the data processing location. Op-amps make a considerable contribution to the effective transmission of these remotely acquired signals. They consume comparatively little power. Consequently, it can be concluded that the versatility brought to measuring systems by electronic means is largely due to the impact of the op-amp.

The continuing steadily improving performance of op-amps since their first introduction around 1960 has been accompanied by significant reduction in their cost. Consequently, op-amps now give measuring system designers a

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

versatile building block component for inclusion in numerous applications to realize many diverse and complex functions. The versatility of op-amps lies in their application using associated feedback networks. Thus, op-amps can be configured to act as summers, subtracters, and difference amplifiers. They can also perform the functions of differentiation, integration, and of other types of filters, or as comparators. This concept has eventually resulted in the universal application of the op-amp for a variety of uses, as is obvious from its universality in contemporary measuring systems. As there is a wide diversity of available types of IC, the task of choosing a suitable op-amp for a particular application is not difficult but requires some knowledge of their nature, scope, characteristics, and formal modeling.

2 CLASSIFICATION OF OP-AMPS

No single op-amp type meets the needs of every application. All practically manufactured forms constitute a compromise among the various aspects and features required. Hence, the design of op-amps is an optimizing process. To give a good overall view, the three main op-amp types will be considered by describing their principal features.

Originally, op-amps were designed for the application of external voltage feedback. This keeps the inverting input current small by maintaining high input impedance as well as by keeping the input difference voltage small. Contemporary designs make the inverting input respond to current using current feedback in such a way that the output voltage is proportional to the current. Major benefits of current feedback are the much larger slew rate and the much decreased influence of stray input capacitance on op-amp bandwidth.

3 TYPES OF SEMICONDUCTOR AMPLIFIER UNITS USED IN OP-AMPS

Bipolar transistor differential op-amp: Op-amps using bipolar technology are probably the most widely applied general-purpose units. They are used as differential amplifiers, which are described in **Article 123, Instrumentation Amplifiers, Volume 2**, in low noise applications with low impedance sources and in low performance, and in noncritical computational applications.

They are popular because of their low cost, modularity, packaging, and wide temperature range. Input bias current, which can be in the range 1 nA to 1 μA at 25 °C, has a typical drift in excess of 0.2 nA with offset voltage drift in the range 0.25 to 100 μV/ °C. Open loop gain is in the range from 10^4 to 3×10^6. (Note that these levels of gain are rarely used in open loop operation – see later.)

Field-effect transistor, or FET, differential op-amp: When it is important to minimize input bias current, it is usual to design an op-amp using a complementary pair of input FETs. This type of input also increases the input impedance of the op-amp. Unfortunately, because the bias current essentially depends on the reverse saturation current of the gate-to-source junction, its bias current drift is much larger than for a bipolar input unit. Their potential for high slew rate and fast settling time is accompanied by capacitive pickup of noise signals due to the high input impedance. Some cases are also known where mechanical vibration causes problems if they introduce movement into the wiring. They find use in general-purpose applications, in differential amplifiers, low noise amplifiers from high impedance sources and sample-and-hold amplifiers and integrators, because of their low bias current.

FET op-amps may use either junction FETs or MOSFETs. They require a bias current in the range of 0.01 to 100 pA at 25 °C, which doubles with every 10 °C increase in temperature. Their drift voltage is around 2 to 100 μV/ °C. Open loop gain is 10^4 to 5×10^5. Because their differential input resistance is very high, at around 10^{11} to 10^{12} Ω, they are particularly suitable for creating noninverting amplifiers. MOSFET types require special input circuitry to protect them against damage by electrostatic charges.

Other measuring system amplifiers: Many amplifiers can be constructed by combining the basic op-amp unit with other components. Those considered here are the instrumentation amplifiers in **Article 123, Instrumentation Amplifiers, Volume 2** and the chopper, chopper stabilized/compensated and auto-zero amplifiers, isolation amplifiers, and the charge amplifier discussed in **Article 124, Specialized Amplifiers for Measurement Systems, Volume 2**.

4 OPEN LOOP VOLTAGE TRANSFER FUNCTION

As shown in Figure 1, the voltage transfer relation of an op-amp is essentially nonlinear especially when v_o is close to either of the supply rail voltages. In normal operation, the op-amp is restricted to the linear range of the voltage transfer relation. Note that when $v_{Ig} = v_{Ng}$ then $v_o = 0$. This corresponds to the case of infinite common mode rejection, or CMR. A figure of merit for an op-amp, which specifies its ability to reject common mode signals, is called the *common mode rejection ratio*, or CMRR.

An op-amp will have an infinite CMRR if there is symmetry of all of its parameters. It is never possible to obtain infinite CMRR because production mismatches

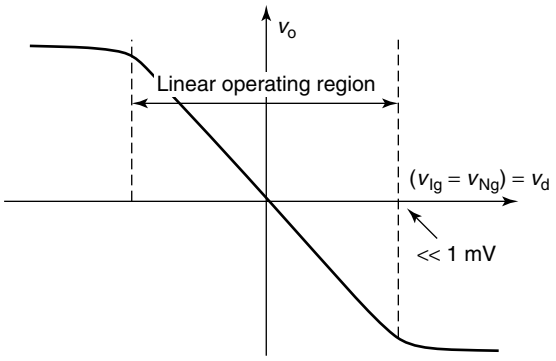

Figure 1. Voltage transfer relationship for op-amp.

always produce asymmetries. This means that the open loop gains of the op-amp to inverting and noninverting inputs are always different. The open loop gain of an op-amp is typically $>2 \times 10^5$, which is sufficiently high for the majority of practical applications.

5 OP-AMP MODEL

Op-amps are usually modeled for their signal handling properties. The simple block diagram and circuit model of an ideal op-amp, which are shown in Figure 2, visualize the op-amp as a voltage controlled voltage source.

Although op-amps require the supply of electrical energy, their connections to the power supply are rarely shown in circuit diagrams.

Various degrees of model complexity exist. Input terminals, referred to as the inverting, I, and noninverting, N, inputs, drive the amplifier as a difference signal to give an output voltage, which is directly proportional to this difference signal. The ideal amplifier has infinite input or output impedance, has an infinite bandwidth of operation without gain change and a gain that is very high, but not quite infinite. This is different from the definition given in many other books where the gain is assumed to be infinite.

Complete symmetry also characterizes the amplifier so there is no input circuit mismatch or gain asymmetry in the signal propagation from I and N to the output.

6 INVERTING CIRCUITS

Basic inverting amplifier with finite gain op-amp: In most practical situations, op-amps are connected with feedback to form a closed loop configuration. One of the two basic closed loop circuits is the single input inverter shown in its general form in Figure 3(a) and for a closed loop gain of 1 in Figure 3(b). A stage gain of $(-R_f/R_1)$ is expected if the op-amp gain approaches infinity. The 5-kΩ resistor in Figure 3(b) is to maintain symmetry for bias purposes. More will be said about this in Section 8.

Assume that the op-amp is ideal in the sense defined before so that $v_o = -A_0 v_{IN}$. Define the frequency independent feedback factor as $\beta_I = R_1/R_1 + R_f$. Also, since the input current $i = 0$ the closed loop gain, A_{CL}, can be shown to be

$$v_o = A_{CL} v_{in} = -\frac{R_f}{R_1} \times \frac{\beta_1 A_0}{1 + \beta_1 A_0} v_{in}$$

$$= -G_0 \frac{\dfrac{1}{1 + G_0} A_0}{1 + \dfrac{1}{1 + G_0} A_0} v_{in} \tag{1}$$

In the case when $\beta_1 A_0 \gg 1$, it can be seen that the closed loop gain has the value $A_{CL} \approx -R_f/R_1 = -G_0$, where G_0 is the low frequency stage gain assuming the op-amp has an infinite open loop gain.

In other words, the closed loop gain at low frequencies is determined purely by the ratio of two resistors. This is an important finding for it means imperfections in manufacture, and the gain actually used, have little effect on the closed loop gain in this feedback configuration. It also shows why basic op-amp units are made with such high values of gain.

Since it is assumed that the op-amp input resistance is infinite, the stage has an equivalent input resistance given by

$$R_{in} = R_1 + \frac{R_f}{1 + A_0} \tag{2}$$

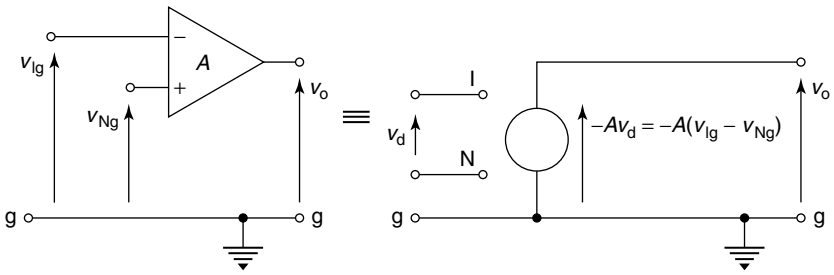

Figure 2. Block diagram and circuit model of an ideal IC op-amp.

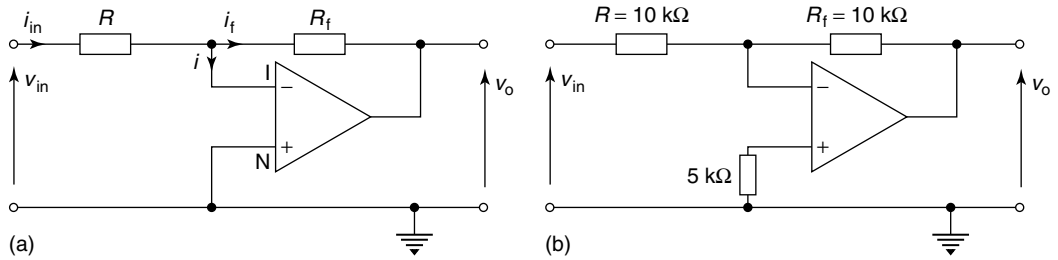

Figure 3. Inverting amplifier.

The term, $R_f/(1 + A_0)$, in (2) is the effect of R_f across the terminals IN of the op-amp in Figure 3 when the Miller effect of R_f is taken into account.

It is obvious that there will be an error in the calculation of the gain if it is assumed that the open loop gain of the op-amp is infinite. To express this error, (1) may be rewritten as

$$v_o = A_{CL}v_{in} = -G_0(1 - \varepsilon_G)v_{in}$$
$$= -G_0\left[1 - \left(1 + \frac{1}{1 + G_0}A_0\right)^{-1}\right]v_{in} \qquad (3)$$

where $\varepsilon_G = (1 + 1/(1 + G_0)A_0)^{-1}$ is the relative error introduced by assuming that the closed loop gain is $G_0 = R_f/R_1$. Usually, but not always so, the variation in gain not being infinite is insignificant.

Summing amplifier: Several inputs may be connected to the summing point as shown in Figure 4.

Assume an infinite gain op-amp so that the inverting input node, I, can be considered as a virtual earth corresponding to $v_i \approx 0$. Assume infinite op-amp input resistance so that i_{IN} may be taken as zero to give

$$i_1 + i_2 + i_3 = -i_f \qquad (4)$$

then

$$\left(\frac{v_1}{R_1}\right) + \left(\frac{v_2}{R_2}\right) + \left(\frac{v_3}{R_3}\right) = \frac{-v_o}{R_f} \qquad (5)$$

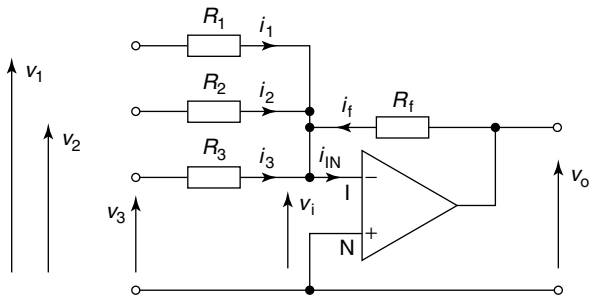

Figure 4. Summing amplifier.

so that

$$v_o = -\left(\frac{R_f}{R_1}\right)v_1 - \left(\frac{R_f}{R_2}\right)v_2 - \left(\frac{R_f}{R_3}\right)v_3 \qquad (6)$$

Hence, also, the channels are noninteracting if the open loop gain is infinite.

Effect of op-amp input resistance: The value of the differential open loop input resistance, R_{indd}, of an op-amp is typically >300 kΩ and is usually neglected.

7 NONINVERTING CIRCUITS

Basic noninverting amplifier: Circuits for noninverting amplifiers are shown in Figure 5. In these circuits the input signal is applied to the noninverting input terminal, N, of the op-amp, which is assumed to have a frequency independent gain of $-A_0$. Taking a voltage sum around the external nodes of the circuit for the noninverting amplifier in Figure 5(a) gives

$$v_{Ig} = v_{IN} + v_{in} = v_{IN} + v_{Ng} \qquad (7)$$

Assume infinite op-amp input resistance so that i_{IN} may be taken as zero. Convert the loop with v_o, R_f, and R_1 into an equivalent voltage source looking left from the terminal I. Also use the frequency independent feedback factor, defined above for (1), to obtain

$$v_{Ig} = \beta_I v_o = \frac{R_1}{R_1 + R_f}v_o = v_{IG} + v_{Ng}$$
$$= -\frac{v_o}{A_0} + v_{in} \quad \text{or} \quad v_o = \frac{A_0}{1 + \beta_I A_0}v_{in} \qquad (8)$$

In the case when $\beta_I A_0 \gg 1$, (5) can be simplified to give

$$v_o = \left(1 + \frac{R_f}{R_1}\right)v_{in} \qquad (9)$$

In the same way as for the inverter, there will be an error in the calculation of the noninverting gain when the

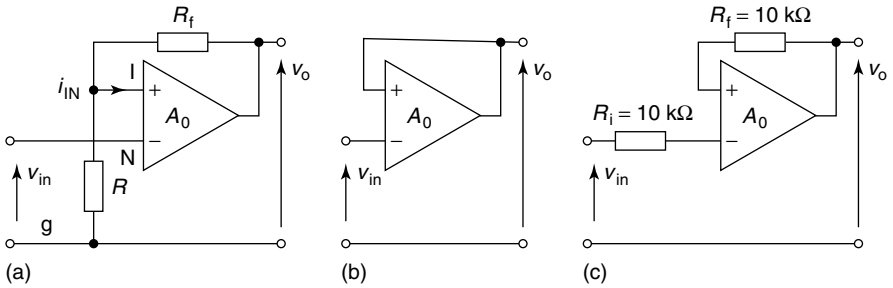

Figure 5. Noninverting amplifiers (a) with gain (b) as a follower and (c) with bias compensation.

open loop gain of the op-amp is assumed to be infinite. To calculate the error, (8) can be rewritten in a similar way as (3) to obtain the expression for the relative error.

Example 1. Deduce an expression for the effective input resistance of the noninverting amplifier whose op-amp has a low frequency open loop gain of A_0 and a differential input resistance of $R_{indd} = 300\,k\Omega$. If $A_0 = 10^6$, $R_f = 100\,k\Omega$ and $R_1 = 10\,k\Omega$, calculate the stage input resistance.

Solution: Represent the loop with the output voltage, v_o, and the resistors R_f and R_1 as an equivalent voltage source. Figure 5(a) can then be redrawn as in Figure 6.

The effective stage input resistance can be deduced immediately as

$$R_{in} = \frac{v_{in}}{i_{IN}} = R_{indd}\beta_I A_0 + \frac{R_1}{R_f} \quad \text{and} \quad \frac{R_1}{R_f} \ll R_{indd}\beta_I A_0$$
$$\approx R_{indd}\left[\frac{A_0}{1+G_0}\right] \text{ with } G_0 = \frac{R_f}{R_1} \tag{10}$$

Completing the calculations gives

$$R_{in} = R_{indd}\left[\frac{A_0}{1+G_0}\right] = \frac{300 \times 10^3 \times 10^6}{1+10} = 27.3\,G\Omega$$

Hence, noninverting amplifiers appear as near open circuits to signals.

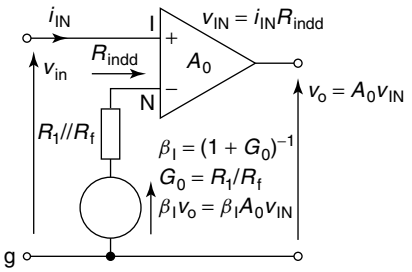

Figure 6. Circuit for evaluating the input resistance of a noninverting amplifier.

Basic voltage follower: The basic voltage follower, shown in two versions in Figure 5(b) and (c), is a special case of the noninverting amplifier in which $R_f = 0$. This circuit is used as a buffer amplifier, allowing a transformation from a high source impedance to a low source impedance. Specific questions of interest are the value of the input resistance and the value of the output resistance. For finite op-amp gain at low frequencies, it is easily shown that

$$v_o = \frac{A_o}{1+A_o} v_{in} \tag{11}$$

The values of R_1 and R_f are not critical. They may be chosen to suit the biasing conditions.

Example 2. An op-amp has an open loop gain of $A_0 = 10^5$. Evaluate the error in the closed loop gain, A_{CL}, of an inverting stage if the feedback resistance is $R_f = 100\,k\Omega$ and the lead-in resistance is $R_1 = 10\,k\Omega$. Also, calculate the input resistance of the stage.

Comment upon the error in calculating the gain in the case of a noninverting amplifier with the same parameter values

Solution: Substituting into (3) gives the gain error as

$$\varepsilon_G = \left(1 + \frac{1}{1+G_0}A_0\right)^{-1} = \left(1 + \frac{1}{11} \times 10^5\right)^{-1}$$
$$\approx \left(\frac{11}{10^5}\right) \approx 110 \text{ parts in 1 million or } 0.011\%$$

The input resistance of the stage is calculated from (4) as

$$R_{in} = R_1 + \frac{R_f}{1+A_0} = 10 + \frac{100}{1+10^5}$$
$$= (10 + 0.001)\,k\Omega \approx R_1$$

The error in calculating the gain of the noninverting stage with the same values is equal to the error for the inverting case.

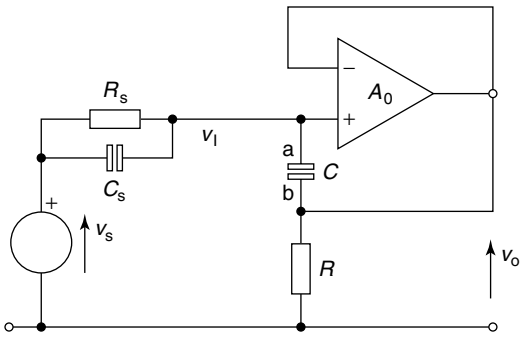

Figure 7. Potential equalization.

Potential equalization: A useful application of the voltage follower is for two nodes of a network to be at the same potential without any physical connection. This can occur on a printed circuit card where it is difficult to isolate items for testing purposes. The circuit points a and b in Figure 7 are at the same potential so there is no current flowing in C. Hence, the source is an open circuit. However, the amplifier drives a current through R. Hence, the source may exhibit an open circuit frequency response.

8 FREQUENCY DOMAIN FACTORS AND BEHAVIOR

Frequency domain parameters of op-amps: Typical values of these parameters can vary widely depending upon op-amp price and application. For example, very low-cost units will have

Unity gain bandwidth = 1 MHz,
Low frequency open loop gain = 2×10^5,
Roll-off rate = −6 dB/octave,
Corner frequency = 5 Hz.

The small signal bandwidth for any closed loop gain $A_{CL} \geq 10$ is given by

$$\text{Bandwidth} \approx \frac{10^6}{A_{CL}}\text{Hz} \tag{12}$$

For ultralow noise and ultralow distortion types these parameters are

Unity gain bandwidth = 100 MHz,
Low frequency open loop gain = 20×10^6,
Roll-off rate = −6 dB/octave,
Corner frequency = 5 Hz.

The small signal bandwidth for any closed loop gain $A_{CL} \geq 10$ is given by

$$\text{Bandwidth} \approx \frac{10^7}{A_{CL}}\text{Hz} \tag{13}$$

Slew rate and full power frequency response: The slew rate of an operational amplifier is the maximum rate of change of output voltage at the rated output.

The slew rate is normally specified for the unity gain follower configuration, as this is often the worst case.

If frequency compensation is optimized, higher closed loop gain often yields higher slew rates. The slew rates for positive and negative swing of the output need not always be the same. For any desired output swing, the slew rate can set the limit for the frequency response obtainable for that particular swing.

An important frequency domain parameter is the full power response frequency, f_p. This is the maximum frequency at which rated output can be obtained without significant distortion. It can be expressed in terms of the slew rate of the amplifier as

$$f_p = \frac{S_r}{2\pi E_o} \tag{14}$$

where S_r is the slew rate and E_o is the rated output voltage.

This relationship is obtained by equating the slew rate to the maximum slope of a sinusoidal signal of peak value, E_o, and frequency, f_p. It indicates that the effective frequency response of an amplifier for a specific output swing is often more limited by the slew rate of the amplifier than by the small signal frequency response predicted by the open loop gain characteristics.

Inverter with frequency dependent gain: Consider the inverting amplifier in Figure 3 with generalized frequency dependent impedances Z_f and Z_1, replacing R_f and R_1 respectively, and an op-amp with an open loop gain $\overline{A_{OL}} = -A_0/[1 + j(\omega/\omega_c)]$. Assume that the op-amp is ideal in every other respect. Define the frequency dependent feedback factor, $\overline{\beta_I} = Z_1/Z_1 + Z_f$. Conduct an analysis similar to that for the basic inverter. To take account of the frequency dependence of all of the circuit parameters, this is done in the frequency domain to obtain the voltage frequency response function as

$$\frac{V_o(j\omega)}{V_{in}(j\omega)} = A_{CL} = -\frac{Z_f}{Z_1}\frac{\overline{\beta_I} \times \overline{A_{OL}}}{1 + \overline{\beta_I} \times \overline{A_{OL}}} \tag{15}$$

Equation (15) provides a general result for frequency domain behavior. Integrators, differentiators, and active filters, which can be analyzed using (13), are described in Section 8, of **Article 124, Specialized Amplifiers for Measurement Systems, Volume 2**.

9 OFFSET VOLTAGE, BIAS, AND NOISE IN OP-AMPS

Asymmetrical fabrication mismatches in the input of op-amps give rise to two undesirable effects. The first is input voltage offset and the second is asymmetry of bias currents. Even when the input voltage of an op-amp is zero, the output is always nonzero.

Input offset voltage is the value of an equivalent input voltage, which would give this output voltage.

The input bias currents are those currents necessary to bias the input transistors of the op-amp for operation. These effects are modeled as shown in Figure 8(a). The offset voltage, v_{os}, and offset current, i_{os}, consist of a nominal component plus components due to its sensitivity to changes in temperature, time, and power supply voltage. It is possible to design the circuit so that the nominal and the temperature components are completely removed.

Voltage offset: Even with the highly sophisticated techniques used in modern IC fabrication, it is virtually impossible to fabricate op-amps without input stage asymmetries. Values of the input offset voltage, v_{os}, can be as high as 2 to 7 mV in low-cost units to as low as 50 to 100 μV in ultralow distortion and ultralow noise units. The polarity of the input offset voltage may differ between units. In practice, the output offset, which is determined by the product of gain and input offset, can be corrected by appropriate offset correction circuits.

The output offset can be calculated in a specific case provided both the input offset voltage, v_{os}, its sensitivity to variations in temperature, power supply voltage and time, as well as the gain of the stage, are known.

Analysis proceeds by treating the input offset voltage as an input at the noninverting terminal of the stage, which is looked upon as a noninverting amplifier like that in Figure 5(a).

Average temperature coefficient of voltage offset: The average temperature coefficient of offset, $\Delta v_{os}/\Delta T$, is typically about 1 to 6 μV/°C. Using this coefficient, the output offset voltage changes can be calculated in specific cases. This approach is also used to calculate temporal drift and power supply changes.

The input bias current: This has a typical value of 0.01 pA to 1.5 μA, with an effective offset current of 80 nA. The bias current is the average of the individual bias currents, I_{B1} and I_{B2}, shown in Figure 8(a). The offset is half the difference. The presence of the bias current introduces an additional offset error, depending on the input and feedback resistors used. Referring to Figure 8(b) the output error, v_o, resulting from the effect of bias current is

$$v_o = \frac{I_{B1}R_f}{R_{i1}} - I_{B2}R_{i2}\left(1 + \frac{R_f}{R_{i1}}\right) \tag{16}$$

The total output offset error will include that due to the input offset voltage. For an amplifier having a typical offset voltage error, V_{os}, and bias current I_B, there is a critical resistance value of $R_i = V_{os}/I_B$. If a value of R_i greater than this is used, the offset error due to bias current will be greater than that due to offset voltage.

Input offset current: The input offset current, i_{os}, is the difference between the bias current I_{B1} and I_{B2}. In many op-amps, the bias currents track each other well with temperature and are very nearly equal in magnitude. Hence, it is possible to minimize the errors due to bias currents by proper choice of input resistors. Note that offset current can exhibit sensitivity to the same circuit variables as the offset voltage. From (16), if

$$R_{i2} = \frac{R_{i1}R_f}{R_{i1} + R_f} \tag{17}$$

then

$$v_o = (I_{B1} - I_{B2})R_f = i_{os}R_f \tag{18}$$

If R_{i2} cannot be selected as in (7), the value of bias current will determine the DC output errors.

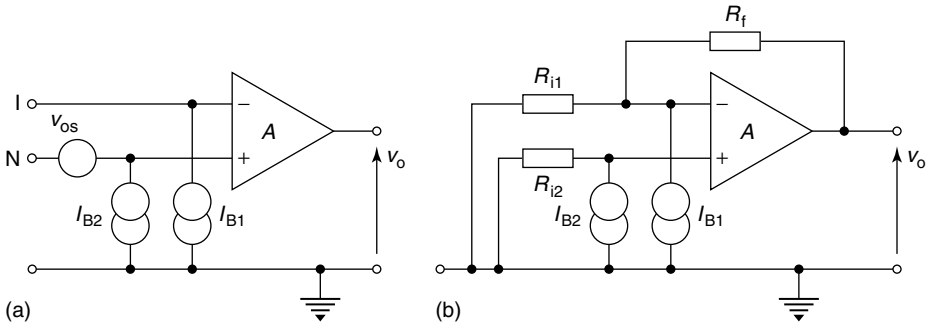

Figure 8. Individual input bias currents in (a) require compensation for resulting offset using (b).

Example 3. Estimate the output offset voltage and its variation from 25 °C to 45 °C for an op-amp in the inverting configuration, as shown in Figure 3(a), having a gain of −10 and a lead-in resistance R_1 of (a) 10 kΩ and (b) 100 kΩ. Assume that op-amp offset parameters are $v_{os} = \pm 2$ mV with a temperature coefficient of $\pm 6\,\mu$V/°C and $i_{os} = 80$ nA with a temperature sensitivity of 1%/°C.

Solution: Consider first (a) $R_1 = 10\,\text{k}\Omega$ at 25 °C. For a gain of −10, $R_f = 100\,\text{k}\Omega$.

The general expression for the output voltage combining the errors due to offset voltage and bias current is

$$v_o = \pm v_{os}\left(1 + \frac{R_f}{R_i}\right) + i_{os}R_f \tag{19}$$

Therefore, taking into account the direction of current flow,

$$[v_o]_{25\,^\circ\text{C}} = \pm 2 \times 10^{-3}(1 + 10) + 80 \times 10^{-9} \times 100 \times 10^3$$
$$= +30 \text{ to } -14\,\text{mV}$$

Knowing the temperature sensitivities, the offset voltage and the bias current, the output offset can be calculated to give

$$[v_o]_{45\,^\circ\text{C}} = +29.3 \text{ to } -17.3\,\text{mV}$$

If the offset voltage correction is arranged at 25 °C, the change in output will be

$$\Delta v_o = (\pm 1.32 - 2)\,\text{mV} = -0.68 \text{ to } -3.32\,\text{mV}$$

Repeating the above calculations for case (b) $R_1 = 100\,\text{k}\Omega$ gives $R_f = 100\,\text{M}\Omega$, $[v_o]_{25\,^\circ\text{C}} = +102$ to $+58$ mV and $[v_o]_{45\,^\circ\text{C}} = +83.3$ to 36.7 mV. Hence,

$$\Delta v_o = -18.68 \text{ to } -21.32\,\text{mV}$$

Note that the errors due to bias current increase as R_1 is increased.

Voltage and current noise: Unfortunately, it is not possible to compensate for the equivalent noise voltage and current in as simple a way as for the offset components. Since the mechanisms that lead to both voltage and current noise are statistical, then, statistical methods, based upon correlation analysis, must be used to calculate effective levels. If the signal is low level, corresponding to small v_d, thus requiring high amplification, usually >100, noise sources will largely determine the fundamental resolution of the amplifier.

Since, op-amps are made from either bipolar or field-effect transistors; the op-amp noise will consist of the same types as occur in these devices. Fabrication technology uses silicon nitride methods, which is a combination of special diffusion techniques and modern surface passivation, to give good surface stability. Bipolar noise is predominantly low frequency voltage noise due to emitter region dislocations, whereas the field-effect MOS device is mostly due to trapping levels within the oxide. Channel carriers jump into these levels and are later expelled back into the channel. Ion-implanted field-effect technology is used in FET input op-amps. These effects are modeled using similar voltage and current sources as for the offset effects.

10 EQUIVALENT CIRCUIT FOR REAL OP-AMPS

Figure 9 illustrates a consolidated op-amp model for assessing the circuit behavior of an op-amp. Assessment is important because the signal propagation properties must be calculable. This can only be done with an effective signal transmission model. Other important aspects are the offset and noise behavior of the op-amp in the actual configuration used.

In the model, the parameters are grouped in a logical manner by offset sources, noise sources, and impedances. Although all of these parameters will generally be asymmetrical as is shown in the model, simplification is possible.

The consolidated equations for offset voltage and current are respectively

$$\begin{aligned} e_{os} &= E_{os} + \frac{\Delta v_{os}}{\Delta T}\Delta T + \frac{\Delta v_{os}}{\Delta V_s}\Delta V_s + \frac{\Delta v_{os}}{\Delta t}\Delta t \\ &= \begin{pmatrix}\text{normal}\\ \text{in } \mu\text{V at } 25\,^\circ\text{C}\end{pmatrix} + \begin{pmatrix}\text{temperature}\\ \text{sensitivity}\\ \mu\text{V}/^\circ\text{C}\end{pmatrix} + \begin{pmatrix}\text{power supply}\\ \text{sensitivity}\\ \mu\text{V}/\%\end{pmatrix} + \begin{pmatrix}\text{temporal drift}\\ \mu\text{V/day}\end{pmatrix} \end{aligned} \tag{20}$$

$$\begin{aligned} i_{os} &= I_{os} + \frac{\Delta i_{os}}{\Delta T}\Delta T + \frac{\Delta i_{os}}{\Delta V_s}\Delta V_s + \frac{\Delta i_{os}}{\Delta t}\Delta t \\ &= \begin{pmatrix}\text{normal}\\ \text{in nA at } 25\,^\circ\text{C}\end{pmatrix} + \begin{pmatrix}\text{temperature}\\ \text{sensitivity}\\ \text{nA}/^\circ\text{C}\end{pmatrix} + \begin{pmatrix}\text{power supply}\\ \text{sensitivity}\\ \text{nA}/\%\end{pmatrix} + \begin{pmatrix}\text{temporal drift}\\ \text{nA/day}\end{pmatrix} \end{aligned} \tag{21}$$

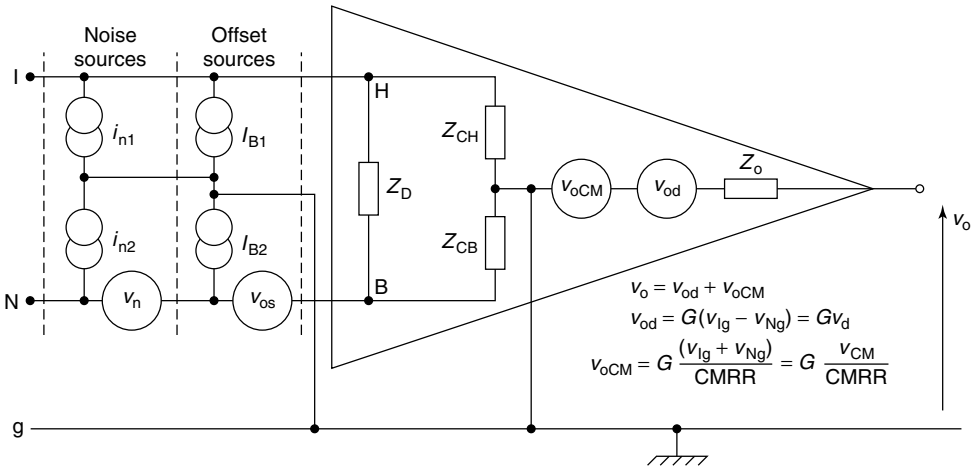

Figure 9. Consolidated signal, offset and noise model for an op-amp.

It can be seen from (20) and (21) that the offset voltage and current can be calculated for any given changes in temperature, power supply voltage and time period from the drift sensitivity coefficients.

It is usually possible to adjust the initial offset voltage and current to zero using a suitable biasing network. The standard practice is always to quote offsets and drift referred to the input in op-amp specifications. This allows the method to be used of multiplying the input referred effects by the noninverting gain to obtain the effect of offsets on the output. The methods used to calculate output offset effects in instrumentation amplifiers, which are different from those used in op-amps are described in Section 6 of **Article 123, Instrumentation Amplifiers, Volume 2**.

Because the noise values are normally considered as energy densities per unit bandwidth, it is more appropriate to perform any noise budgeting analysis in the frequency domain.

1 THE ELECTRONIC INSTRUMENTATION AMPLIFIER

An instrumentation amplifier, or IA, is a closed-loop, dedicated circuit differential input gain block. These units can justifiably be considered as one of the most important elements in contemporary measuring systems.

The primary function of an IA is precision amplification of the differential signal applied to its inputs, while rejecting any existing common-mode signals. Ideally, an IA only responds to the difference in voltage between the two signals applied to its input terminals. This difference is often called the *differential input voltage*.

IAs also exhibit extremely high impedances between the I and N input terminals, and from each of these terminals to ground. The output voltage, which is equal to the product of the amplifier gain and the differential input voltage, is also developed as a single-ended output with respect to ground. Note that an IA differs fundamentally from an op-amp. An op-amp is an uncommitted open-loop device, whose closed-loop performance can be designed depending upon the external networks used to close the feedback loop.

To extend the common-mode rejection ratio (CMRR) of the configurations, IAs using discrete realizations of two and three op-amp configurations were widely employed. In contemporary systems where the trend is toward 12-bit, 14-bit, or even higher resolution, the discrete approach is no longer satisfactory. This trend for better resolution also means that tighter specifications for nonlinearity, offset and gain drift, and noise are usually required for instrumentation amplifiers.

In this article, the foundational design principles of flexible high performance IAs are described. These properties are presently obtained by combining additional specially designed circuits with high performance op-amps on the same monolithic chip. Hence, the section commences with a description of the basic difference stage and the differential-input to differential-output stage, which are the two constituent stages of the most common realization of IAs. This is followed by details of the two op-amp and three op-amp forms of IA realization. The importance of dealing with common-mode signals is considered at different places.

2 DIFFERENTIAL INPUT TO SINGLE-ENDED OUTPUT STAGE

The circuit for the general case of an asymmetrical differential stage, sometimes also called a *difference amplifier*, is given in Figure 1. In differential amplifiers, asymmetries

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

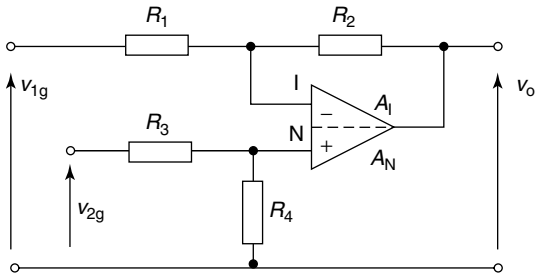

Figure 1. An asymmetrical difference amplifier.

in all of the parameters of the circuit must be considered. Asymmetries will occur because of the inherent asymmetry of the op-amp used. In addition to the offset asymmetries, there will be gain asymmetry in the signal paths between the inverting input and the output and between the noninverting input and the output.

Offset effects may be treated separately on the basis that stage linearity allows the application of superposition. Although the resistors in the stage are high-tolerance components, it is still necessary to take these tolerances into account.

Analyzing the stage gives its output voltage as

$$v_o = -A_I v_{Ig} + A_N v_{Ng} \tag{1}$$

Define

$$\beta_I = \frac{R_1}{R_1 + R_2} \quad \text{and} \quad \beta_N = \frac{R_3}{R_3 + R_4} \tag{2}$$

Hence,

$$v_{Ig} = \frac{R_2}{R_1}\beta_I v_{1\,g} + \beta_I v_o \quad \text{and} \quad v_{Ng} = \frac{R_4}{R_3}\beta_N v_{2g} \tag{3}$$

Substitute (2) into (3) and the result into (1) and simplify to obtain

$$v_o = -\frac{R_2}{R_1}\frac{\beta_I A_I}{1 + \beta_I A_I} v_{1g} + \frac{R_4}{R_3}\frac{\beta_N A_N}{1 + \beta_I A_I} v_{2\,g} \tag{4}$$

Assume that $\beta_I A_I > 1$. Now let $v_{1g} = -v_{2g} = 1/2v_d$ to obtain the differential mode output voltage, v_{od}, as

$$v_{od} = -\frac{1}{2}\left(\frac{R_2}{R_1} + \frac{R_4}{R_3}\frac{\beta_N A_N}{\beta_I A_I}\right) v_d = -A_{vd} v_d \tag{5}$$

where the difference mode–voltage gain, A_{vd}, is

$$A_{vd} = -\frac{1}{2}\left(\frac{R_2}{R_1} + \frac{R_4}{R_3}\frac{\beta_N A_N}{\beta_I A_I}\right) \tag{6}$$

In a similar way, let $v_{1g} = v_{2g} = v_{CM}$ to obtain the common mode–output voltage, v_{oCM}, as

$$v_{oCM} = -\left(\frac{R_2}{R_1} - \frac{R_4}{R_3}\frac{\beta_N A_N}{\beta_I A_I}\right) v_d = -A_{vCM} v_{CM} \tag{7}$$

where the common mode–voltage gain, A_{vCM}, is

$$A_{vCM} = \left(\frac{R_2}{R_1} - \frac{R_4}{R_3}\frac{\beta_N A_N}{\beta_I A_I}\right) \tag{8}$$

Using superposition, the total output voltage, which includes a difference-mode component and a differential mode component, can be written as

$$v_o = -A_{vd} v_d - A_{vCM} v_{CM} = -A_{vd}\left(v_d + \frac{1}{CMRR} v_{CM}\right) \tag{9}$$

where the common-mode rejection ratio, or CMRR, is given by

$$CMRR = \frac{A_{vd}}{A_{vCM}} = \frac{1}{2}\frac{\dfrac{R_2}{R_1} + \dfrac{R_4}{R_3} \times \dfrac{\beta_N}{\beta_I} \times \dfrac{A_N}{A_I}}{\dfrac{R_2}{R_1} - \dfrac{R_4}{R_3}\dfrac{\beta_N}{\beta_I} \times \dfrac{A_N}{A_I}} \tag{10}$$

This rejection ratio is an important figure of merit for a differential amplifier, since it allows a comparison of the ability of one arrangement to reject common-mode signals with the same ability of some other arrangement.

If it is momentarily assumed that the op-amp is ideal and the circuit is symmetrical, then $\beta_I A_I = \beta_N A_N$. This shows that the matching condition for infinite rejection of common-mode inputs corresponds to the denominator of (5) being zero or $(R_2/R_1) = (R_4/R_3)$.

However, all of the circuit resistors have manufacturing tolerances and the op-amp has asymmetrical gain. These inadequacies ensure that there is a practical limit to the common-mode rejection property of the stage. To evaluate the effects, it is possible to express the *CMRR* as

$$CMRR = \frac{1 + G_{0Q}}{\pm\delta_1 \pm \delta_4 \pm \delta_2 \pm \delta_3 \pm (1 + G_{0Q})CMRR^{-1}} \tag{11}$$

where the nominal closed-loop gain to inverting inputs is $G_{0Q} = R_{2Q}/R_{1Q}$ and the factor *cmrr* is the common mode–rejection ratio of the op-amp itself.

Equation (11) is easily understood. It demonstrates that the *CMRR* of a practical differential amplifier depends upon

both the matching of the circuit resistors and the *cmrr* of the op-amp.

It is instructive to consider typical numerical values. Let the stage have $G_{0Q} = 1$ and also that $cmrr_{dB} = 100 \equiv 20\log_{10}\ (A_{vd}/A_{vCM})$ so that $cmrr = (A_{vd}/A_{vCM}) = 10^5$, which is a typical value. This gives the last term in the denominator of (5) a value of 2×10^{-5}.

Compared to typical resistor tolerances of $\pm 1\%$, or 0.01, this figure of 2×10^{-5} can be neglected. It is only when $(1 + G_{0Q})\ cmrr^{-1} \geq 0.004$ that the term due to op-amp *cmrr* needs to be taken into account. This will correspond to $G_{0Q} \approx 4 \times 10^{-3} \times cmrr = 400$ for *cmrr* equal to 10^5. Hence, for good common-mode rejection, use tightly matched resistors, which can track each other well with temperature, select a low value for G_{0Q} and a high value for *cmrr*. Even for values of resistor tolerance of $\pm 1\%$ and $G_{0Q} = 1$, the value of the stage *CMRR* is still only ≈ 50, which is not very impressive. Clearly, steps need to be taken to design a differential amplifier with a much higher *CMRR*.

In the above analysis, it has been assumed that the common mode–input resistance/impedance of the op-amp has been neglected. To give a more complete interpretation, the effects of asymmetry in these resistances need to be taken into account.

It is easily understood that the common-mode resistance between both I and N op-amp inputs and ground act as voltage dividers when combined with their external circuit components. The problem is especially evident if the lead-in resistors are increased in value in an attempt to increase the common mode–input resistance of the stage. This can be counterproductive, since it will lead to increased offset and drift. In the case of FET type op-amps, which can tolerate large values of lead-in resistance because of their significantly lower bias current, such an increase might be counterproductive by introducing an increase in noise and a decrease in bandwidth when combined with the stray circuit capacitance.

Resistor tolerance has been shown to be the critical factor in determining the *CMRR* of the stage, since the tolerance of this component exerts a much greater influence than the *cmrr* of the op-amp used. Resistance asymmetry for whatever reason or from whatever cause, effectively converts common-mode interference into series mode interference. These series mode sources are indistinguishable from the true difference-mode input.

Although trimming the resistors can help improve the *CMRR*, this may be of no benefit if the trimmed resistors do not track each other with changes in temperature. Other sources of drift are due to sensitivity to changes with time, such as temperature drift and aging effects, and power supply voltage.

3 DIFFERENTIAL-INPUT TO DIFFERENTIAL-OUTPUT STAGE

Another important disadvantage of the basic difference amplifier considered before in Section 2 is its comparatively low input resistance. This can be improved using a suitable form of the type of noninverting amplifier previously considered in Section 6 of **Article 122, Operational Amplifiers, Volume 2**.

It will be recalled from (10), in **Article 122, Operational Amplifiers, Volume 2**, that the input resistance of the noninverting stage and the follower stage are very much higher than that of the inverting stage. Also, noninverting stages essentially buffer a high-impedance source to a low-impedance source. The need for high input resistance and high *CMRR* in amplifiers for low-level signals are satisfied by combining differential-input to differential-output amplifiers with the differential-input to single-ended stage in Section 1.

Of the candidate circuits shown in Figure 2, consider the first Figure 2(a) using only follower stages. This combination stage provides a differential output from a differential input with a very high input resistance. Provided the op-amps are well matched, it also has a low common-mode gain. Its only real disadvantage is its unity differential gain.

Consider the second circuit in Figure 2(b), consisting of two cross-connected noninverting stages. The voltages around the circuit are

$$v_w = v_1 \quad \text{and} \quad v_z = v_2 \tag{12}$$

The current, i_0, flowing in the resistor, R_0, is seen to have the value $(v_w - v_z)/R_0$ so that the output voltages, v_{o1} and v_{o2}, are given by

$$v_{o1} = v_1 + \frac{v_1 - v_2}{R_0} R_2 \quad \text{and} \quad v_{o2} = v_2 - \frac{v_1 - v_2}{R_0} R_2 \tag{13}$$

When there is no differential mode input, then $v_1 = v_2$ so that $v_{o1} = v_{o2} = v_{CM}$ giving a common-mode voltage gain

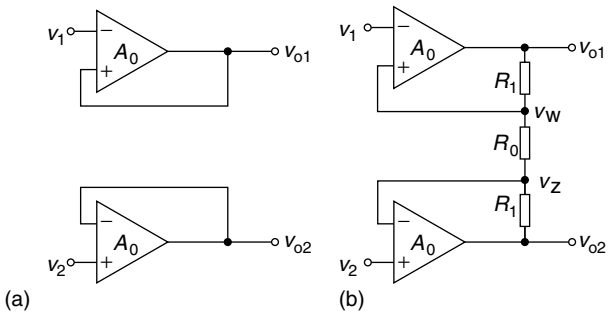

Figure 2. Candidate circuits for differential-input to differential-output stages.

A_{vCM} of unity. For difference-mode inputs corresponding to $v_1 = 1/2v_d$ and $v_2 = -1/2v_d$, the stage has a difference mode–voltage gain, A_{vd}, given by

$$A_{vd} = \frac{v_{o1} - v_{o2}}{v_d} = \left(1 + 2\frac{R_2}{R_0}\right) \tag{14}$$

Because $A_{vCM} = 1$, the *CMRR* of the stage is thus numerically equal to the difference-mode gain, which can be chosen to be very high simply by reducing the value of R_0. Since the stage consists of noninverting amplifiers, the output resistance at each of the output nodes will be very low.

Common-mode signals, which are transmitted with unity gain by both op-amps, can be converted to series mode–interfering components if the op-amps used are not exactly matched. With such asymmetry, any common-mode signal, v_{CM}, will give rise to a differential signal given by

$$v_{CM}\left(\frac{1}{CMRR_1} - \frac{1}{CMRR_2}\right) \tag{15}$$

4 TWO OP-AMP CONFIGURATION

Basic two amplifier configuration: A circuit diagram for a basic two amplifier IA realization is shown in Figure 3.

The voltages around the circuit are

$$v_A = v_1[1 + (1 + R_1/R_2)] = \frac{v_1}{B_{1I}} \quad \text{with} \quad B_{1I} = \frac{R_2}{R_1 + R_2} \tag{16}$$

$$v_o = -\left(\frac{R_4}{R_3}\right)v_A + \left(\frac{v_2}{B_{2I}}\right) \quad \text{with} \quad B_{2I} = \frac{R_3}{R_3 + R_4} \tag{17}$$

$$v_o = -\left(\frac{R_4}{R_3}\right)\left[\frac{R_1 + R_2}{R_2}\right]v_1 + \left[\frac{R_3 + R_4}{R_3}\right]v_2 \tag{18}$$

With $R_4 = R_2$ and $R_1 = R_3$, this becomes

$$v_o = \left[\frac{R_1 + R_2}{R_1}\right](v_1 - v_2) = \left(1 + \frac{R_2}{R_1}\right)v_d \tag{19}$$

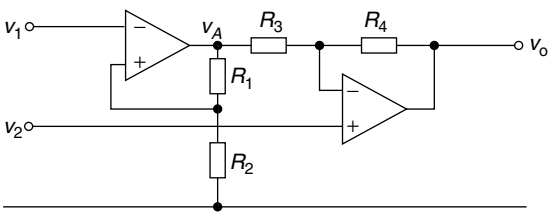

Figure 3. Basic instrumentation amplifier configured using two op-amps.

5 THREE OP-AMP CONFIGURATION

Three op-amp IA configuration: This configuration, illustrated in Figure 4, has a high accuracy and excellent common-mode rejection. Provided that the amplifiers, A_1 and A_2, are well-matched, low-noise, low-offset, and high-gain units then precision difference amplification with high common-mode rejection may be obtained.

The input stages, A_1 and A_2, constitute a differential-input to differential-output stage so that $v_{o1} - v_{o2}$ has an amplified component of v_d and an unamplified component of v_{CM}. The stage A_3 is a standard differential-input to single-ended output stage with unity gain and a high CMRR.

The equations around the circuit are

$$v_{o1} = \left[1 + \left(\frac{2R_1}{R_o}\right)\right]^{\frac{1}{2}} v_d + v_{CM}$$

$$v_{o2} = -\left[1 + \left(\frac{2R_1}{R_o}\right)\right]^{\frac{1}{2}} v_d + v_{CM} \tag{20}$$

Taking into account the finite $CMRR_3$ in A_3 and using (17) gives the output voltage as

$$\begin{aligned} v_o &= -\left(1 + 2\frac{R_1}{R_0}\right)v_d + \frac{1}{CMRR_3}v_{CM} \\ &= -Gv_d + \frac{1}{CMRR_3}v_{CM} \\ &= -G\left[v_d + \frac{1}{G \times CMRR_3}v_{CM}\right] \\ &= -G\left[v_d + \frac{1}{CMRR_o}v_{CM}\right] \end{aligned} \tag{21}$$

where $CMRR_o$ is the overall *CMRR* of the stage.

Note that $CMRR_o = G \times CMRR_3$ shows that the *CMRR* is increased by the difference gain $G = (1 + 2R_1/R_0)$ of the differential-input to differential-output stage. This is

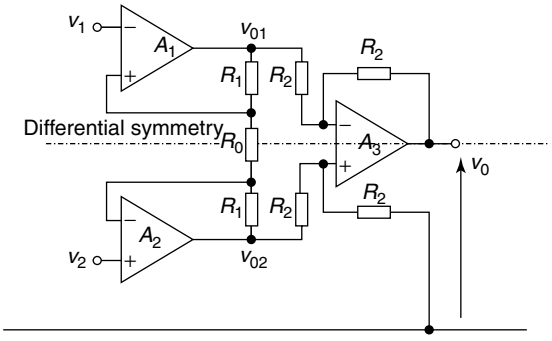

Figure 4. Three op-amp configured instrumentation amplifier.

possible because the common-mode gain of this stage equals unity. The common-mode rejection ratio of A_3, $CMRR_3$, is completely determined with negligible error by the tolerance of the resistors, R_2, in accordance with (11). Since the common-mode rejection ratio of A_3, $CMRR_3 = 1/2\delta_2$, (21) can be written finally as

$$v_o = -G\left[v_d + \frac{2\delta_2}{G} v_{CM}\right] \tag{22}$$

Example 1. A three op-amp IA, which uses resistors with a tolerance of ±1%, has a closed-loop gain of 200. Calculate the common-mode rejection ratio of the stage.

Solution: Since $CMRR_o = G \times CMRR_3$, and $CMRR_3 = (1 + G_3)/4\delta$, the overall $CMRR$ is calculated as $CMRR_o = 200 \times (1 + 1)/(4 \times 0.01) = 10\,000$, which is equivalent to $CMRR_{odB} = 20 \log_{10} 10\,000 = 20 \times 4 = 80$ dB.

6 SPECIFYING INSTRUMENTATION AMPLIFIERS

Closed-loop gain and nonlinearity: The idealized transfer function is

$$v_o = -G(v_1 - v_2) \tag{23}$$

The amplifier gain, G, is usually set by the user to give typical values of 1,200,500, and 1000 with a single external resistor. Temperature coefficient of the gain and gain nonlinearity, shown in Figure 5, can be found on manufacturer's data sheets.

Gain nonlinearity, which is defined as the peak deviation from a best-fit straight line, expressed as a percentage of peak-to-peak full-scale output, is possibly of more importance than the gain accuracy, since the value of the gain can be adjusted to compensate for simple gain errors.

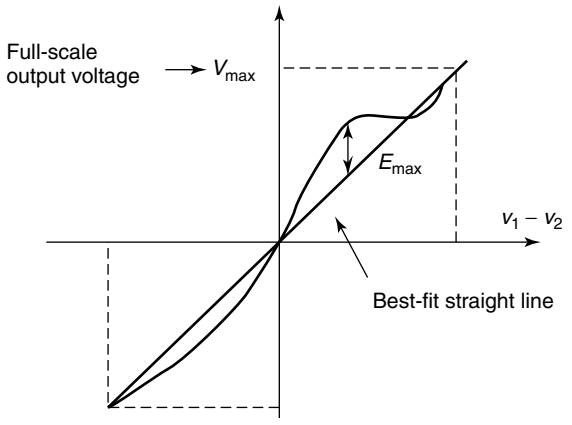

Figure 5. Illustration of nonlinearity error.

Note that for programmable gain IAs, commonly used in computerized data-acquisition systems, the gain control is accomplished through a number of digital inputs.

Offset voltage and input bias currents: Voltage offset and input bias current are often considered as the key figures of merit for IAs.

Offset voltage is defined as the voltage required at the input to drive the output to zero in exactly the same way as for op-amps. While initial offset can be adjusted to zero, shifts in offset voltage in temperature and time introduce errors. They are by far the most important source of error in precision IAs. The temperature coefficients of these parameters, which are always specified by IA manufacturers, have typical values of the order of 1.0 μV/°C in the temperature range $-25\,^{\circ}C \le T_A \le +85\,^{\circ}C$.

The offset at the output of an IA consists of two terms. The first is output offset, V_{os}, sometimes referred to as *unity gain output offset*, while the second is $+GV_{os}$, sometimes referred to as *inverting gain offset*.

The input bias currents, which are currents flowing into or out of the two inputs of the amplifier, correspond to the base currents I_{B1} for BJT and FET leakage currents, depending upon the specific type of op-amp input stage. In the same way as for other op-amp circuits, the bias currents flowing through the source resistance will generate a voltage offset. Although initial bias currents are often adjustable to zero, their drift with temperature, especially for FET type input stages, is very troublesome. Recall from Section 1 of **Article 122, Operational Amplifiers, Volume 2** that the JFET leakage current can double every 10 °C.

There are differences between the methods of calculating offset and drift effects in op-amps and in IAs.

In the case of op-amps, as pointed out in Section 8 of **Article 122, Operational Amplifiers, Volume 2**, offset parameters are always quoted as values referred to as their inputs.

In IAs, extra care needs to be taken because of the effect of the gain-determining nature of the external component. For fixed gain IAs, it does not matter whether the offset parameters are quoted as referred to the input or as referred to the output, because one can be calculated knowing the other, provided the gain is also known.

With adjustable gain IAs, it is essential to remember that each of the offset parameters will give rise to different calculated effects depending upon the gain. In many cases, when the drift sensitivities are quoted at two values of gain, typically 1 and 1000, it is easy to calculate the effective drift at other values of gain. This is achieved by assuming that there is a linear relationship between the drift sensitivity

and the gain. Subsequently, the calculation in specific cases of temperature and power supply ranges and time periods proceeds in the same way as for the op-amp in Section 8 of **Article 122, Operational Amplifiers, Volume 2**.

Frequency response: Specifications such as bandwidth, slew rate, and settling time are defined and specified as for op-amps.

Output impedance: IA output impedance, which is ∼10 to 20 Ω, allows very easy and direct interfacing with other following modules. IAs have much lower output impedances compared with the open-loop output resistance of op-amps.

Consolidated signal, offset, and noise model: This model, shown in Figure 6 may be summarized as possessing the properties of high-input impedance, low offset and drift, low nonlinearity, stable gain, high common-mode rejection, and low effective-output impedance. Hence, it is widely used for applications requiring these advantages. Examples include amplification for various types of transducers such as strain-gauge deflection bridges, load cells, resistance and thermistor thermometer networks, thermocouples, current shunts, and many more, as well as where small differential signals superimposed on high common-mode voltages require preamplification.

Common mode–rejection ratio: An ideal IA must respond only to the difference between the input voltages. The output of the ideal IA will be zero if the input voltages are equal so that $v_1 = v_2 = v_{CM}$, the common-mode voltage.

However, the output voltage of practical IAs has one component proportional to the differential input voltage and a second component proportional to the common-mode input voltage. The common-mode voltage, which appears at the amplifier's input terminal is defined as

$$v_{CM} = \frac{v_1 + v_2}{2} \tag{24}$$

7 IMPROVING THE CMRR – SHIELDING AND GROUNDING

A major source of error in instrumentation amplifier–based systems is the coupling of undesired interfering currents and voltages into systems with low-level signals. This kind of coupled interference, which usually takes the form of common-mode voltages and currents, can occur in many ways through

- differences in potential due to ground loop current flow;
- electrostatic coupling through mutual capacitance between adjacent conductors, such as power supply lines and other high frequency sources;
- electromagnetic coupling through mutual inductive coupling in closed conductive loops;
- asymmetrical effects such as loading of the signal leads.

Handling common-mode signals is crucial in precision low-level measurements, where it is especially essential to improve the *CMRR*. Figures 7 and 8 illustrate two examples of common-mode interference.

In Figure 7, the emf, e, that develops across a thermocouple, which is bonded to a metal plate, has to be measured. This metal plate is at a potential v_{CM}.

In Figure 8, mechanical stress is to be measured with a strain-gauge deflection bridge. When the applied stress is zero, the bridge is at balance and the emf, e, is equal to zero. However, the common-mode voltage, which is applied at the amplifier's input terminal, is equal to

$$V_{CM} = \frac{V_A + V_B}{2} \approx \frac{E}{2} \tag{25}$$

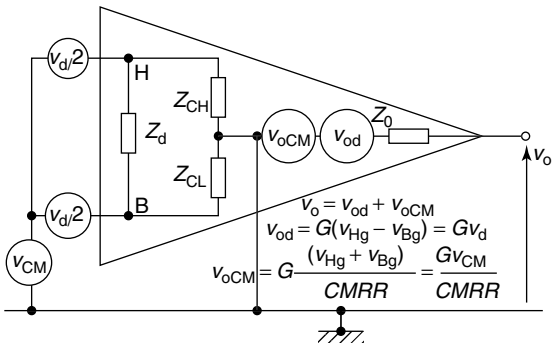

Figure 6. A simplified consolidated model of an instrumentation amplifier.

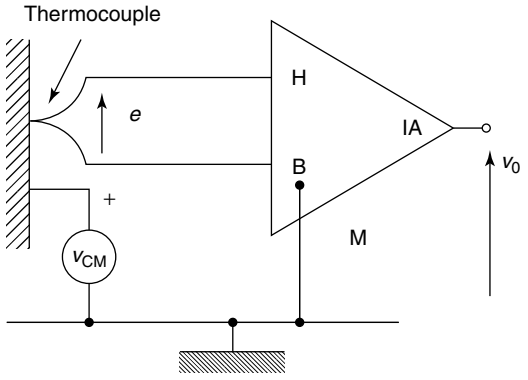

Figure 7. Thermocouple bonded to a metal plate which is at a potential v_{CM}.

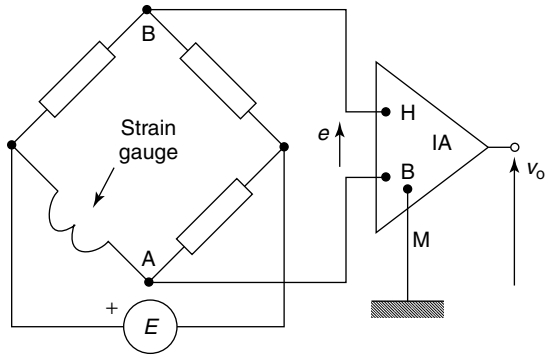

Figure 8. Circuit for measurement of mechanical strain with a strain gauge.

Common-mode interference can exert a critical, sometimes even determining, influence in such systems as industrial-process control systems whose remote transducers are often spread over large distances from their measurement instruments. Analog data must be transmitted over these long distances. Since the input lead resistances are no longer negligible, the undesirable voltages, which can be developed, are added both to any common-mode signal and potential difference between two ground connections, which may influence many transducer circuits.

In the equivalent circuit of a measuring scheme shown in Figure 9(a), R_1 and R_2 represent the input lead resistances, Z_d the IA input impedance, and Z_{CH} and Z_{CB} the leakage impedances from H to ground and B to ground respectively.

Considering only the common-mode voltage, v_{CM}, this circuit may be drawn as shown in Figure 9(b). It is clear that the undesirable voltage, v_P, produced by v_{CM} is zero only when the bridge is perfectly balanced.

When specifying the error caused by v_{CM}, it is usual to consider the worst-case off-balance. Assume that the IA used in this measurement system has infinite *CMRR*. The IA measures the potential difference, v_P which exists across the H and B input terminals. The *CMRR* of the measurement system, expressed in dB, is

$$CMRR_{dB} = 20 \log_{10} \frac{v_{CM}}{v_P} \tag{26}$$

The worst-case off-balance specified by measuring instrument manufacturers is that R_1 is zero, while R_2 is some finite resistance such as, say, 1 kΩ. The equivalent circuit is now shown in Figure 9(c) so that the

$CMRR_{dB}$ is

$$CMRR_{dB} = 20 \log_{10} \left[\frac{Z_{CB} + R_2 \| Z_d}{R_2 \| Z_d} \right] \tag{27}$$

Normally, $Z_d \gg R_2$ and $Z_{CB} \gg R_2$, so (27) simplifies to

$$CMRR_{dB} = 20 \log_{10} \frac{Z_{CB}}{R_2} \tag{28}$$

Example 2. In a certain measuring system, it is known that there is a direct common-mode voltage, V_{CM}. The

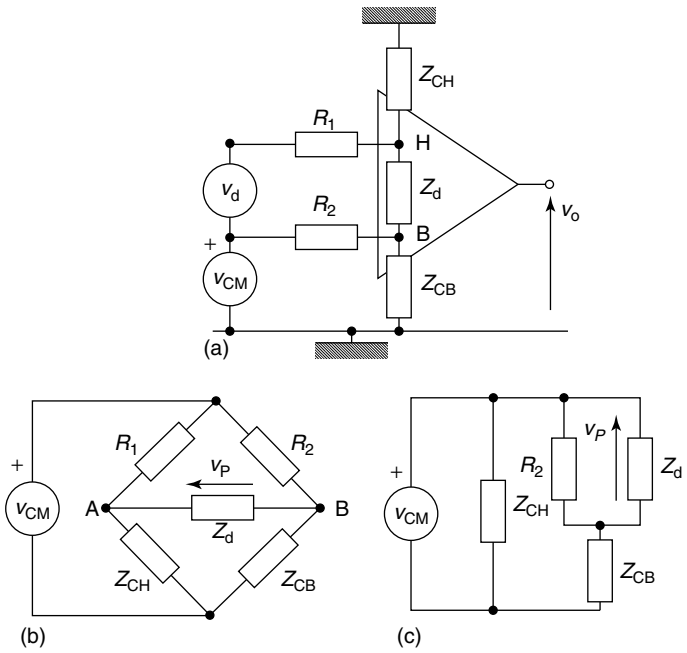

Figure 9. Measuring system in (a) has the parasitic voltage, v_P, in (b) produced by common-mode voltage, v_{CM}, may be analyzed by the equivalent circuit in the worst-case unbalance ($R_1 = 0$) in (c).

leakage impedance, Z_{CB}, between the B terminal of the IA and ground is purely resistive with a value of $R_{CB} = 100\,\text{M}\Omega$ and the off-balance resistance is $R_2 = 1000\,\Omega$. Calculate the $CMRR_{dB}$.

If the common-mode voltage is now alternating, and the leakage impedance is the parallel combination of $R_{CB} = 100\,\text{M}\Omega$ and a capacitance of 100 pF, calculate the $CMRR_{dB}$ if the frequency of v_{CM} is 50 Hz.

Solution: Immediately applying (28) gives

$$CMRR_{dB} = 20\,\log_{10}\frac{10^8}{10^3} = 100\,\text{dB} \tag{29}$$

Now calculate to get

$$|Z_{CL}| = \left|\frac{R_{CB}}{1 + j\omega R_{CB}C}\right| = \left|\frac{10^8}{1 + j2\pi 50 \times 10^8 \times 10^{-7}}\right| \approx \frac{10^8}{2\pi 50 \times 10^8 \times 10^{-7}} \approx 320 \times 10^3 = 320\,\text{k}\Omega$$

Substituting in (28) gives

$$CMRR_{dB} = 20\,\log_{10}\frac{320 \times 10^3}{10^3} \approx 50\,\text{dB} \tag{30}$$

8 IMPROVING THE CMRR – GUARD TECHNIQUES

Guard techniques allow effective shunting of the common-mode bridge and at the same time they provide high common-mode impedances, Z_{CH} and Z_{CB}.

To improve the *CMRR*, the input circuits of the IA are mounted inside a guard shield, which must be well isolated from the ground and connected directly to the common-mode source, v_{CM}, as shown in Figure 10(a) and its equivalent circuit of Figure 10(b).

Note that R_G must be as low as possible and Z_L represents the leakage impedance from the guard shield to ground.

Referring to Figure 10 allows the unwanted voltage, v_P, to be written as

$$v_P = v_{CM}\frac{R_G}{R_G + Z_L} \times \frac{R_2}{Z_{CB}} \approx v_{CM}\frac{R_G}{Z_L} \times \frac{R_2}{Z_{CB}} \tag{31}$$

Hence, using (26), the $CMRR_{dB}$ can be expressed as

$$CMRR_{dB} = 20\,\log_{10}\frac{Z_{CB}}{R_2} \times \frac{Z_L}{R_G} \tag{32}$$

Example 3. An IA mounted inside a guard shield has $Z_{CB} = 1000\,\text{M}\Omega$. If the guard shield leakage impedance is $Z_L = 1000\,\text{M}\Omega$, $R_2 = 10^3\,\Omega$, and $R_G = 100\,\Omega$ calculate the $CMRR_{dB}$ if v_{CM} is direct.

Comment upon the $CMRR_{dB}$ if v_{CM} is alternating.

Solution: Using (32) gives $CMRR_{dB} = 20\log_{10}\ 10^6 + 20\log_{10}\ 10^7 = 260\,\text{dB}$.

When v_{CM} is alternating, the effects of stray capacitance must be taken into account.

Consider the connections illustrated in Figure 11. The instrumentation amplifier often has a very high common mode–rejection ratio. This ensures that the common mode–voltage gain of the amplifier is very low compared to its gain for differential mode signals. In cases in which a cable with a length of 1 m or more runs from the transducer to the amplifier, the common-mode signals presented to the amplifier will not be the same as those at the transducer.

This arises because of mismatches in the resistance and capacitance of the cable. For example, in Figure 11(a)

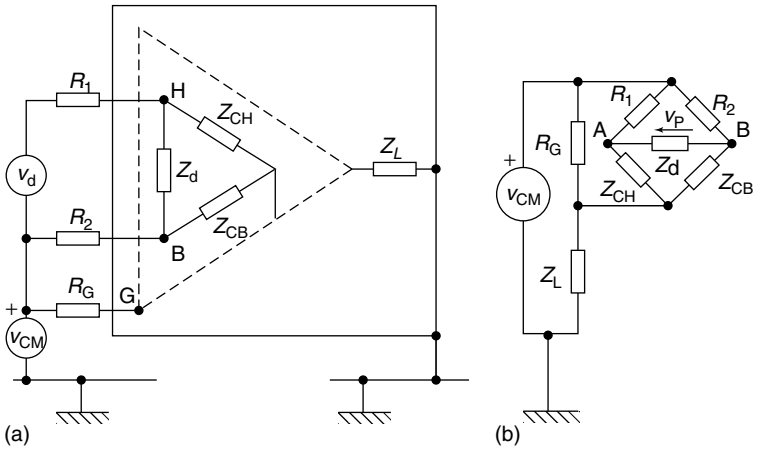

Figure 10. IA mounted inside a guard shield in (a) has the equivalent circuit in (b).

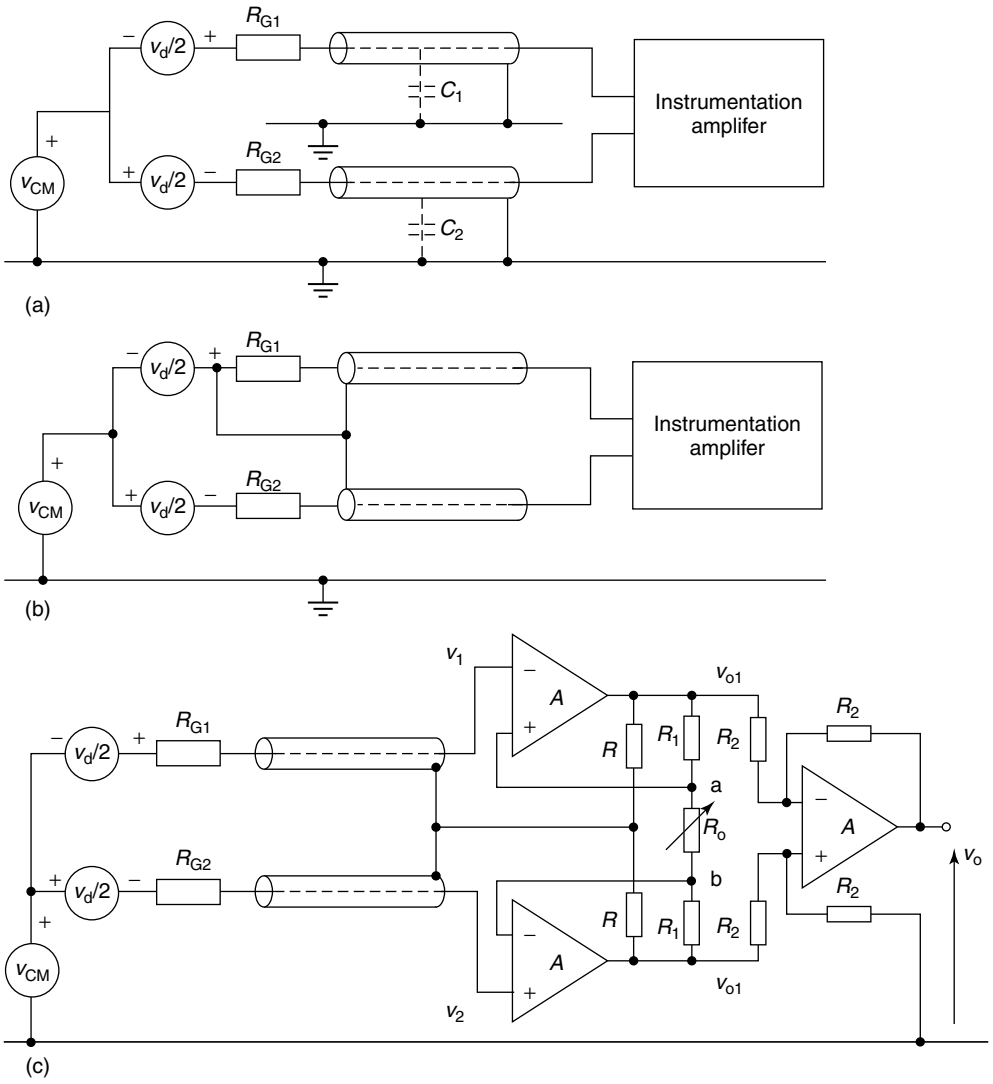

Figure 11. Input guarding showing the effect of cable capacitance in (a), driving the shield from one of the inputs to enhance *CMRR* in (b) and deriving the common-mode signal for driving the shielded cable in (c).

suppose that $R_{G1}C_1$ is not equal to $R_{G2}C_2$, where R_{G1} and R_{G2} are the source resistances and C_1 and C_2 are the cable capacitances. In that case, the common-mode voltage, which is converted to a series mode interfering signal, is then amplified by the differential mode gain. Consequently, the common mode–rejection ratio of the system deteriorates significantly. This problem can be tackled by connecting the cables preferably to the common-mode voltage, instead of to the ground, so that the voltage across the cable capacitance then reduces to the difference-mode signal. In this manner, the common-mode voltage at the input of the amplifier is now unattenuated by the cable capacitance.

When the common-mode voltage, v_{CM}, is high, the cables can be driven by one of the input signals itself, as shown in Figure 11(b).

If the common-mode voltage, v_{CM}, is not large compared to the difference-mode signal, v_d, it is necessary to derive the common-mode voltage as the average of the two input signals. In the schematic shown in Figure 11(c), this is achieved by the resistive summing of the outputs of amplifiers, A_1 and A_2, to get $v_{CM} = 1/2\ (v_1 + v_2)$ where $v_{01} = v_{CM} + Gv_d$ and $v_{02} = v_{CM} - Gv_d$, where G is the difference-mode gain of the first stage.

In situations in which large shield capacitances are to be driven at high frequencies, the divider resistances, R, have to be low. If this causes excessive output loading on the differential-input to differential-output stage, a unity gain buffer amplifier should be added between the summing-point output and the shield connection.

1 AMPLIFIERS FOR LOW-LEVEL SIGNALS

Instrumentation amplifiers (IA) covered in **Article 123, Instrumentation Amplifiers, Volume 2** will solve many measuring system amplification and conditioning problems but not all. There exist many situations in which low offset and low noise preamplification are required. Additionally, in many other applications, it is essential to ensure that the sensing input sections of the measuring system are galvanically isolated from the rest of the system.

Chopper amplifiers and others based upon the principles of signal chopping, or more precisely modulation, are perhaps the most common form of low-level signal amplifiers based upon the op-amp. All of them can help reduce undesirable variations at low frequencies such as voltage and current offset, drift effects, and flicker noise effects. The three chopper type amplifiers to be described in this article are the chopper amplifier, the chopper stabilized amplifier, and the auto-zero amplifier.

In the case in which isolation is required, applying a generic type of amplifier known as an *isolation amplifier* is usually appropriate. The magnetic isolation barrier amplifier and the optical isolation barrier amplifier are also described.

2 CHOPPER AMPLIFIER

A chopper amplifier, which operates in the manner outlined in Figure 1, uses an important method to reduce to a great extent the effects of low-frequency drift and noise in low-level amplification. In measuring systems, the frequency ranges of most of the interference noise and inherent noise sources at least overlap the bandwidths of the sensor signals if they do not totally coincide with them. Interference-type noise is picked up from outside the circuit under consideration. Inherent noise, which arises inside the circuit under consideration, can be due to the equipartition of energy, the randomness in flowing current or in the characteristics, and fabrication of the materials.

Interference noise, which may be periodic, irregularly occurring, or essentially random, can be minimized, if not very substantially reduced or even eliminated, using suitable precautions to avoid electrostatic and electromagnetic pickup from nearby radiators of electrical energy.

Inherent noise is usually totally random in nature although a nonrandom inherent interference such as chopper noise in chopper amplifiers can occur. Random inherent noise usually takes the form of:

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

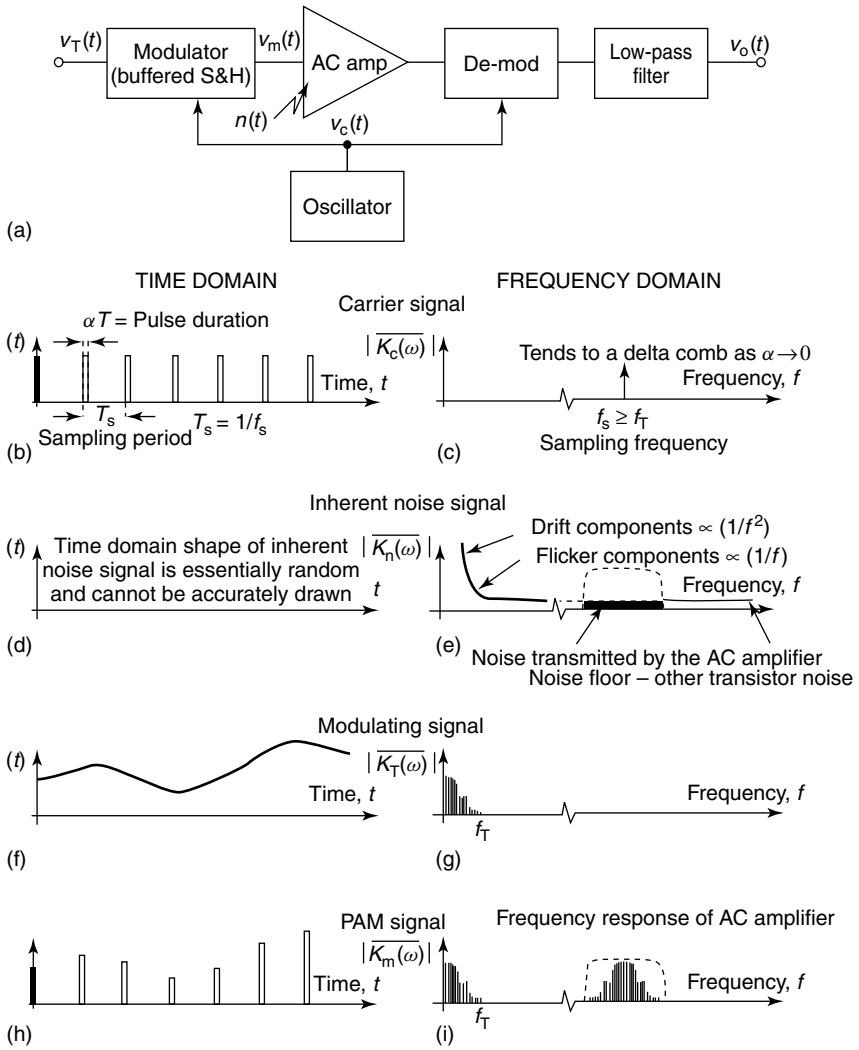

Figure 1. Block diagram and operational waveforms of a chopper amplifier.

- Johnson noise, which occurs in resistors;
- Schottky noise, which results when current carriers flow through a region depleted of carriers, such as the junctions of semiconductors;
- flicker noise, or $(1/f)$ noise, which is mainly caused by surface effects and crystalline dislocation, which are particularly troublesome deficiencies in semiconductor devices;
- popcorn noise, which is caused by erratic jittering of the forward current gain of bipolar transistors.

The only really effective way to minimize the effects of random inherent noise is to use modulation to shift the spectrum of the sensor signal into a band in which flicker effect is much less. Hence, these op-amp-based structures include some form of modulation and demodulation. In effect, they allow the use of very narrow bandwidth filtering in a stable manner.

Consider Figure 1. An oscillator, whose output signal, $v_c(t)$, has the time domain waveform with the frequency, f_s, in Figure 1(b), also has the frequency domain spectrum, $K_c(\omega)$, shown in Figure 1(c).

This carrier signal is pulse amplitude modulated by the transducer signal, $v_T(t)$, shown in Figure 1(f), whose typical spectrum, $K_T(\omega)$, is given in Figure 1(g). For the purposes of comparison, the internal drift and noise in the AC amplifier is shown in Figure 1(e). Note that the drift gives rise to the $(1/f^2)$ asymptote, flicker noise gives the $(1/f)$ asymptote, and other amplifier noise gives rise to the base, or floor, level noise. The resulting pulse amplitude modulated signal, $v_m(t)$, shown in Figure 1(h), which has the spectrum, $K_m(\omega)$, in Figure 1(i), is applied to the AC band-pass amplifier whose frequency response is shown in Figure 1(i).

If the AC amplifier has internal drifts and noise, their spectrum being as shown in Figure 1(e). Comparison of the

region where this interference spectrum is concentrated with Figure 1(i) shows that only the noise inside the bandwidth of the band-pass amplifier, with the comparatively low-level noise floor spectrum, will be transmitted. If the bandwidth adequately covers that of the transducer spectrum around f_s, then the net mean square value of the transmitted noise appearing at the amplifier output will be very low. The chopper has removed most of the amplifier interference.

3 CHOPPER STABILIZED AMPLIFIER

Chopper amplifiers can be employed with other high-performance op-amps to compensate for the already small inadequacies of these high-quality op-amps. The resulting combination, shown in Figure 2, gives a circuit called a *chopper stabilized amplifier*, which was first patented more than 50 years ago. Its designed aim was to combat the drift of directly coupled amplifiers by converting the DC voltage to an AC voltage.

The most important disadvantage of this inverting chopper stabilized stage is the relatively low input resistance, which is the same order as the lead-in resistance. A non-inverting, high input resistance version of the chopper stabilized type first appeared about 30 years ago. By causing interference from digital switching noise, the bandwidth is limited. Intermodulation distortion (IMD) between the clock and the input signal, which is similar to aliasing, produces errors at the sum and difference frequencies. Although both of these types have now been ostensibly replaced by the auto-zero amplifier, which is described in Section 4, they are still worth examining.

The chopper amplifier in Figure 2 measures the voltage of the inverting input of a conventional high-performance op-amp and then applies its amplified output to the non-inverting input of the same op-amp. In this way, any disturbances occurring inside the feedback loop are reduced in accordance with the well-known theory of negative feedback. To illustrate this reduction, consider that a disturbance $\overline{K_d}$, shown in Figure 2, occurs inside the feedback loop.

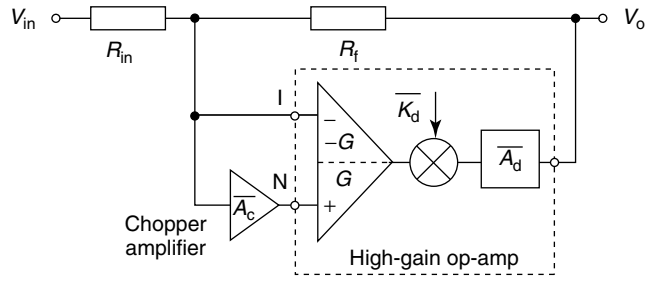

Figure 2. Chopper stabilized amplifier.

Analyzing in the frequency domain, it can be seen that the relations in the circuit are

$$V_o = -\overline{A_d} \times \overline{K_d} G V_{Ig} + \overline{A_d} \times G \times \overline{A_c} V_{Ig} \qquad (1)$$

Assuming very large input impedance at I gives

$$V_{Ig} = \frac{R_1}{R_f + R_1} V_o + \frac{R_f}{R_f + R_1} V_{in} = \beta_I V_o + G_{ex} \times \beta_I V_{in} \qquad (2)$$

where the feedback factor β_I is defined as $\beta_I = R_1/R_f + R_1 = 1/1 + G_{ex}$ and the external ideal gain G_{ex}, which is defined as $G_{ex} = R_f/R_1$, is the gain, assuming an ideal op-amp.

Inserting (2) into (1) and simplifying gives

$$\begin{aligned} V_o &= -\frac{R_f}{R_1} \frac{\beta_I \overline{A_d} \times G(1 - \overline{A_c})}{1 + \beta_I A_d \times G(1 - A_c)} V_{in} \\ &\quad + \frac{\overline{A_d}}{1 + \beta_I \overline{A_d} \times G(1 - A_c)} \overline{K_d} \\ &= \text{Desired output signal} \\ &\quad + \text{Disturbance caused output signal} \end{aligned} \qquad (3)$$

Assuming that $\beta_I \overline{A_d} \times G(1 - \overline{A_c}) \gg 1$ allows (3) to be written as

$$\begin{aligned} V_o &= -\frac{R_f}{R_1} V_{in} + \frac{1}{\beta_I G(1 - \overline{A_c})} \overline{K_d} \\ &= -\frac{R_f}{R_1} V_{in} + \frac{1 + (R_f/R_1)}{G(1 - \overline{A_c})} \overline{K_d} \end{aligned} \qquad (4)$$

When $\overline{A_c} \equiv 0$, which corresponds to a conventional inverting amplifier circuit, (4) becomes

$$V_o = -\frac{R_f}{R_1} V_{in} + \frac{1 + (R_f/R_1)}{G} \overline{K_d} \qquad (5)$$

Hence, with chopper stabilization, the disturbance input, $\overline{K_d}$, is reduced by the factor $(1 - \overline{A_c})^{-1}$. Note that the chopper amplifier gain $\overline{A_c}$ should be inverting at low frequencies, corresponding to $\overline{A_c(\omega \to 0)} = -A_{c0}$.

4 AUTO-ZERO AMPLIFIER

Operating principle: Auto-zero chopper stabilized amplifiers, with the block diagram in Figure 1, are now the most widely available form of chopper stabilized amplifiers. Their operation consists of two phases. During Phase 1, as in Figure 3(a), the input is applied only to the main amplifier, A_1, whose nulling input voltage, V_{N1}, is supplied by the voltage on capacitor, C_{M1}.

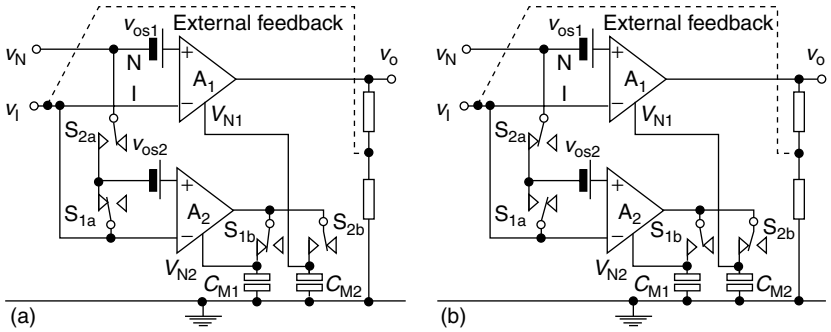

Figure 3. Phase 1 of an auto-zero amplifier in (a) is followed in operation by Phase 2 in (b).

Meantime, the I and N inputs of amplifier, A_2, are connected by S_{2a} to allow this amplifier to measure its auto-zero voltage that is stored on capacitor, C_{M1}. At the start of Phase 2, the make-before-break switches, S_1 and S_2, each change over. This allows the previously measured auto-zero values for A_2 to be applied at V_{N2}. When Phase 2 is complete, the whole sequence of operations is repeated.

Applications and characteristics of auto-zero amplifiers: Auto-zero amplifiers possess a number of highly desirable characteristics. They are eminently suitable where very high input impedance buffering is necessary. For this reason, they are mostly applied in integrators, electrode buffers, ionization chamber buffers, and electrometer-type applications for femto-ampere current measurement.

Although the clock frequency is in the range from 100 Hz to a few kHz, the gain bandwidth product can be about 1 to 3 MHz or even more. The open-loop, low-frequency gain is $>10^7$ while at the same time offering very low offset voltages in the region of 1 μV. Offset drift, which is a negligible 50 nV per month, gives the auto-zero amplifier the lowest drift of all contemporary types of amplifiers.

The same comment can be made about offset temperature sensitivity, which is ≈5 to 10 nV/°C. The CMRR and the power supply rejection ratio, or PSRR, which are also strongly affected by these low levels of offset, can have values in the order of 140 dB or more. They are also characterized by low voltage and low current noise.

The high-speed chopper action means that the low-frequency noise is nearly uniform down to zero frequency. This should be compared with the flicker noise problems of other noncompensated amplifiers, whose flicker noise corner frequency can be in the range from ≈5 to 10 Hz. Auto-zero amplifiers use MOS input devices, which ensures that the bias currents required are in the range 10 to 20 pA at 25 °C while exhibiting drifts of about 0.5 pA/°C. This is a considerable advantage if large value source resistances are likely. Chopper radiation can sometimes cause problems due to intermodulation distortion. This type of distortion, which is very similar to aliasing in sampled data theory, can be reduced by a careful layout design.

5 MAGNETIC AND OPTICAL ISOLATION AMPLIFIERS

The isolation amplifier is particularly appropriate in data acquisition systems where galvanic isolation (i.e. no DC electrical connection path) between the input and the output circuits is important such as in the following examples:

- amplification of low-level measurement signals in high common-mode environments;
- breaking of ground loops;
- isolation protection of personnel and equipment due to hazardous common-mode situations such as in biological monitoring.

They also allow effective utilization of gain by inserting the gain at the signal source where the bandwidth is likely to be lowest. The isolation barrier may be a screened transformer or an optocoupler.

Isolation amplifiers, which are represented in Figure 4(b), appear inside the isolation units of the general system architecture shown in Figure 4(a). A generalized data acquisition system in an industrial process environment, requiring multiple signal isolation solutions, is given in this system block diagram.

A diversity of signals is acquired from a range of resistance type transducers, voltage sources, current sources, and perhaps other types of transducers such as thermocouples.

Each of these signal sources is associated with an individual conditioning card, whose function is to perform any necessary energizing power supply, screening, guarding, and grounding, and perhaps preamplification. Power supply and control lines connect the conditioning card to the isolation units.

Isolation amplifiers consist of three parts. The first part is a power supply, which is necessary for correct

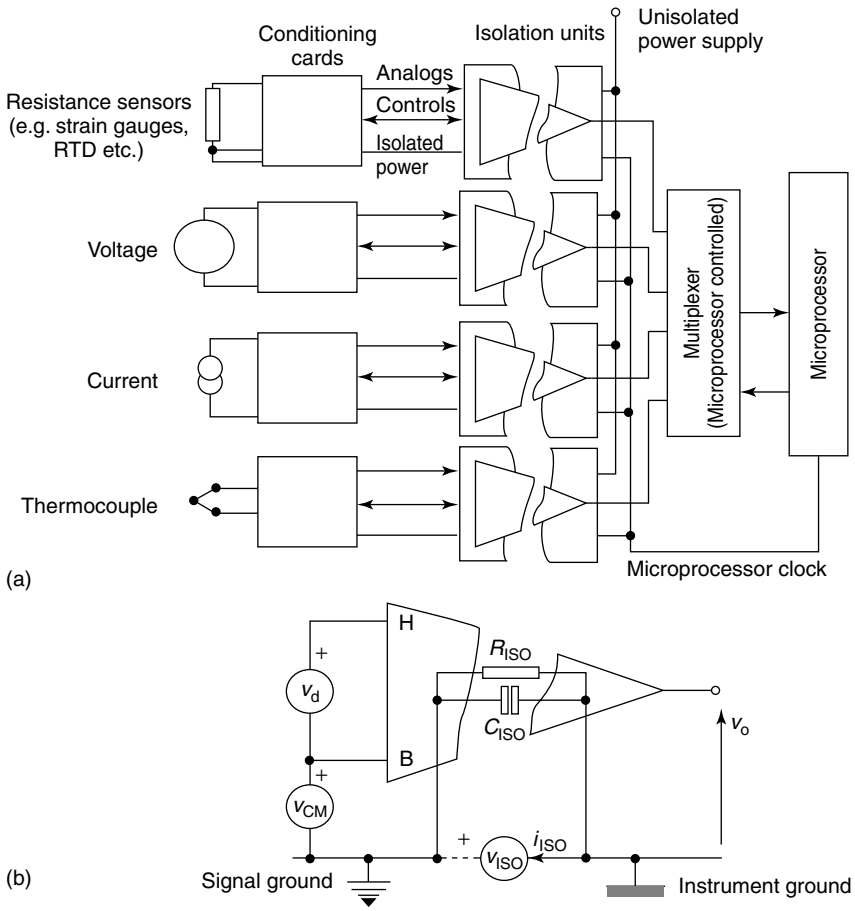

Figure 4. A data acquisition system using isolation units containing isolation amplifiers in (a) has a model for isolation amplifiers given in (b).

operation. It is arranged using some kind of isolating and chopping DC-to-DC converter. An input stage with floating input connections and an output stage with output connections are the other two subunits. All of the subunits are electrically isolated from each other. Residual and stray impedances will always be associated with practical isolation amplifiers. As in Figure 4(b), isolation resistance and isolation capacitance, which are the most important parameters influencing the effectiveness of the isolation between the signal input terminals and the output terminals, have respective values of 10^{10} to $10^{12}\,\Omega$ and 10 to 20 pF, so ensuring isolation potentials up to about 5 kV and leakage currents $i_{ISO} \approx 0.5$ to $2\,\mu$A.

It can be seen from Figure 4(b) that the effect of v_{ISO} is very similar to v_{CM}. For this reason, it can be taken into account in numerical evaluations by using a figure of merit called the *isolation mode rejection ratio*, or *IMRR*, which is defined to give

$$v_o = G\left(v_d + \frac{v_{CM}}{CMRR}\right) + \frac{v_{ISO}}{IMRR} \qquad (6)$$

Where bandwidth and response speed are important, optical isolation amplifiers are preferable to the magnetic type, which are best suited for gain accuracy and linearity.

Magnetic barrier isolation amplifier: The most commonly encountered form of isolation amplifier, which has a block diagram similar to that in Figure 5, uses magnetic isolation barriers in the form of miniature toroidal transformers.

A high-power oscillator is magnetically coupled through a DC-to-DC converter to provide the power supply for the input stages. It is necessary to provide two stages of isolating modulation and demodulation units. One of these units allows transmission of the signal from the input across the magnetic isolation barrier to the output. A second modulator and demodulator allows transfer of the output signal back into the isolation side for feedback purposes.

Magnetic barrier isolation amplifiers can cope with typical continuous DC isolation voltages of 2 kV or a value of 1.4 kV rms for alternating isolation voltages. The

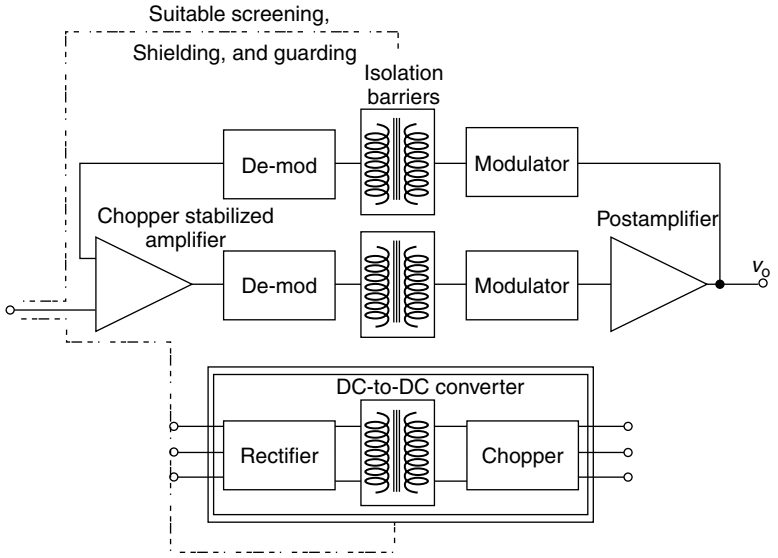

Figure 5. Block diagram of a magnetic barrier isolation amplifier.

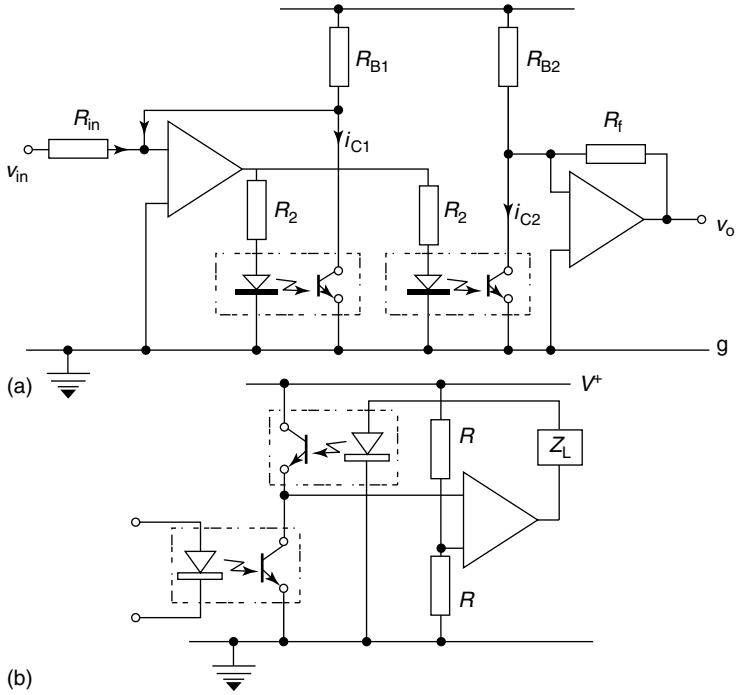

Figure 6. Optical barrier isolation amplifier.

IMRR is about 160 dB for direct voltages and 130 dB for alternating forms. Leakage current can be about 0.5 μA.

Optical barrier isolation amplifier: Figure 6 illustrates two versions of optical isolation amplifiers for two different possibilities. When optoisolation of analog voltages is required, Figure 6(a) shows how feedback in the preamplifier can be used to linearize the response of the optoisolator.

The current in the input LED, which requires a standing bias current, I_B, to ensure full range input swing, is controlled by the input op-amp. The standing bias is $I_B = V^+/R_B$. Hence, the collector current of the transistor in the input optoisolator is

$$i_{C1} = \frac{v_{in}}{R_{in}} + \frac{V^+}{R_{B1}} \tag{7}$$

If the two optocouplers are closely matched, the currents, i_{C1} and i_{C2}, in the collectors of the two transistors will be equal. It can be seen that the output op-amp is configured as a current to voltage converter so that its output voltage is

$$v_o = \frac{R_f}{R_{in}} v_{in} + \frac{V^+}{R_{B1}} - \frac{V^+}{R_{B2}} = \frac{R_f}{R_{in}} v_{in} \quad \text{for} \quad R_{B1} = R_{B2} \tag{8}$$

In the case when the measured variable has been converted to a current, a circuit like that in Figure 6(b) can be used. The input current, i_{in}, which consists of a standing bias current, I_B, and the signal current, i_s, means that the collector current of the input transistor $i_{C1} = i_{in}$. The output current $i_o = v_o/Z_L$, which is fed back to constrain the potential at the inverting input, I, of the op-amp to consist of a component due to the standing bias current at the input and another component proportional to the signal current. The component due to the standing bias current is backed off with the potential at the noninverting input, N. The output current is therefore directly proportional to the input signal current, i_{in}.

Optoisolators have DC isolation voltages up to about 2 kV, which becomes about 5 kV for a pulse test. Their rejection ratio is usually better than 140 dB for DC conditions or 120 dB at 50 to 60 Hz. Their leakage current is typically 0.25 μA and isolation leakage capacitance ≈2 pF.

6 NECESSITY FOR THE CHARGE AMPLIFIER

Quartz and barium titanite are asymmetrical crystalline materials that produce an electrical charge when weights are placed on them. Piezoelectric transducers (PZT), which are used for force measurement, particularly in accelerometers, utilize this property where the produced electrical charge, Q, is proportional to the applied force F. As a consequence, PZT can be modeled as a current source $i = dQ/dt$ in parallel with a capacitor, C_c.

Transducers are often remote from measurement amplifiers in practical measurement systems. The connection between the transducer and an amplifier, as in Figure 7, is realized with coaxial cables. These present a capacitance C, depending on the cable length, appearing in parallel with the amplifier input resistance R_{IN}.

Referring to Figure 7, it can be seen that

$$\begin{aligned} V_c(s) &= \frac{sR_{IN}}{1 + sR_{IN}(C_c + C)} Q(s) \\ &= \frac{sR_{IN}(C_c + C)}{1 + sR_{IN}(C_c + C)} \left[\frac{Q(s)}{C_c + C} \right] \\ &= \frac{(s/\omega_{ci})}{1 + (s/\omega_{ci})} \left[\frac{Q(s)}{C_c + C} \right] \end{aligned} \tag{9}$$

The stage acts like an active high-pass filter, whose Bode frequency response in Figure 7 has a cutoff frequency, f_{ci}, given by

$$f_{ci} = \frac{\omega_{ci}}{2\pi} = \frac{1}{2\pi R_{IN}(C_c + C)} \tag{10}$$

As the frequency response at low frequencies is restricted, slowly varying phenomena cannot be measured. A charge amplifier is needed to interface the PZT so that the high-pass corner frequency can be reduced.

Since the output voltage of the transducer depends on C and thus on the cable length, a new calibration has to be carried out every time the cable length is changed. This is an unfortunate drawback of this measurement system.

7 PRINCIPLES AND PRACTICALITIES OF A CHARGE AMPLIFIER

In the simplified charge amplifier of Figure 8, assume that the amplifier, A, is ideal as described previously in Section 1 of **Article 122, Operational Amplifiers, Volume 2**.

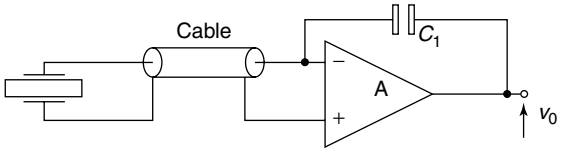

Figure 8. Functional diagram of a charge amplifier.

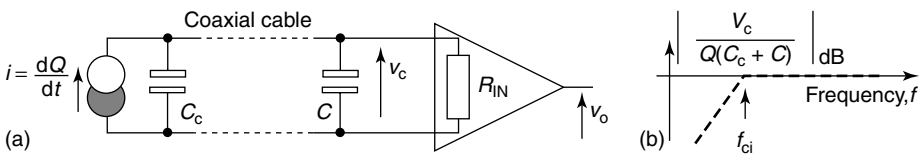

Figure 7. A piezoelectric transducer in (a) connected to an amplifier with a coaxial cable with a capacitance depending on its length has the Bode frequency response in (b).

The charge, Q, produced by the transducer will be stored in the capacitor, C_1. Therefore the amplifier output voltage will be equal to

$$v_o = \frac{Q}{C_1} \tag{11}$$

As this is no longer dependent on C and R, recalibration is not necessary when the cable length is changed.

Charge amplifier with a real op-amp: Suppose the amplifier is nonideal with finite values of gain, A_0, and input resistance, R_{IN}. Using the relations in Section 7 of **Article 122, Operational Amplifiers, Volume 2** with appropriate modifications, the amplifier output signal can be expressed as

$$v_o(s) = -Q(s)\frac{A_0 s R_{IN}}{1 + sR_{IN}[C_c + C + C_1(1 + A_0)]} \tag{12}$$

Owing to the Miller effect transformation, the feedback capacitance appears as a high-value capacitor $C_1(1 + A_0)$ in parallel with the cable and the transducer capacitance. Since $C_1(1 + A_0) \gg (C_c + C)$, the output signal is effectively independent of the cable length.

By contrast with (10), the cutoff, or corner frequency, is now

$$f_c = \frac{1}{2\pi R_{IN} C_1(1 + A_0)} \ll f_{ci} \tag{13}$$

The high input resistance, R_{IN}, implies the need for an op-amp with a low input bias current. This can be met by using either op-amps with FET input stages or BJT input stages, specifically designed with low input bias currents. Although FET input op-amps have well under 1-nA input bias current at 25 °C, this current rises with increasing temperature to values above that of bipolar input types. This small bias current, i_b, causes an output voltage that increases with time in the manner

$$v_o = -\frac{i_b}{C_1}t \tag{14}$$

Hence, care must be taken to choose an adequate op-amp in the design of charge amplifiers. It is possible to avoid this integration effect by placing a large resistance, R_1, with a value of the order of 1 to 10 MΩ in parallel with C_1. Unfortunately, this also causes an output offset voltage with a value of

$$\Delta v_o = -R_1 i_b \tag{15}$$

8 INTEGRATORS

The need for integrators and differentiators often arises in measuring systems. Integrators are employed when the acceleration measured has to be converted to velocity or when velocity has to be converted to displacement. Conversely, to obtain velocity from displacement, differentiators are required.

The basic integrator circuit is shown in Figure 9(a). It has limited practical use because the nonzero input offset errors produce high output offset errors when they are integrated at very low frequencies.

These errors can be minimized by reducing the gain at very low frequencies by the low-frequency feedback in the 15-MΩ resistor in Figure 9(b). Though this results in nonideal integrator characteristics, the final circuit is useful for many applications over a limited frequency range. For the component values indicated, the phase lag of this circuit is $\pm 270^\circ$ $\pm 0.5^\circ$ compared with $+270^\circ$ for an ideal inverting integrator working over a frequency range of 10 Hz to 10 kHz. At very low frequencies, the gain is limited to -1000, resulting in output drift of less then a few millivolts.

The gain, which is approximately -10 at 10 Hz, reduces to about 0.01 at 10 kHz. To ensure that the output at 10 kHz does not become comparable with the drift v_{in} at this frequency, this should be of the order of a few volts. The phase error at the high-frequency end is the direct result of the limited unity gain bandwidth of the op-amp used. Low-frequency phase errors are related to the basic

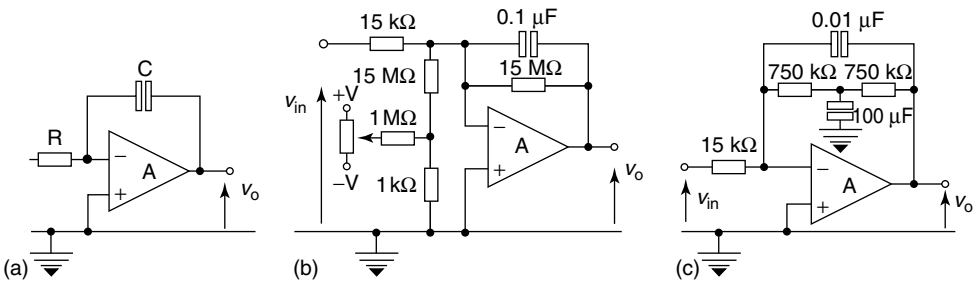

Figure 9. Integrator with the basic configuration of (a) is practically realized using (b) whose performance with frequency is improved with (c).

low-pass characteristics of the configuration used with a −3 dB cutoff, or corner, frequency of approximately 0.1 Hz, relative to DC gain. The useful operating range of this integrator can be shifted to a frequency range of 1 Hz to 1 kHz by increasing the feedback capacitance to 1 μF.

Further reduction of DC errors can be obtained by providing higher feedback for DC and making this feedback ineffective for AC use in the desired frequency range. The arrangement shown in Figure 9(c) has a DC gain of 100, reducing the output DC errors by a factor of 10, as compared to the performance of the integrator shown in Figure 9(b).

9 DIFFERENTIATORS

The basic differentiator shown in Figure 10(a) has limitations. Owing to the 6 dB/octave rolloff of the op-amp gain at high frequencies and the differentiating characteristics of the configuration at the operating frequency, the closed-loop gain shows a peak in its frequency response, similar to that in Figure 10(b). Using a low cost op-amp with the parameters in Section 1 in **Article 122, Operational Amplifiers, Volume 2** and a value of $RC = 0.16$ s, the gain is unity at 1 Hz with the peak at a frequency of approximately 1 kHz. The damping factor, ζ, is obtained from the equation

$$\frac{V_o}{V_i} = \frac{-RCs}{1 + \frac{1}{A_0}(\tau_A + RC)s + \left(\frac{RC\tau_A}{A_0}\right)s^2} \tag{16}$$

as

$$\zeta = \sqrt{\frac{(\tau_A + RC)^2}{RC\tau_A}}\frac{1}{A_0} \tag{17}$$

where A_0 is the low-frequency open-loop gain and τ_A is the open-loop time constant of the op-amp. If $A_0 = 10^5$ and $\tau_A = 0.016$ s, then $\zeta = 1/1000$ for $RC = 0.16$ s. This corresponds to a unity gain bandwidth product of 1 MHz.

The peaking of the frequency response means that the differentiator, however, gives a very noisy output since it amplifies its own internal noise in the 1-kHz range by as much as 10 times. If the amplifier has a response rolling off at more than 6 dB/octave, the circuit may even oscillate.

The modified differentiator shown in Figure 10(c) can be used in practical situations since the closed-loop response is designed to be well damped. With the values shown in Figure 10(c), the response is typically as shown in Figure 10(d). The resistance in series with the input circuit capacitance flattens the response at about 30 kHz. At 100 kHz, the response starts to roll off because of the influence of the open-loop gain of the op-amp. For this to happen at 100 kHz, the unity gain bandwidth of the op-amp should be ≈10 MHz. This can be achieved readily with many op-amps using an external compensating capacitor with a typical value of 3 pF. The phase shift is 90° lead, in addition to the 'inversion' of the amplifier, with less than 2° error for all frequencies less than 1 kHz. At frequencies of

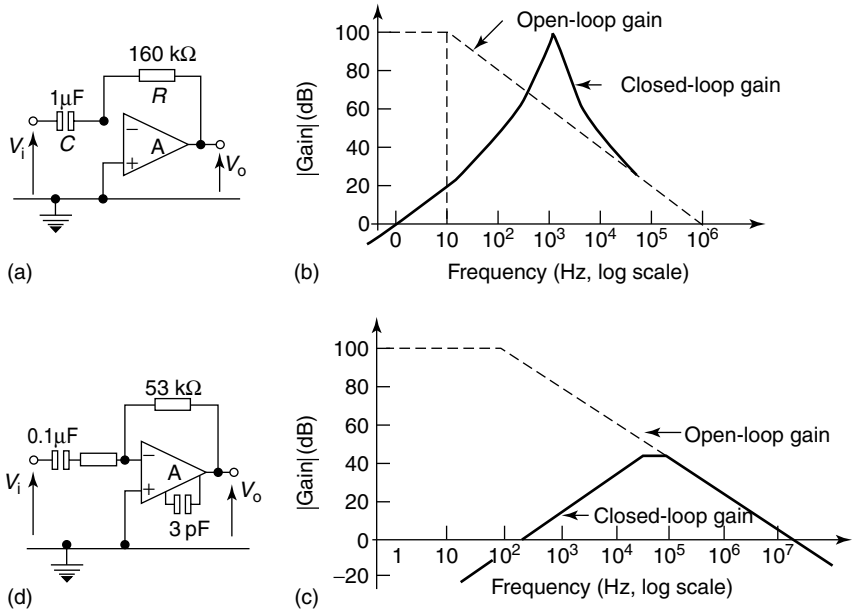

Figure 10. A basic differentiator in (a) has the frequency response in (b), while the modified differentiator of (c) has the frequency response of (d).

0.1 Hz and below, the reduced gain for the input signal can affect the performance. A differentiator for the frequency range of 0.01 to 100 Hz is achieved by using the op-amp with 30 pF compensation and by changing the input circuit capacitance to 1 μF.

1 ROLE OF A SIGNAL FILTER

It is always the case that the signal acquired from a sensor or transducer requires conditioning of some kind or another. Even after passive conditioning with constant voltage, constant current or bridge circuits, or active conditioning with various kinds of amplifiers, there will still be the need to introduce some form of filtering. Filters, which usually are regarded as modifiers in the terminology of **Article 109, Structure and Energy in Sensor Systems, Volume 2**, are specially designed to modify the range of their transmitted frequencies. Filtering operations may treat analog or digital signals. Although the filters used in measurement and instrumentation use electric circuit realizations, filters exist in other energy forms. Electric filters are also called *electric wave filters*.

The frequency ranges of filters can be used as a means of defining their different types. For example, filters using passive *R-L-C* elements, frequently referred to as *passive filters*, are used in the range from about 100 Hz to >100 MHz. *Active filters*, which are widely applied in the frequency range from <0.01 Hz to about 100 kHz, are normally realized using individual resistors, capacitors, and op-amps. Microwave filters, also called *cavity resonators*, as their name implies, operate in the microwave frequency range above about 10 to 50 MHz. Crystal filters using piezoelectric techniques cover the range from about 100 Hz to the low microwave region. Monolithic filters, which use large-scale integration for their realization, cover the same basic range as active filters but have the possibility for higher frequency operation because of their smaller general physical dimensions. This is because the *R-C* elements used are normally included on a chip.

Analog filters are classified as passive if they use only passive *R-L-C* elements. More recently, active filters using combinations of passive *R-C* elements and active op-amps have been widely developed. Digital filters, which process discrete interval sampled data signals, are realized using dedicated digital hardware structures or software programs. The digital hardware used takes the form of shift registers, multipliers, and accumulators.

The concepts of filtering provide the measurement system designer with additional tools to tackle the problems of minimizing error, signal-to-noise ratio, response time, and bandwidth. At the same time, analog filters allow modification of the frequency content of the acquired signal so that the problems of *foldover* associated with digital signal processing are at least minimized by the use of *antialiasing* precautions. Before the era of ICs, filters were exclusively realized using passive *R-L-C* elements. Presently, the op-amp has exerted a profound influence upon the design of data filters for analog signals. This

Table 1. Advantages and disadvantages of active filters.

Advantages	Disadvantages
1. Small in size and weight because there are no inductors	1. Limitations on voltage/current levels makes them unsuitable in electrical power systems
2. Fairly easily designed	2. Inadequacies due to imperfections in the static and dynamic characteristics of the active elements
3. Easily 'tuned' to give the desired response	3. Parasitic oscillations may occur when feedback is used
4. Isolation between cascaded stages	4. High sensitivity to tolerances of passive components
5. Large available gain so amplification is possible	5. A power supply is required

means that for frequencies up to about 100 kHz there is no need for inductors.

The design techniques for active analog filters are largely the same as for passive filters. However, as active networks contain op-amps employing feedback, the stability of the filters needs to be considered. Also, as inductors are bulky, it is preferred that only R and C elements are used, even though inductors may be realized using gyrators. Gyrators will not be considered further. A general treatment is quite difficult as there is such a large variety of possible methods. Table 1 gives advantages and disadvantages of active filters.

2 FEATURES THAT NEED SELECTING OR FILTERING OUT

Filtering is essentially a signal-processing operation to obtain optimal detection of some specified parameter or parameters of a signal immersed in interference or noise. Problems of filter design are concerned with optimizing the preservation of the important signal parameters and removing or at least minimizing the effect of the noise.

The first item of interest is the signal and the manner in which it carries the measurement information. Information can be carried in the amplitude, the phase, or the frequency of an analog measurement signal, or perhaps in the shape in the case of a pulse modulated signal. When the amplitude carries the information, the design of the filter concentrates upon uniform amplification of the frequencies within the band of interest so that the relative magnitudes of each frequency component are maintained after the filtering operation. Ideally, all signal components outside the band of interest should be attenuated by as large an amount as possible. Using the same reasoning, filter design concentrates on optimizing the phase characteristic of the filter if the information is carried in the phase angles of the signal components. In this case, optimal retention of the relative phases of the frequency components within the band of interest after filtering is the aim. This is especially important if the shape of the waveform needs to be maintained. In some cases, information is carried in both the amplitude and the phase of the measurement signal. Simultaneous preservation of relative amplitude and relative phase difference are conflicting requirements. In these cases, it is necessary to design some filter that compromises between the two requirements.

Interference, more widely known as noise, occurs in all measurement systems. It is shown in **Article 68, Setting the System Boundaries, Volume 2** that noise may penetrate a measurement system from the outside, in which case it may be called *interference* or *interfering noise*. Noise may also arise inside a measurement system owing to imperfections in system design or of the materials used in its construction. All of these noise sources contribute to the overall error. Errors should be minimized to realize the overall aim of measurement, which Solopchenko (1994) asserts as being the discovery of errors and their minimization.

One of the most commonly occurring problems in measurement and instrumentation systems is due to interfering pickup, or 'hum', from the electric supply systems used in the electrical elements of the overall system. Thus, undesirable inductive and capacitive coupling into the more sensitive parts of the system from nearby electrical sources needs to be guarded against. Removal of this type of interference may also be accomplished using a band-reject filter, sometimes also called a *notch filter*. Other kinds of interference may be due to cosmic effects.

Naturally occurring fundamental fluctuations are endemic throughout nature. In mechanical systems, they are manifested in Brownian motion, while in electrical systems, they are referred to as thermal, Johnson, or Nyquist noise. These fluctuations, which are due to the equipartitioning of energy, have a uniform power spectral density up to about 10 GHz. Quantum corrections must be applied beyond this frequency. Since most measurement systems use electrical/electronic building blocks, other types of noise such as flicker, or low frequency noise, shot noise, and other types of noise characteristic of semiconductor components require precautions to be taken to minimize their effects.

In some cases, the measurement information is associated with a narrow range of frequencies. To ensure that unwanted components outside this range are not transmitted in the measuring system, band-pass filters are used.

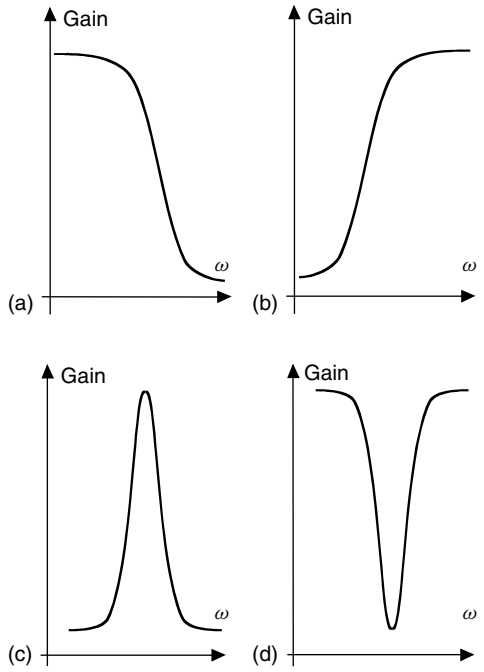

Figure 1. Classes of filters: (a) low pass, (b) high pass, (c) band pass, and (d) band stop/notch.

3 CLASSIFICATION OF ACTIVE FILTER TYPES

There are four main types of frequency responses realized using active filters as in Figure 1. Low-pass sections, which widely occur in instrumentation systems, are used to overcome some limitations of a sensor signal by removing unwanted higher frequency noise and providing some antialiasing protection. The other three are the high-pass section, the band-pass section and the band-reject or notch-filter section. All-pass sections, which are not shown in Figure 1, are used as phase equalizers. They possess a flat amplitude response with a phase response, which can be designed to a given value of phase delay or advance.

4 APPLICATION OF FILTERS

The rapid development of large-scale communication systems provided a major impetus in the need for and development of both passive and active filters. In this field, an very important application is the pulse-code modulation coder/decoder, or PCM-CODEC, in digital telephony. In this application, the filters require very tight specifications of both their cutoff sharpness and pass band ripple. Other communication system examples of filtering occur in signal preemphasis, equalization, impedance matching in repeaters, and for harmonic suppression in some low-frequency applications.

A major application area of filters is in measurement and instrumentation systems. When measuring voltages with digital voltmeters, it is important to reject interference from noise sources and from power line harmonics. Similar requirements for noise rejection occur in the study of vibration and shock. Many physiological signals such as those occuring in heart monitoring by electrocardiogram, or ECG, or in brain wave monitoring by electroencephalogram, or EEG, have the information content of their spectrum in a three-decade band below about 20 Hz. Special filters to remove ultralow-frequency interference below about 0.002 Hz, and noise penetration above 20 Hz are required.

Electric wave filters, and especially active filters, are also widely used in control systems, such as servo-systems and motor drive controllers, as well as in process control equipment, consumer and entertainment systems such as stereo amplifiers, videocassette recorders, or VCRs, digital versatile disc, or DVD, systems and in all types of public broadcast receivers.

Applications also occur in sonar systems, telemetry systems, prefilters for analog-to-digital converters, spectrum analyzer systems and many others.

5 COMPARISON OF ANALOG AND DIGITAL FILTERS

Some advantages and disadvantages of analog filters have been given above. Digital filters take the form of recursive filters, also called *infinite impulse response filters*, or *IIR filters*, and nonrecursive filters, sometimes referred to as *finite impulse response filters*, or *FIR filters*.

Digital filters have some significant advantages over analog filters. In the first place, digital types possess guaranteed accuracy, which is only limited by the number of bits, and guaranteed reproducibility since there are no variations due to component tolerances or aging or temperature drift. In contrast, the accuracy and reproducibility of analog filters cannot be guaranteed because they can depend heavily upon the tolerance of the R and C elements, upon the characteristics of the op-amps used, and upon the aging and temperature drift effects, which they are all subjected to. Thus, digital filters have superior performance over analog types. The flexibility of digital filters arises from their programmable nature, which allows a variety of functions to be performed using a single hardware structure. It is impossible to provide this flexibility with analog filters.

Nevertheless, digital filters possess three main disadvantages. Designing DSP can be time consuming unless the

development resources and knowledge are available. Realizing DSP can be quite expensive, especially with wideband signals. Such signals need fast, and thus expensive, analog-to-digital and digital-to-analog converters. Because real-time applications are implemented using only a limited number of bits, there is a real possibility for errors due to quantization effects.

6 OVERVIEW OF ACTIVE ANALOG FILTER DESIGN METHODOLOGY

Only the design of active analog filters will be described. Many authors have described the methodology (Bowron and Stephenson, 1979; Chen, 1986; Horowitz and Hill, 1980; Huelsman, 1993; Lang, 1987; Ludeman, 1987; McGhee *et al*., 2001; Rangan, Sarama and Mani, 1983; Schaumann and Van Valkenburg, 2000; Temes, 1985; Winder, 2002).

In all cases, the design commences with a specification of the filter frequency characteristics based upon the information bearing parameters of the signal, its frequency range, and the likelihood and types of any noise and their sources. This specification will most likely lead to an ideal filter, also called a *brick-wall filter*. If the specification points in the direction of high-pass, band-pass or notch sections, they are transposed to an equivalent low-pass region for a low-pass design. This design is then retransposed using suitable frequency domain transformations to gain the desired design. Since ideal filters cannot be realized in practice, a suitable approximation must be designed on the basis of the four main possibilities. These are

- the maximally flat amplitude filters, or *Butterworth filters*;
- the maximally flat delay filters, also called *Thomson filters* or *Bessel filters*;
- the equiripple pass-band filter, or Chebyshev type 1 filter;
- the elliptic filter, or Chebyshev type 2 filter.

Both kinds of Chebyshev filters are considered in the references given at the end of this article.

In this way, the three main frequency regions of a low-pass filter may be described. If a band-pass, high-pass, or band-notch filter is required, these may be achieved using suitable low-pass-to-band-pass, low-pass-to-high-pass, and low-pass-to-notch transformations (Ludeman, 1987; Rangan, Sarama and Mani, 1983) features.

7 PROPRIETARY FILTER MODULES

There are many IC manufacturers such as Burr-Brown, now a division of Texas Instruments, Maxim (http://www.miximic.com), Linear Technology (http://www.linear.com) Mixed Signal Integration, or MSI (http://www.mix-sig.com), and many others.

1 BALANCE IN MEASUREMENT CIRCUITS – GENERAL REMARKS

In the measurement process, special circuit states, such as equality of two nodes' potentials or of two branch currents connected, for example, in the common node as shown in Figure 1(a), are of special significance. Such states are known as balanced states. Hence, existing relations between circuit parameters are called *balance conditions*.

A circuit could have more than one state of balance. If the potentials of two nodes are equal, it is possible to connect them together directly, or by some impedance, without changing the current and voltage distribution in all the circuit branches.

Similarly, after disconnecting two such linked branches from the node, no changes will appear because the currents are opposite to each other – see Figure 1(b).

The equations describing balance conditions are usually much simpler than those describing the circuit in general conditions, and, therefore, are often used for measurements.

An unknown parameter, or combination of a few of them, is measurable if it is possible to calculate them from balance equations as a function of other known values of parameters obtained after balancing the circuit.

Opportunities given by balanced states are used both in a single bridge, and also in the more sophisticated measurement circuits including a bridge as a part of them.

In the circuits with time-variable signals, the variety of other possible balance states are also applied for measurements, for example, the equality of

- node potentials or branch currents as above, but only in some instants of time, for example, as in successive approximations balance circuits, and A/D converters;
- integrals of two signals: in the different types of integral A/D converters;
- both, module and phase of two pure sinusoidal signals of the same frequency, or of harmonic components of the differently disturbed periodic signals;
- only amplitudes, or only phases called the *quasi-balanced state*;
- maximum, mean, or RMS values of two signals of different shapes.

Other possible balance states also exist.

External and internal voltage and current sources, of stationary magnitude or that are adjustable, are used in the measuring circuit.

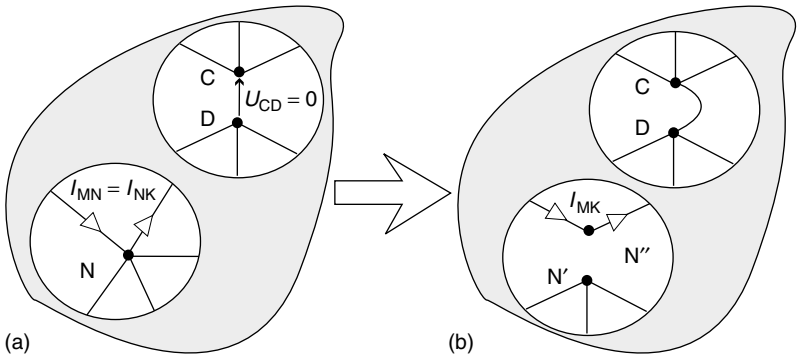

Figure 1. (a) Examples of the voltage and current circuit balance states and (b) possible modifications of the circuit.

Adjustable parameters of circuit elements may be changed or modulated, either manually or automatically, inside or outside the main circuit, such as in a bridge.

If, in the measurement process, the relationships between circuit parameters in the balance state are only taken for obtaining measuring results then such a method of measurement is called a *balanced* or *null-balance* method.

If changes of parameters result in a different state from the null-balance one, such a method is a differential one and the circuit is called *deflection*, *off-balance*, or *unbalanced* one.

Both methods offer high accuracy and are widely used not only in electrical measurements.

2 BASIC BRIDGE DEFINITIONS

An electrical measurement circuit including at least one quadrilateral topology network having all possible branches present is called a *bridge circuit*, or in short, the *bridge*.

Usually, such a circuit is excited (driven, powered supplied) across one of its diagonals and has the output on the other one (see Figure 2 as an example of the bridge).

Bridges could work as balanced or unbalanced measurement circuits.

Discovery of the various bridge circuits resulted originally from the measurement needs of electricity and magnetism science for an explanation of its historical emergence – *see also* Sydenham (1979).

Later, their development became necessary for the research and practice of a rapidly growing electrical technology, telecommunication, and other disciplines.

More accurate measurements of the resistance R and conductance G in the direct current (DC) circuits were initially needed. Later, alternating current circuit parameters such as resistance R, inductance L, capacitance C, mutual inductance M, components of impedance Z or admittance Y, frequency, and other auxiliary parameters were measured in the continuously rising range of frequencies that

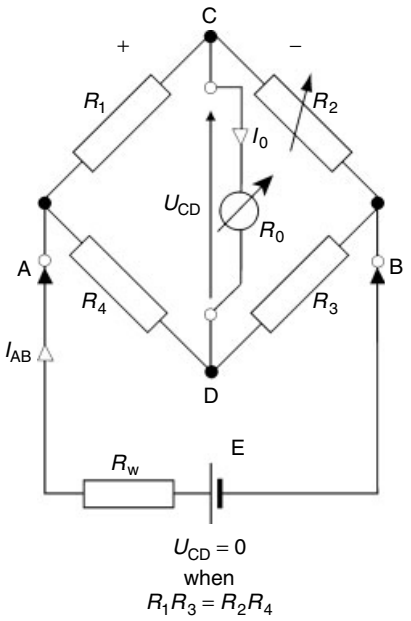

Figure 2. Wheatstone bridge and its balance condition $R_1, \ldots R_4$ – resistance of bridge arms; R_0 – resistance of galvanometer (bridge load resistance R_L); R_w – source internal resistance (series resistance to the primary bridge circuit R_G).

find application. They not only included measurements of parameters of the two terminal components but also their values in circuits with different structures of lumped and distributed elements.

Presented here is the basic unchanging foundational knowledge useful for setting up and understanding practical bridge application.

The term *bridge* is used with two different meanings: for a circuit and for a measuring device utilizing this circuit as its main part. During recent years, the term 'bridge' has also been used sometimes by some instrument producers, for a device measuring the same parameters as, for example, RLC bridges, but working on a completely different measuring principle.

Basic properties of different bridge-like circuits and the background of their applications in measurements are presented in detail in the literature given in the end and in **Article 127, Unbalanced DC Bridges, Volume 2**.

Detailed technical data of bridge instruments, converters, and computer measurement systems working with them that are offered on the market are given in the manufacturer's publications, including the Internet.

3 WHEATSTONE BRIDGE AND HISTORY OF BRIDGE DEVELOPMENTS

The history of bridges and their development is some 170 years old now. The DC bridge principle was first introduced by Christy in 1833, but it was unnoticed during the next ten years. In 1843, Charles Wheatstone applied the bridge arrangement for the comparison of resistors in his 'differential analyzer' gaining it a place as a basic electrical circuit. It is, thus, well known since as the Wheatstone bridge.

Together with its balance condition for $U_{CD} = 0$ this bridge is shown in Figure 2. Resistance R_1 is the one to be measured, R_2 is the adjustable resistance and auxiliary resistances R_3 and R_4 are equal and used to set the potential of point D. A battery is connected across A B diagonal. A galvanometer (this was originally an electromechanical detector but is now usually an electronic amplifier) 'bridges' the C D points and is used to detect the balance of their potentials. No current will flow through the galvanometer R_0 if R_2 is adjusted to be equal to R_1. At that state, the value of R_1 follows directly from the obtained value of R_2.

By analogy to the process of mass weighing, resistances R_3 and R_4 were called by Wheatstone as the *arms of the balance*. This term, shortened to *bridge arms* has been used up to now for all the bridge side branches.

Five years later, in 1848, Werner von Siemens developed a simple method of changing the range of R_1 measurements. He applied unequal arms R_3, R_4 with any desired ratio. The balance condition of the Wheatstone bridge given in Figure 2 was obtained from application of Kirchoff and Ohm's laws for linear resistances. It is independent of the voltage value of source E and of resistances connected in both diagonals. Siemen's idea made it possible to use a slide-wire or decade adjustable resistor R_2 for different ranges of R_1. The bridge ratio R_4/R_3 then is changed in set sequences, for example, 10^n.

The range, accuracy, and sensitivity of bridge measurements are limited by

- accuracy, values, and permissible power (as balance currents still flow in all resistors!) loads of R_2, R_3, R_4;
- resolution of adjustable resistor ΔR_2;
- value of applied voltage E;
- sensitivity of the galvanometer now more usually called the *detector* – for details refer to Dally, Riley and McConnell (1993) and Karandeev (1966).

The influence of the thermoelectric voltages formed in these circuits should be avoided when two measurements are made for opposite directions of supply. The correct result is then found as a mean value of the two readings that average out the effects.

The structure of the Wheatstone bridge was later applied to the design of several bridge versions for making R, L, C, and M measurements.

The Wheatstone bridge is also commonly used in off-balance measurements. In such a case, the supplying source E and resistances connected to both diagonals should be set to appropriate values and kept stable during the measurements. Then no additional adjustments are needed to obtain the result.

The output signal level depends on changes of all arm resistances from their values in the balance state. It can be measured by a direct reading instrument or conditioned, converted, and transmitted to remote display devices, or to the computer system.

Measurement of the ratio of the unbalanced bridge output signal and of its supply current or voltage is also used. Not long ago, a quadrilateral structure was also applied in active bridges with computer controlled voltage sources, for example, in the Cutkosky bridge.

The Christy–Wheatstone bridge principle opened the 170-year-long history of bridge circuit developments and their numerous applications in measurement, control, testing, monitoring, and diagnostics. The first 15 years of this history are covered already in Section 3.

In 1862, Sir Thompson Kelvin developed a 'double' – six-arm DC bridge for measurements of small values of resistances, lower than 1 Ω. This bridge provided the means for avoiding the influence of the resistance of connecting lead wires and of their changes during measurements. With this arrangement, small value, high precision four-terminal standard resistances could be easily measured and compared with high accuracy.

The next invention was the application of the bridge circuit to measure and to compare passive parameters such as inductance L, mutual inductance M and capacitance C.

The steady and transient states of the bridge circuit were used together. Firstly, the bridge is balanced in the steady state by adjusting one of the resistances for the DC supply. It is then also balanced in the unsteady state by L or C adjustments of its arms to avoid pulse (AC) movements of the galvanometer working in the ballistic regime. The pulses are generated just after repeated commutations of the supplying voltage or current DC (they can be switched off,

switched on, or reversed) and are imposed. Such 'ballistic bridges' were developed, one after another, by de Sauty in 1871 – for C measurements; by Maxwell in 1873 – for the L, M, LM measurements; by Carry-Foster in 1887 – for the C, M measurements; and also used and improved by Perry, Ayrton, and Brulion. After the invention of the telephone by Bell in 1875, Lord Rayleigh, Hevisade, Hughes, Kohlrausch, and others tried to use it in the above bridges supplied by an induction coil generator, but its voltage was of unknown shape and not of one frequency.

The principle of the first modern AC bridge was introduced by Max Wien in 1891 – for C measurements. He first used an alternating current supply of defined steady frequency and a 'vibrating' galvanometer mechanically adjusted to resonance with this frequency. Its very light moving part was equipped with a small mirror, and a light beam pointer.

Wien's AC bridge, together with such a galvanometer, was subsequently used for several decades, mainly at frequencies up to a few kilo hertz. For higher frequencies, high sensitivity electronic tube (valve) resonance amplifiers were developed.

Presently, for all frequency ranges, integrated, solid state, very high sensitivity, adjustable resonance amplifiers, and also phase detectors and shifters with operational amplifiers are commonly applied in AC bridges. Use of the electromechanical indicator has all but become a museum piece but its performance will still sometimes be useful in standard work.

The balance state: $U_{\mathrm{CD}}(t) = 0$, in the four-arm AC bridge demands that for every frequency of this voltage there is equality of products of the complex impedances of the opposite arms. This results in two real equations for equality of the polar or rectangular components of those two products. Here it is not always possible to obtain the solution.

Furthermore, only a few AC bridges have their balance conditions independent of the signal frequency. In the balancing process, two, but not any two, circuit parameters should be adjusted for a successively smaller and smaller readout from the detector.

Thus, in all AC bridges, the process of balancing is much more complicated than for DC bridges.

In the early days of development, dozens of AC bridge variation were developed for measurement of AC passive parameters under different conditions. Between them in 1920, Schering introduced a high voltage bridge to measure the capacity C of a condenser and its dielectric losses (expressed by tg δ) measurements, used up to now. In 1924, Robinson presented a bridge for frequency measurements.

More about the history of the first period of developments of AC bridges and deep studies of many circuits and their properties can be found in the references at the end, revised by T.R. Foord, edition of Hague and Foord (1971) famous book.

Parallel to this, classical DC bridges have also been continuously improved. In the beginning of the second part of the twentieth century, analog immittance measurements, provided by DC and AC bridges and by DC potentiometers, obtained levels of accuracy, sensitivity, and measurement ranges not very far from the present day ones. However, they were not as 'user friendly' as the modern instruments, because they needed many manual lengthy adjustments to obtain balance and much skilled experimental experience.

During the last fifty years, new revolutionary technological possibilities have been coming up for use in measurements. This has been made possible by the avalanche of inventions and developments in physics and electronics, such as transistors; new almost perfect ferromagnetic materials; Zener diodes; solid-state operational amplifiers (OPAMP)s; analog to digital A/D and digital to analog D/A signal converters; integrated digital and analog solid-state circuits; microprocessors; application specific integrated circuits (ASIC); huge software possibilities; programmable digital signal processors (DSP); and so on.

An important stage in high accuracy AC bridges was that connected with the development of high precision, adjustable induction dividers. They were made on cores of new ferromagnetic materials of very high permeability, very narrow hysteresis loop, and very low losses. These offered highly accurate, up to seven decades, AC voltage division dependent nearly exactly on the ratio of the coils' winding turns.

The accuracy of earlier developed precision resistance decade dividers is limited, because it depends on the stability of the resistor material and of their specialized technology process. The principle of the transformer bridge was shown quite early by Walsh in 1930, but in practice it was only first applied in 1949. Developments for high precision measurements have been due to Hill, Miller, and Decon in the 1962–1968 period.

A new idea in DC bridges was introduced by Milianic and others in 1962, and by Kuster and Moore in 1964–1966. They made use of the high precision adjustable induction current comparator. In this device, the zero of the DC magnetic flux in a ferromagnetic core is precisely detected due to additional AC coils, as in transductors. They gave the possibility of accurate comparing DC ampere turns of a few core windings.

In the book edited by Schnell and Sydenham (1993), Osvad presented the details of the development of the transformer bridges and also of active circuits based on operational amplifiers, both dedicated to immittance measurements.

Some basic information about bridges are in instrumentation handbooks, for example, in one edited by Nolting (1995) and revised by Boyes *et al*. (2003), and also in the latest one by Dyer (2001). Some valuable information about bridges can also be found in several academic textbooks and engineering books, including those given below in the References and Further Reading at the end of this article.

During recent years, research on AC impedance measurement has focused on the development of virtual measurement circuits. High accuracy, high speed, and precise DSP processors are used for that; they make it possible to build virtual bridges. These circuits could include only two hardware arms: the measured and the reference impedance. Results obtained in the laboratory are comparable with the best technical data of hardware automatic digital bridges. New algorithms for such measurements have also been found, but it seems that the stability of the best R or C and M reference elements is still better than that of the A/D converters used as DSP inputs.

4 BRIDGES IN MEASUREMENT OF NONELECTRICAL QUANTITIES

Applications of the bridges in the measurement of nonelectrical quantities by indirect means based on electrical detection began after immittance sensors of various quantities were developed.

Siemens, in 1871, tried to design platinum resistance sensors for temperature measurement, but without success. Callendar, in 1891, described such a sensor and also formulated the relation of its resistance to temperature.

Finally, in 1925, van Dusen developed corrections to this curve, which has now been standardized. According to these contributions, it became possible to build specialized, laboratory and portable temperature bridges. In recent decades, electronic analog and digital intelligent industrial transmitters have been made with bridges at their inputs.

For recording temperature, Leeds, and Northrop Company, about 1940, designed the first automatic bridge recorder. A robust electromechanical galvanometer was used with periodically operated special scissors closing on its deflected pointer. They actuated the clutch of a precision slide-wire resistor balancing the bridge step by step. Such an instrument had enough power to move the ink pen on a slowly moved circular, or strip recording paper. This instrument was still being used in dangerous areas even up to 1975. Their new versions with electronic amplifier and servomechanism were applied later and it is still possible to meet them in industry or in laboratories.

Thompson discovered the piezoresistive effect in 1856, but it was applied firstly in measurements by Simmons (CallTech) and by AC Rugy (MIT) in 1937. Very soon Baldwin Southwork Corp. started the production of metal strain gauges glued on paper background, ready to be stuck to a measured stressed object with a special adhesive. For their applications in static and in dynamic measurements, special AC resistance bridges were developed.

Some other immittance sensors, such as photoresistors and magnetoresistors, can work in the DC or AC bridges. Self- and mutual-inductance sensors and capacitance sensors have to use AC bridges.

In all industrial and laboratory intelligent transmitters, and in measuring cards of computer systems working with immittance sensors, unbalanced bridge circuits of both passive and active forms, are now commonly used. They are the input part of the signal conditioning circuits and still offer many properties not given by other circuits.

Bridge circuits and their theoretical backgrounds are still very useful in measurements, mainly for the following reasons:

- Most physical quantities can be measured using analog immittance sensors connected in the bridge circuit.
- Influence on sensor parameters of additional, not measured quantities, can be easily eliminated by using a differential sensor connected to the half-bridge or two such sensors in the full bridge circuit.
- If the measured changes of a sensors parameters are very small (e.g. lower than 0.5%, as it is in metallic strain gauges), the bridge circuits give accurate output signals.
- Bridges can also easily operate with multiparameter sensors for simultaneous measurements of a few variables.
- The equivalent circuit of four or more terminal sensors that is integrated within a bridge circuit is accessible only from external terminals.
- Bridge circuits are also used in the measurement of tensor components of material properties and of the distribution of multiparameter fields; and in nondestructive testing, impedance tomography, and diagnostics of circuit parameters.

Knowledge of bridge circuits and their properties are very important not only for designers but also for users of instrumentation. Thus, a unified description of bridge circuits is needed.

5 BRIDGE CIRCUITS CLASSIFICATION

Bridge circuits are commonly called by the names of their inventors; bridge instruments – by the names given by their manufacturers; or according to the field of their

applications, or parameters to be measured. A large diversity of bridge circuits, especially AC ones, demands that there is a clear criteria of their classifications. Some of them are presented below. Bridges could be classified according to

- static characteristic of the parameters (validity of the use of the superposition law in the circuit): linear, nonlinear (for at least one parameter), being quasi-linear around the working for relatively small excursions;
- type or number of supplied sources:
  - DC and AC of different frequency ranges,
  - current or voltage sources,
  - low or high voltage,
  - one, or several sources,
  - stationary and controlled sources;
- type of the bridge circuit:
  - passive, active;
- number of branches:
  - four, five, or six arms, and so on.
- number of external terminals:
  - four, six terminal, and so on.
- number of output:
- number of measured parameters;
- number of variable arms;
- variability of the circuit structure:
  - invariable, switched;
- type and range of measured parameters:
  R, RC, RLC bridge, low impedance, high impedance, and so on;
- type of application: high precision, laboratory, portable;
- accuracy of measurement of different parameters for different ranges in percents;
- field of application:
  - temperature bridges, strain gauge bridges, conductometric bridges, and so on.

AC bridges can also be classified according to the phase relations of circuit arms.

6 Z MATRIX EQUATIONS OF TWO PORT

In the general case, a bridge circuit can be considered as multinode, multiloop, and multiterminal [n-T] network in which, for obtaining measurement result, its one, or several branch parameters are changed or modulated externally.

The two Kirchoff Laws are valid in any case, at any time and any part of the circuit having negligible electromagnetic propagation. The circuit is linear if the superposition theorem is valid for it. It can then be described by a set of linear equations: algebraic ones for DC; complex form for AC of one frequency; Fourier transforms for few frequencies; Laplace transforms for any shape of signals in time; and partial differential equations for the distributed parameter circuits.

For a single supply and single output set up, any bridge could be transformed to a two port (two-terminal-pair) circuit – see Figure 3.

A set of equations of any linear circuit working as a two-port device could be reduced to a set of only two linear relations between currents and voltages at their ports.

It is thus possible to write these relations in six different ways; and for simplicity in matrix form. Then the one of the following matrices expresses the two-port parameters: **Z**, **Y**, **A**, **B**, **H**, **H′**. If it is needed, anyone of them could be easily transformed to another one.

For a particular circuit, some of the above matrices will not exist at all or their parameters are infinite in some states, for example, parameters of the transmission matrix **A** of the balanced bridge – see Hague and Foord (1971). More valuable information about the two-port circuit theory can be found in academic textbooks on electrical circuits, for example, such as the classic one by Carter and Richardson (1972).

Impedances are used commonly to describe the bridge arms. Therefore, the **Z** matrix will be taken for further consideration as the main one. Also, it is very important that this matrix exists in the balanced states of the bridge, but matrix **A** does not.

The linear two-port device with all typical symbols is given in Figure 3. An additional assumption is taken that there are no stationary sources inside a two-port circuit. If it is not so, the influence of such sources is eliminated from measurement considerations by short-circuiting the voltage ideal sources and disconnecting the current ones. They can also be taken into account in the next steps of the bridge circuit analysis, for example, by the superposition method.

The **Z** type matrix equation for a two-port device is the following:

$$\mathbf{U} = \mathbf{ZI} \tag{1}$$

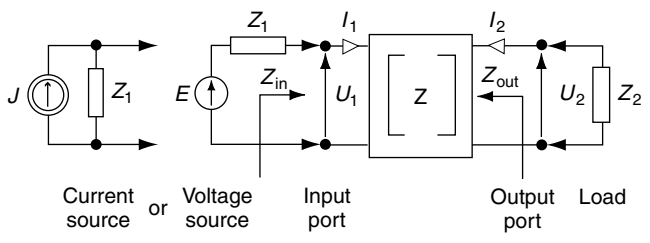

Figure 3. Two port network: standard conventions of currents, voltages, and impedances.

or in expanded form

$$\begin{vmatrix} U_1 \\ U_2 \end{vmatrix} = \begin{vmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{vmatrix} \begin{vmatrix} I_1 \\ I_2 \end{vmatrix} \tag{1a}$$

In the algebraic form it is:

$$\begin{aligned} U_1 &= z_{11}I_1 + z_{12}I_2 \\ U_2 &= z_{21}I_1 + z_{22}I_2 \end{aligned} \tag{1b}$$

In the general case, all impedance coefficients z_{ij} are different. A linear two-port circuit could include different, but only linear, two- and more terminal passive elements, for example, R L C single or coupled impedances, transformers, and so on, and only sources controlled proportionally by the circuit's voltages or currents.

If the two-port is nonreciprocal, then $z_{12} \neq z_{21}$ holds. For only one source supplying input or output port, the two-port has two different balance states on its terminals: $z_{21} = 0$ and $z_{12} = 0$.

If $z_{12} = z_{21}$, then the **Z** matrix has only three independent impedance elements.

If external circuits connected to both ports are also linear, then according to the Thevenin (after Carter and Richardson (1972) this theorem first developed by H. Hemholtz 30 years earlier) or Norton theorems, they have linear equivalent circuits. Such a one is shown for the primary side of the two-port of Figure 3.

Input and output equivalent impedances, terminal currents, and voltages under different load Z_2 and source Z_1 impedances are given in Table 1.

These relations are valid for all linear two-ports including bridge circuits. If elements of circuits connected to any side of the two-port are of known nonlinearities, it is possible also to find the terminal currents and voltages of this two-port by using its equations for each value of supply voltage E or current J.

The practical meaning of the **Z** matrix elements is apparent from the equations of Table 1. It is seen that element z_{11} is the input impedance Z_{in} of the two-port if the output circuit is open, and z_{22} is the output impedance Z_{out} when $Z_1 \to \infty$.

Element z_{12} and z_{21} of the two-port matrix **Z** are current to voltage transmittances, respectively in the reverse and forward direction of transmission when the output port is open.

It is possible to find all elements of the **Z** matrix from two-port terminal parameters measured with an open or short-circuited output port that is, $Z_2 = \infty$, $Z_2 = 0$ or $Z_1 \to \infty$, $Z_1 = 0$.

Equations of Table 1 could also be presented in different forms. For example, after inserting equations for Z_{in} and Z_{out} to the equation of voltage U_2 we obtain

$$U_2 = J\frac{Z_1 Z_2 z_{21}}{(Z_1 + z_{11})(Z_2 + z_{22}) - z_{12}z_{21}} \tag{1c}$$

Then, if z_{ij} elements were known from calculations or terminal measurements for a particular bridge working as the two-port, equations of Table 1 would be a useful tool to analyze it as a passive or active electrical linear circuit with variable parameters.

7 IMPEDANCE BRIDGE AS TWO PORT AND ITS Z MATRIX

As it was mentioned earlier, four-terminal bridges including only linear elements, could operate as linear two-ports. If the bridge is a part of the larger circuit, it can be considered as a two-port set up, only when it has two pairs of terminals with currents opposite to each other in each pair. It means that currents in connections around the bridge that is, between two terminals, each of a different pair, are negligible, or their influence additionally balanced. If it is not so, the bridge should be treated as a four-terminal (4-T) or generally an n-terminal (n-T) circuit.

Any four arms being used in a linear impedance bridge is the X-type two-port. It is shown in Figure 4. Designations of the two-port in Figure 3 are here changed to the ones used in bridges, similar to the Wheatstone bridge in Figure 2.

The impedance matrix **Z** of the linear passive bridge is given below

$$\mathbf{Z} = \begin{vmatrix} \dfrac{(Z_1 + Z_2)(Z_3 + Z_4)}{\sum Z_i} & \dfrac{Z_1 Z_3 - Z_2 Z_4}{\sum Z_i} \\ \dfrac{Z_1 Z_3 - Z_2 Z_4}{\sum Z_i} & \dfrac{(Z_1 + Z_4)(Z_2 + Z_3)}{\sum Z_i} \end{vmatrix} \tag{2}$$

where $\sum Z_i \equiv Z_1 + Z_2 + Z_3 + Z_4$.

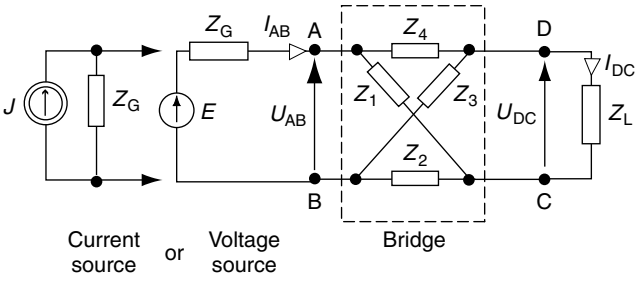

Figure 4. Notations of four-arm impedance bridge as X type two port.

Table 1. Definitions and basic equations of terminal impedances, currents and voltages of linear two port under work of linear load and supply source.

Parameters and basic relations			General case	Particular cases			
			$\infty > Z_1 > 0, \infty > Z_2 > 0$	$Z_1 = \infty$	$Z_1 = 0$	$Z_2 = \infty$	$Z_2 = 0$
Port impedance	Input	$Z_{\text{in}} \equiv \frac{U_1}{I_1}$	$z_{11} - \frac{z_{12}\, z_{21}}{z_{22} + Z_2} = \frac{\det \mathbf{Z} + Z_2\, z_{11}}{z_{22} + Z_2} = Z_{\text{in}}^{\infty} \frac{Z_{\text{out}}^{0} + Z_2}{Z_{\text{out}}^{\infty} + Z_2}$			$Z_{\text{in}}^{\infty} = z_{11}$	$Z_{\text{in}}^{0} = \frac{\det \mathbf{Z}}{z_{22}}$
	Output	$Z_{\text{out}} \equiv \frac{U_2}{I_2}$	$z_{22} - \frac{z_{12}\, z_{21}}{z_{11} + Z_1} = Z_{\text{out}}^{\infty} \frac{Z_{\text{in}}^{0} + Z_1}{Z_{\text{in}}^{\infty} + Z_1}$	$Z_{\text{out}}^{\infty} = z_{22}$	$Z_{\text{out}}^{0} = \frac{\det \mathbf{Z}}{z_{11}}$	$z_{22} - \frac{z_{12}\, z_{21}}{z_{11} + Z_1} = \frac{\det \mathbf{Z} + Z_1\, z_{22}}{z_{11} + Z_1}$	
Supply source E or J in primary port	Output variables	U_2	$\frac{E}{Z_{\text{in}} + Z_1} z_{21} \frac{Z_2}{Z_{\text{out}} + Z_2}$	0	$\frac{E}{Z_{\text{in}}} \frac{z_{21}\, Z_2}{Z_{\text{out}}^{0} + Z_2}$	$\frac{E\, z_{21}}{z_{11} + Z_1}$	0
			$J \frac{Z_1}{Z_{\text{in}} + Z_1} z_{21} \frac{Z_2}{Z_{\text{out}} + Z_2}$	$J \frac{z_{21}\, Z_2}{z_{22} + Z_2}$	0	$J \frac{Z_1\, z_{21}}{z_{11} + Z_1}$	0
		$-I_2$	$\frac{E}{Z_{\text{in}} + Z_1} \frac{z_{21}}{Z_{\text{out}} + Z_2}$	0	$\frac{E}{Z_{\text{in}}} \frac{z_{21}}{Z_{\text{out}}^{0} + Z_2}$	0	$\frac{E}{Z_{\text{in}}^{0} + Z_1} \frac{z_{21}}{Z_{\text{out}}}$
			$J \frac{Z_1}{Z_{\text{in}} + Z_1} \frac{z_{21}}{Z_{\text{out}} + Z_2}$	$J \frac{z_{21}}{z_{22} + Z_2}$	0	0	$J \frac{Z_1}{Z_{\text{in}}^{0} + Z_1} \frac{z_{21}}{Z_{\text{out}}}$
Supply source E or J in primary port	Input variables	U_1	$\frac{E\, Z_{\text{in}}}{Z_{\text{in}} + Z_1}$	0	E	$E \frac{z_{11}}{z_{11} + Z_1}$	$E \frac{\det \mathbf{Z}}{\det \mathbf{Z} + Z_1\, z_{22}}$
			$J \frac{Z_{\text{in}}\, Z_1}{Z_{\text{in}} + Z_1}$	$J\, Z_{\text{in}}$	0	$J \frac{z_{11}\, Z_1}{z_{11} + Z_1}$	$J \frac{Z_1 \det \mathbf{Z}}{\det \mathbf{Z} + Z_1 z_{22}}$
		I_1	$\frac{E}{Z_{\text{in}} + Z_1}$	0	$\frac{E}{Z_{\text{in}}}$	$\frac{E}{Z_1 + z_{11}}$	$\frac{E\, z_{22}}{\det \mathbf{Z} + Z_1 z_{22}}$
			$J \frac{Z_{\text{in}}\, Z_1}{Z_{\text{in}} + Z_1}$	J	0	$J \frac{Z_1}{z_{11} + Z_1}$	$J \frac{Z_1\, z_{22}}{\det \mathbf{Z} + Z_1\, z_{22}}$

Note: Where $\det \mathbf{Z} = z_{11}\, z_{22} - z_{12}\, z_{21}$.

It is a symmetric matrix, that is, $z_{12} = z_{21}$, because the circuit is reciprocal. This means that open circuit output voltages U_{DC} and U_{AB} are equal when the bridge is supplied by the same value current $I_{\text{AB}} = I_{\text{DC}}$ at primary AB or secondary DC port. Then the balance conditions for $U_{\text{DC}} = 0$ or $U_{\text{AB}} = 0$ for both ways of supply are equal and the following applies:

$$Z_1 Z_3 - Z_2 Z_4 = 0 \tag{3}$$

Or for arm admittances $Y_i = 1/Z_i$

$$Y_1 Y_3 - Y_2 Y_4 = 0 \tag{3a}$$

Balance condition could be also expressed in ratio forms for example,

$$\frac{Z_1}{Z_2} = \frac{Z_4}{Z_3} \text{ or } \frac{Z_1}{Z_4} = \frac{Z_2}{Z_3} \tag{3b) or (3c)}$$

Input and output bridge diagonal impedances are, in the general case, different. They depend mainly on the bridge arm impedances and to a smaller degree also on the impedance connected to the opposite diagonal. Only in the balanced state they are independent of the last ones, as it results from Figure 1(a).

If the supply source E or J, as well as Z_L and Z_G are given, the output voltage U_{DC} of the loaded bridge as two-port (see equation (1c)) is

$$U_{DC} = I\frac{Z_G Z_L z_{21}}{(Z_G + z_{11})(Z_L + z_{22}) - z_{21}^2} \tag{4}$$

Inserting in (4) the values of bridge matrix elements given in (2) we obtain:

$$U_{DC} = J\frac{Z_G Z_L (Z_1 Z_3 - Z_2 Z_4)}{Z_G Z_L \sum Z_i + Z_L (Z_1 + Z_2)(Z_3 + Z_4) + Z_G (Z_1 + Z_4)(Z_2 + Z_3) + A} \tag{5}$$

Where:

$$A = \sum Z_i Z_j Z_k = Z_1 Z_2 (Z_3 + Z_4) + Z_3 Z_4 (Z_1 + Z_2) = \cdots$$

Moving the product of $Z_G Z_L$ to the denominator we get:

$$U_{DC} = J\frac{Z_1 Z_3 - Z_2 Z_4}{\sum Z_i + \frac{1}{Z_G}(Z_1 + Z_2)(Z_3 + Z_4) + \frac{1}{Z_L}(Z_1 + Z_4)(Z_2 + Z_3) + \frac{A}{Z_G Z_L}} \tag{6}$$

From the equations of lines 1 and 2 in Table 1 it is also possible to find Z_{in} and Z_{out} impedances of the analyzed bridge for different values of source impedance Z_G and of the load one Z_L – *see* **Article 127, Unbalanced DC Bridges, Volume 2**.

8 BASIC EQUATIONS OF UNBALANCED BRIDGES

In the analysis of bridges in off-balance conditions and properties of unbalanced (deflection) bridges, it is convenient to express matrix $\mathbf{Z}$ as a sum of two components

$$\mathbf{Z} = \mathbf{Z_0} + \mathbf{\Delta Z} = \mathbf{Z_0} + \mathbf{\Delta Z}(\varepsilon) \tag{7}$$

or in the expanded forms:

$$\mathbf{Z} = \begin{vmatrix} Z_{AB0} & 0 \\ 0 & Z_{CD0} \end{vmatrix} + \begin{vmatrix} \Delta Z_{AB} & z_{21} \\ z_{21} & \Delta Z_{CD} \end{vmatrix} = \begin{vmatrix} Z_{AB0} & 0 \\ 0 & Z_{CD0} \end{vmatrix} + \begin{vmatrix} \varepsilon_{AB} Z_{AB0} & t_0 f(\varepsilon_i) \\ t_0 f(\varepsilon_i) & \varepsilon_{CD} Z_{CD0} \end{vmatrix} \tag{8}$$

Where $\mathbf{Z}_0 - \mathbf{Z}$ matrix in the bridge balanced state; $\mathbf{\Delta Z}$ – matrix of absolute increments Δz_{ij} from this state; $\mathbf{\Delta Z}(\varepsilon)$ – above matrix expressed by relative increments of impedances and by the initial sensitivity t_0 and unbalance function $f(\varepsilon_i) = \Delta L(\varepsilon_i)/M(\varepsilon_i)$ of the output voltage given below.

All bridge parameters corresponding to the balance state have now additional subscript 0. Then the arm impedances are

$$Z_i \equiv Z_{i0} + \Delta Z_i = Z_{i0}(1 + \varepsilon_i) \tag{9}$$

$\Delta Z_i;\ \varepsilon_i \equiv \dfrac{\Delta Z_i}{Z_{i0}}$ – absolute and relative increments of impedances Z_i, from their values Z_{i0} in the balance state;

$t_0 \equiv \dfrac{Z_{10} Z_{30}}{\sum Z_{i0}}$ – initial voltage sensitivity per one unit of current I_{AB} of the open output of the bridge;

$f(\varepsilon_i) = \dfrac{\Delta L(\varepsilon_i)}{M(\varepsilon_i)}$ – voltage unbalance relative function of bridge impedance increments and

$\Delta L(\varepsilon_i) = \varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4$ – numerator and

$M(\varepsilon_i) = 1 + \dfrac{\sum \Delta Z_i}{\sum Z_{i0}} = 1 + \dfrac{\sum \varepsilon_i Z_{i0}}{\sum Z_{i0}}$ – denominator of the above function.

The following additional relations of arm initial impedances to the value of Z_{10} are defined as

$$Z_{20} \equiv mZ_{10};\ Z_{40} \equiv nZ_{10};\ Z_{30} \equiv mnZ_{10} \tag{10}$$

Two-port matrix $\mathbf{Z}$ parameters of the bridge, in the above new notation, are presented in Table 2.

The output voltage of the loaded bridge, given by (6) also could be written now as

$$U_{DC} \equiv T_0 \frac{\Delta L(\varepsilon_i)}{M_L(\varepsilon_i)} \tag{11}$$

$T_0 \equiv JZ_{10}Z_{30}/M_{UJ0}$ – initial voltage sensitivity of loaded bridge;

$M_{UJ} \equiv M_{UJ0} + \Delta M_{UI}(\Delta Z_i)$ – denominator in (6) of U_{DC}.

$\Delta L(\varepsilon_i) = \varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4$ – numerator as before,

$M_L(\varepsilon_i) \equiv 1 + \Delta M_{UJ}(\Delta Z_i)/M_{UJ0}$ – new denominator of the voltage relative unbalance function of the loaded bridge with a nonideal supply source.

Increment $\Delta M_{UJ}(\Delta Z_i)$ of the denominator is a complicated function of the balance impedances and of their increments for general cases of value Z_G and Z_L, because:

Table 2. Parameters of matrices **Z, Z**$_0$, **Δ Z** (ε_i), **ΔZ** of the four-arm linear impedance bridge as two port.

No	Matrix	Bridge state	z_{11}		$z_{12} = z_{21}$	z_{22}	
1	$\mathbf{Z}_0$	In balance	Z_{AB0}	$\dfrac{Z_{40}(Z_{10}+Z_{20})}{Z_{10}+Z_{40}} = Z_{10}\dfrac{n(1+m)}{1+n}$	$\dfrac{Z_{10}Z_{30}-Z_{20}Z_{40}}{\sum Z_{i0}} = 0$	Z_{CD0}	$Z_{20}\dfrac{Z_{10}+Z_{40}}{Z_{10}+Z_{20}} = Z_{10}\dfrac{m(1+n)}{1+m}$
2	**Z**	Out of balance	Z_{AB} ($Z_L = \infty$)	$\dfrac{(Z_1+Z_2)(Z_3+Z_4)}{\sum Z_i}$ or	$\dfrac{Z_1Z_3-Z_2Z_4}{\sum Z_i}$	Z_{CD} ($Z_G = \infty$)	$\dfrac{(Z_1+Z_4)(Z_2+Z_3)}{\sum Z_i}$ or
3				$Z_{AB0}[1+\varepsilon_{AB}]$	or		$Z_{CD0}[1+\varepsilon_{CD}]$
4	ε		ε_{AB} ($Z_L = \infty$)	$\dfrac{1}{M(\varepsilon_i)}\left(\dfrac{n\varepsilon_{12}}{1+n}+\dfrac{\varepsilon_{43}}{1+n}+\varepsilon_{12}\varepsilon_{43}\right)$		ε_{CD} ($Z_G = \infty$)	$\dfrac{1}{M(\varepsilon_i)}\left(\dfrac{m\varepsilon_{14}}{1+m}+\dfrac{\varepsilon_{23}}{1+m}+\varepsilon_{14}\varepsilon_{23}\right)$
			ε_{12}	$\varepsilon_{12} = \dfrac{\varepsilon_1+m\varepsilon_2}{1+m}$	$t_0\dfrac{\Delta L(\varepsilon_i)}{M(\varepsilon_i)}$	ε_{14}	$\varepsilon_{14} = \dfrac{\varepsilon_1+n\varepsilon_4}{1+n}$
			ε_{43}	$\varepsilon_{43} = \dfrac{\varepsilon_4+m\varepsilon_3}{1+m}$		ε_{23}	$\varepsilon_{23} = \dfrac{\varepsilon_2+n\varepsilon_3}{1+n}$
5	$\Delta\mathbf{Z}$		ΔZ_{AB} ($Z_L = \infty$)	$\dfrac{Z_{AB0}}{\sum Z_{i0}+\sum \Delta Z_i} \times \left[\begin{array}{c} n(\Delta Z_i+\Delta Z_2)+\dfrac{1}{n}(\Delta Z_3+\Delta Z_4) \\ +\dfrac{(\Delta Z_1+\Delta Z_2)(\Delta Z_3+\Delta Z_4)}{Z_{AB0}} \end{array}\right]$		ΔZ_{CD} ($Z_G = \infty$)	$\dfrac{Z_{CD0}}{\sum Z_{i0}+\sum \Delta Z_i} \times \left[\begin{array}{c} m(\Delta Z_1+\Delta Z_4)+\dfrac{1}{m}(\Delta Z_2+\Delta Z_3) \\ +\dfrac{(\Delta Z_1+\Delta Z_4)(\Delta Z_2+\Delta Z_3)}{Z_{AB0}} \end{array}\right]$

Note: Where initial bridge output voltage to current sensitivity – $t_0 \equiv \dfrac{T_0}{J} = \dfrac{Z_{20}Z_{40}}{\sum Z_{i0}} = \dfrac{Z_{10}mn}{(1+m)(1+n)}$,

numerator of unbalance function – $\Delta L(\varepsilon_i) = \varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4$,

denominator of unbalance function – $M(\varepsilon_i) = 1 + \dfrac{\sum \Delta Z_i}{\sum Z_{i0}} = 1 + \dfrac{\varepsilon_{12}+n\varepsilon_{43}}{1+n} = 1 + \dfrac{\varepsilon_{14}+m\varepsilon_{23}}{1+m} = 1 + \dfrac{\varepsilon_1+m\varepsilon_2+n(\varepsilon_4+m\varepsilon_3)}{(1+m)(1+n)}$.

$$\Delta M_{UJ}(\Delta Z_i) = \sum \frac{\partial M_{UJ}}{\partial Z_i}\Delta Z_i + \sum_{i\neq j}\frac{\partial^2 M_{UJ}}{\partial Z_i \partial Z_j}\Delta Z_i \Delta Z_j + \sum_{\substack{i\neq j\neq k \\ i\neq k}}\frac{\partial^3 M_{UJ}}{\partial Z_i \partial Z_j \partial Z_k}\Delta Z_i \Delta Z_j \Delta Z_k \qquad (12)$$

There are 14 elements to add together $(4+6+4)$. If modules of related resistance increments $|\varepsilon_i|$ are not too high, the last sum in the above equation, dependant on the products of the three of them, can be neglected; and also for $\varepsilon_i \ll 1$, the second sum is negligible.

Further simplification of (6) and (11) is obtained assuming ideal J or E supply sources $|Z_G| \gg |Z_{AB}|$ or $|Z_G| \ll |Z_{AB}|$ respectively, for ideal voltage output $|Z_L| \gg |Z_{CD}|$ or ideal current output $|Z_L| \ll |Z_{CD}|$.

It is also the case if some initial bridge arm impedances are equal, or not changing and if pairs of the increments, or all of them, are of the same absolute value but of the opposite signs in the neighboring arms. Such cases are very common in practice. Detailed discussion of these cases are in books by Bentley (1995), Dally, Riley and McConnell (1993), Holman (1994), Tattamangalam (2000), Schnell and Sydenham (1993), and also in **Article 127, Unbalanced DC Bridges, Volume 2**.

1 INTRODUCTION

Bridge circuits are still commonly used in the input of autonomic immitance measurement instruments and transmitters of industrial systems. It is so for the following reasons:

- They are either directly sensitive to changes of immitance components or else they are indirectly sensitive to other variables actuating the immitance of analog sensors.
- They perform some simple signal-conditioning functions, such as dependence of output signal on changes of parameters of several sensors easily and accurately.

During the last decades, many new input signal-conditioning circuits have been developed (see – Anderson (1997), Kester (1999), Zakrzewski (2000), printed catalogs and Internet information of National Instruments™ (2004) and of Analog Devices Co.). They use various differential operational amplifiers, feedback loops, single and double stabilized supply sources, many methods of switching (e.g. integrating or successive approximation AD converters). Ratio measurements are also applied when analog circuit and AD converter are supplied by a common source. However, classic unbalanced DC bridges are still most commonly used either on their own or in above mentioned circuits for measurement of resistance and conductance for their merits and simplicity. They work most often with nearly unloaded (open circuit) voltage output, sometimes with current output loaded with resistance or short circuited, and they deliver measurement signals for amplifying and converting them to the digital form.

Furthermore, measured objects as well as multiterminal solid state and integrated semiconductor sensors can also include inseparable bridge structures in their equivalent circuits. Parameters of this structure are measurable indirectly only on terminals of the circuit or on electrodes used to check material properties.

Below, properties of the four terminal (4T) unbalanced resistance bridge networks are analyzed in detail. The relevant knowledge in design and understanding of measurement bridge circuits and in programming digital circuits connected with them is required. Some new developments have also been introduced. A short history of measuring bridges and their basic equations have already been given in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**.

2 FOUR-TERMINAL (4T) DC CIRCUITS

Four-terminal circuits (4T) could have arbitrary currents of three terminals and the fourth one determined by Kirchoff's Law. If there are two pairs of opposite terminal

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

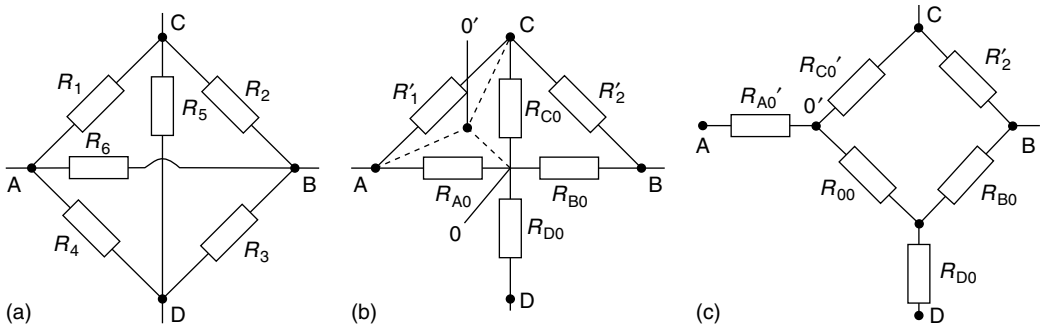

Figure 1. Examples of 4T circuit, every one equivalent to each other: (a) without nodes inside – four arms bridge with diagonals; (b) with one node inside; (c) with two nodes inside.

currents, then the 4T circuit behaves as the twoport – see, for example, Carter and Richardson (1971). Only passive and reciprocal 4T circuits are taken below for analysis. Their basic equivalent circuit has six immitance branches, which are connected to the quadrilateral network given for DC on Figure 1(a).

Terminals are also the only nodes in this network, and it has the structure of the four-arm bridge with two diagonals. There is a direct relation of the admittance of each branch and the value of the off-diagonal element of the circuit admittance matrix with the sign 'plus'. Any of four-terminal circuits, which are more complex inside, can always be transformed to the above network or to some of its simpler structures.

In Figure 1(b) and (c), there are shown two other networks of six branches equal to the first one. They had originally been developed by the author for the reciprocal part of the Hall devices' equivalent 4T network to find zero correction circuits that were stabile in a wide range of temperatures – see Warsza (1980). The network in Figure 1(b) has one node inside. It was obtained from circuit in Figure 1(a) by circuit substituting two smaller resistances, each one of two smaller opposite resistances' products, for example, R_1 and R_2 by two parallel ones respectively R_1', R_1'' and R_2', R_2''. So, that is $R_1'' R_3 = R_2'' R_4 = R_5 R_6$ and to the network of these six resistances the Rosen's theorem of the four-arm star-delta inverse transformation is applicable. The last network, given in Figure 1(c) has two nodes inside. It is obtained from the previous one by transformation of elements of the triangular ACO to the equivalent star. There are six different networks of two serial immitances connected to neighboring nodes of the inside bridge and they are equivalent to each other. All bridges of networks of Figure 1 are in balance together.

The four-arm bridge (4R) is a particular case of the above networks of six immitances. It has no other four branch circuits that are equivalent to it. Then, in the circuit theory it plays an analogous role to the prime number in mathematics.

Resistance or conductance 4T circuits could be applied in measurements in different ways. In addition to measurements of branch immitances, they could be used for indirect measurements of one and theoretically up to six variables differently influencing these immitances.

In measurements, a bridge could be supplied from voltage or current sources, ideal ones, or of the particular internal resistance. The classic type supply is connected to one of the bridge diagonals and the output is taken from the second one. Two sources could be connected in different ways, for example, voltage sources, one in the diagonal and the second one in the bridge arm or in the output diagonal. Both the ones in the bridge branches, also have been used. Some years ago, this author proposed to use unconventional power supply for the bridge by providing two equal and ideal current sources connected in parallel to opposite bridge arms, or by only one such source switched between these arms and averaging of two measurement results obtained. Such a bridge has two outputs from both diagonals and offers original metrological possibilities. It could be used simultaneously for two and more variable measurements – see Warsza (2002), (2004) and the literature list in it.

3 BASIC EQUATIONS OF THE FOUR-ARM RESISTANCE BRIDGE (4R) AS TWOPORT

In Figure 2, the four-arm resistance bridge circuit (4R) classically powered from current or from voltage source is given. This bridge appears under the name of Wheatstone bridge. It is drawn here as the twoport.

In the general case, the bridge input current I_{AB} depends on supply source parameters J and R_G, or E and R_G and also on the equivalent input bridge resistance R_{AB}. The last one is a function of actual values of all bridge resistances R_i and of its load R_L, if any. Then, for a full description of the bridge from Figure 2 as a linear

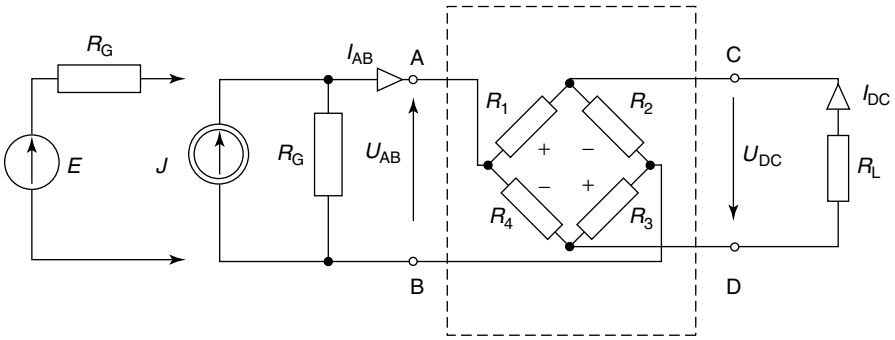

Figure 2. The four-arm bridge as twoport, together with the single supply source J or E of the internal resistance R_G and the load R_L, both connected to its diagonals.

circuit of variable parameters, twoport equations could be used – see such bridge equations of the impedance type given in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2** and of the particular case when all parameters are real, and matrix $\mathbf{Z} = \mathrm{Re}(\mathbf{Z}) \equiv \mathbf{Z_R}$. In generalized form, it is

$$\mathbf{U} = \mathbf{Z_R I}$$

and after expansion of matrices:

$$\begin{vmatrix} U_{AB} \\ U_{DC} \end{vmatrix} = \begin{vmatrix} r_{11} & r_{12} \\ r_{21} & r_{22} \end{vmatrix} \begin{vmatrix} I_{AB} \\ I_{CD} \end{vmatrix} \equiv \begin{vmatrix} R^{\infty}_{AB} & r_{12} \\ r_{21} & R^{\infty}_{CD} \end{vmatrix} \begin{vmatrix} I_{AB} \\ I_{CD} \end{vmatrix} \quad (1)$$

where current $I_{CD} = -I_{DC}$,

$r_{11} \equiv R^{\infty}_{AB}, r_{22} \equiv R^{\infty}_{CD}$ – input and output resistances of twoport when the opposite side port is opencircuited.
r_{12}, r_{21} – current to voltage both direction transmittances (transfer resistances) when the opposite side port is open circuited ($R_G \to \infty$, or $R_L \to \infty$). (Superscript ∞ or 0 is used here for open or shorted circuit of the opposite side of the bridge and subscript 0 – for the balance state).

Formula (1) in algebraic form and with the opposite direction output current I_{DC} as shown in Figure 2, is

$$\begin{aligned} U_{AB} &= R^{\infty}_{AB} I_{AB} - r_{12} I_{DC} \\ U_{DC} &= r_{21} I_{AB} - R^{\infty}_{CD} I_{DC} \end{aligned} \quad (1a)$$

Matrix $\mathbf{Z_R}$ of the four-arms resistance bridge is:

$$\mathbf{Z}_R \equiv \begin{vmatrix} \dfrac{(R_1+R_2)(R_3+R_4)}{\sum R_i} & \dfrac{R_1R_3 - R_2R_4}{\sum R_i} \\ \dfrac{R_1R_3 - R_2R_4}{\sum R_i} & \dfrac{(R_1+R_4)(R_2+R_3)}{\sum R_i} \end{vmatrix} \quad (2)$$

where $\sum R_i = R_1 + R_2 + R_3 + R_4$ – sum of resistances of bridge main loop A B C D;

Because of the equivalence of both directions' bridge transmittances (or transfer resistances) $r_{21} = r_{12}$, only three elements of the matrix $\mathbf{Z_R}$ are different, but they depend on four bridge circuit resistances. Values of these elements are always finite, including balance state when $r_{21} = 0$ and

$$R_1 R_3 = R_2 R_4 \quad (2a)$$

Let us consider a general case of the bridge when variable resistances are in all arms. As it was introduced in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**, analysis of the circuit of Figure 2 should be more general and easier if resistances are referenced to one of them, for example, to R_{10}, and their changes – to initial values of resistances in the balanced state. Then,

$$R_i \equiv R_{i0} + \Delta R_i \equiv R_{i0}(1 + \varepsilon_i) \equiv r_{i0} R_{10}(1 + \varepsilon_i) \quad (3)$$

where R_{i0} – initial (in balance) value of the R_i resistance;
$\Delta R_i, \varepsilon_i$ – are absolute and relative increments;
r_{i0} – relative values of arms' resistances in balance conditions.

The open circuit output voltage U^{∞}_{DC} is given by the equation

$$U^{\infty}_{DC} = I_{AB} r_{12} = \frac{I_{AB}(R_1R_3 - R_2R_4)}{\sum R_i} \quad (4)$$

where $\Sigma R_i = R_1 + R_2 + R_3 + R_4$

With the notations given by formula (3) and after transformation of (4), one gets

$$\begin{aligned} U^{\infty}_{DC} &= I_{AB} R_{10} \frac{r_{20} r_{40}}{\sum r_{i0}} \\ &\quad \times \frac{(\varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4)}{1 + \dfrac{\sum r_{i0}\varepsilon_i}{\sum r_{i0}}} \\ &\equiv T'_0 \times f'(\varepsilon_i) \end{aligned} \quad (5)$$

where $T_0' \equiv I_{AB} t_0'$ – initial output voltage sensitivity to the unbalance function $f'(\varepsilon_i)$.

When the bridge is in balance, output voltage $U_{DC}^{\infty} = 0$ and balance condition (2a) could be now written as:

$$R_{30} = r_{20} r_{40} R_{10}; \tag{5a}$$

Balance state of the bridge is the property of this particular network. Output signal is equal to zero only if the bridge is supplied from the single source connected to one of its diagonals.

If, for more simplicity of the notation, we put down additionally: $R_{20} \equiv mR_{10}$, $R_{40} \equiv nR_{10}$, then it is $R_{30} = mnR_{10}$ and initial open circuit sensitivity of transmittance r_{21} is

$$t_0' \equiv \frac{R_{10} R_{30}}{\sum R_{i0}} = R_{10} \frac{mn}{(1+m)(1+n)} \tag{5b}$$

and unbalance function of r_{21}:

$$f'(\varepsilon_i) = \frac{(\varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4)}{1 + \dfrac{\varepsilon_1 + m\varepsilon_2 + n(m\varepsilon_3 - \varepsilon_4)}{(1+m)(1+n)}} \equiv \frac{\Delta L \varepsilon_i}{1 + \varepsilon_{\Sigma R}(\varepsilon_i)} \tag{5c}$$

where $\Delta L(\varepsilon_i); \varepsilon_{\Sigma R}$. – increments of its numerator and denominator.

$\sum R_{i0}$ – value of ΣR_i of the balanced bridge.

From (5) and (5c), it is clear how output open-circuited voltage U_{DC}^{∞} and transmittance r_{21} depend on signs and values of relative increments ε_i of resistances of particular bridge arms. These increments of opposite signs in neighboring arms, given in Figure 2, unbalance the bridge in the same direction. If absolute values of these increments are the same, the output voltage is proportional to the number of variable arms (e.g. multiplied by 2 or by 4).

Transmittance r_{21} and its unbalance function $f'(\varepsilon_i)$ theoretically could take values from the range $(-\infty, +\infty)$. In practice, there are some limitations due to existing or permitted extreme values of ε_i, maximum dissipated powers of arms and maximum voltage of the current source or maximum current of the voltage source. Transmittance $r_{21} = 0$, if $f'(\varepsilon_i) = 0$. It could happen for many different combinations of ε_i. The basic balance state is defined in such a one as all $\varepsilon_i = 0$.

Open circuit bridge terminal resistances are

$$R_{AB}^{\infty} = R_{AB0}(1 + \varepsilon_{AB}^{\infty}) = R_{AB0} \frac{(1+\varepsilon_{12})(1+\varepsilon_{34})}{(1+\varepsilon_{\Sigma R})} \tag{6}$$

$$R_{CD}^{\infty} = R_{CD0}(1 + \varepsilon_{DC}^{\infty}) = R_{CD0} \frac{(1+\varepsilon_{14})(1+\varepsilon_{23})}{(1+\varepsilon_{\Sigma R})} \tag{7}$$

where

– input and output bridge resistances in the balance state:

$$R_{AB0} = R_{10} \frac{n(1+m)}{1+n} \tag{6a}$$

and

$$R_{CD0} = R_{10} \frac{m(1+n)}{1+m} \tag{7a}$$

– relative increments of R_{AB} and of R_{CD} from the balance state:

$$\varepsilon_{AB}^{\infty} = \frac{1}{1 + \varepsilon_{\Sigma R}(\varepsilon_i)} \left(\frac{n\varepsilon_{12} + \varepsilon_{43}}{1+n} + \varepsilon_{12}\varepsilon_{43} \right) \tag{6b}$$

and

$$\varepsilon_{CD}^{\infty} = \frac{1}{1 + \varepsilon_{\Sigma R}(\varepsilon_i)} \left(\frac{m\varepsilon_{14} + \varepsilon_{23}}{1+m} + \varepsilon_{14}\varepsilon_{23} \right) \tag{7b}$$

– relative increment of the sum of $R_i + R_j$ resistances of i, j arms;

$$\varepsilon_{ij} \equiv \frac{\Delta R_i + \Delta R_j}{R_{i0} + R_{j0}} \tag{8}$$

– relative increment of the sum $\sum R_i$ of bridge resistances:

$$\varepsilon_{\Sigma R} \equiv \frac{\varepsilon_{12} + n\varepsilon_{43}}{1+n} = \frac{\varepsilon_{14} + m\varepsilon_{23}}{1+m} \tag{9}$$

Matrix $\mathbf{Z_R}$ from (2) could now also be written in a different form as

$$\mathbf{Z}_R = \begin{vmatrix} R_{AB0}^{\infty}(1 + \varepsilon_{AB}^{\infty}) & t_0' f'(\varepsilon_i) \\ t_0' f'(\varepsilon_i) & R_{CD0}^{\infty}(1 + \varepsilon_{CD}^{\infty}) \end{vmatrix} \tag{10}$$

In Tables 1(a) and (b), are given elements of the matrix $\mathbf{Z_R}$ of the resistance bridge 4R operating as the twoport X. In subsequent lines, there are open circuit terminal parameters r_{21}, R_{AB}^{∞}, R_{DC}^{∞} and their components. The first column of Table 1(a) corresponds to the general case of the bridge. In columns a to d of this table and in columns e to j of Table 1(b), there are few particular cases depending on

- the number of variable arms,
- the relations between their increments, and
- the relations between initial arm resistances (in balance).

On the basis of these tables, it is possible to find terminal parameters of the four-arm bridge in any kind of its operation as twoport. Some particular cases of unbalanced 4R bridge are discussed in detail by Dall (1992), Karandeev (1966), Morris (1993), Padmanabhan (2000), Sanderson in Bentley (1995) handbook, Warsza (2004) and by others.

4 SIMPLIFIED BRIDGE EQUIVALENT CIRCUITS

In particular cases of the operation of the bridge as the twoport type **X**, some of its equivalent circuits could also be applied. Two of them are given in Figures 3(b) and 3(c).

The circuit in Figure 3(b) is twoport of type T. It has only the same values of input–output terminal parameters as the bridge (elements of its matrix $\mathbf{Z_R}$) and could be used when outside the bridge there is no other connection between circuits of both sides. In this twoport, two terminals, B and C, are connected together but in the bridge they are not. The equivalent circuit type **Π** of twoport X also exists and could be sometimes more proper, for example, for describing the short circuit current of the conductance bridge.

The other circuit, given in Figure 3(c), is the type 2T symmetric twoport. Two horizontally drawn resistances of circuit in Figure 3(b) are divided here to two parts each. They depend on bridge resistances, each one differently as follows

$$R_{\mathrm{A}0'} = \frac{R_4(R_1 + R_2)}{\sum R_{\mathrm{i}}} \tag{11a}$$

$$R_{\mathrm{B}0''} = \frac{R_2(R_3 + R_4)}{\sum R_{\mathrm{i}}} \tag{11b}$$

$$R_{\mathrm{C}0''} = \frac{R_4(R_2 + R_3)}{\sum R_{\mathrm{i}}} \tag{11c}$$

$$R_{\mathrm{D}0'} = \frac{R_2(R_1 + R_4)}{\sum R_{\mathrm{i}}} \tag{11d}$$

This circuit not only keeps the twoport matrix parameters equal but voltages of all terminals as well. Only input resistances from the arms' sides are here different from ones of 4R bridge, for example, input resistance from terminals AD. This equivalent circuit of the bridge has not been found in literature yet but could be very useful in the analysis of the bridge and different circuits connected to it, including operational amplifiers, in the case in which they are supplied from the common source.

In both the equivalent circuits given above, the vertical resistance simulates the transmittance r_{21}. If r_{21} is negative, this resistance should also be negative or wires of output terminals should be reversed.

In conclusion, it is clear that in the general case it is impossible to describe the operation of any four-terminal circuit, working as the twoport in full ranges of its internal resistance increment changes, only by three-terminal circuit

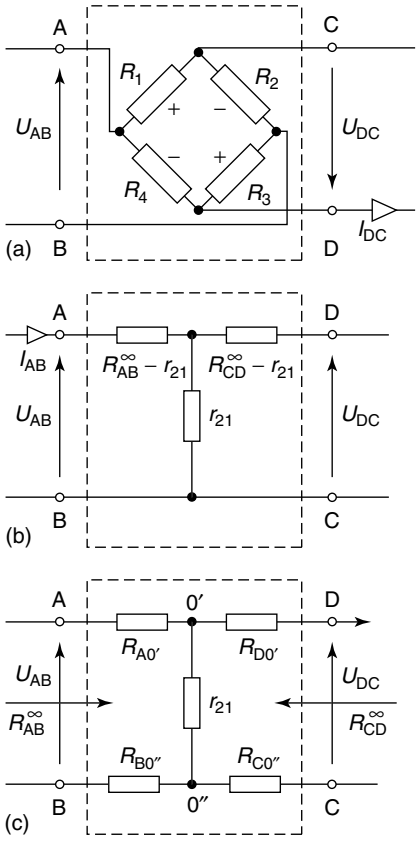

Figure 3. Bridge 4R as twoport and its equivalent T and 2T twoport circuits: (a) bridge as differently drawn twoport **X**, (b) twoport T circuit equivalent only for one sign of U_{DC} and of input and of output parameters of the bridge (the same elements of matrix $\mathbf{Z}_R$); (c) 2T symmetric twoport equivalent as circuit b) and of all terminal voltages.

of **T** or of **Π** type structure. Reversing of output lines is needed when output signal is crossing zero. Then the only proper circuit for simulating in such a case is the twoport X, that is, the four-arm bridge itself.

5 RELATIONS BETWEEN OPEN CIRCUIT TERMINAL PARAMETERS OF THE 4R BRIDGE

From (6a) and (7a) of terminal resistances $R_{\mathrm{AB}0}$, $R_{\mathrm{CD}0}$, of the balanced 4R bridge, it resulted that their product was also equal to the product of opposite arms' resistances as in the balance condition (2a) or (5a), then

$$R_{\mathrm{AB}0}R_{\mathrm{CD}0} = mn\ R_{10}^2 = R_{10}R_{30} = R_{20}R_{40} \tag{12}$$

The above expression could be called *extended balance condition of the four-arm bridge*.

Additionally, from (5b) results also the simple relationship for initial parameters of the balanced 4R bridge

$$\frac{R_{AB0}R_{CD0}}{\sum R_{i0}} = t_0' \tag{13}$$

Then they are related to each other and an arbitrary value cannot be assigned to all of them. Two above relationships could be applied to the syntheses of elements of the 4R bridge equivalent to the unknown network's inside structure, based only on the results of measurements performed on its terminals.

From the values of resistances R_{AB0}, R_{CD0}, ratios m and n of balance state resistances of the four-arm bridge could be directly obtained:

$$m = \frac{r_{CD0}\left(r_{AB0} - 1\right)}{r_{CD0} - 1} \tag{14a}$$

and

$$n = \frac{r_{AB0}\left(r_{CD0} - 1\right)}{r_{AB0} - 1} \tag{14b}$$

where: $r_{AB0} \equiv R_{AB0}/R_{10}$; $r_{CD0} \equiv R_{CD0}/R_{10}$.

When resistance R_{10} is given then single solutions $m > 0$, $n > 0$ are obtain when $r_{AB0} > 1$ and $r_{CD0} > 1$ or $r_{AB0} < 1$ and $r_{CD0} < 1$. If $r_{AB0} = 1$ and $r_{CD0} = 1$ then there is infinite number of solutions $n = m^{-1}$.

These values of m and n and condition (13) should be taken also as some kind of criterion to choose the structure of the equivalent circuit of the two ports 'black box'. Could it be considered only as a four arms resistance bridge or if some additional resistances in series to bridge nodes are needed.

It follows from (6) and (7) that relative increments $\varepsilon_{AB}^{\infty}$ and $\varepsilon_{CD}^{\infty}$ of the bridge resistances R_{AB}^{∞}, R_{CD}^{∞} are related to each other through the common expression $1 + \varepsilon_{\Sigma R}$, as follows

$$\begin{aligned}\frac{1+\varepsilon_{CD}^{\infty}}{1+\varepsilon_{AB}^{\infty}} &= \frac{\left(1+\varepsilon_{14}\right)\left(1+\varepsilon_{23}\right)}{\left(1+\varepsilon_{12}\right)\left(1+\varepsilon_{34}\right)} \\ &= \left(\frac{1+m}{1+n}\right)^2 \frac{\begin{matrix}\left(1+n+\varepsilon_1+n\varepsilon_4\right) \\ \times\left(1+n+\varepsilon_2+n\varepsilon_3\right)\end{matrix}}{\begin{matrix}\left(1+m+\varepsilon_1+m\varepsilon_2\right) \\ \times\left(1+m+\varepsilon_4+m\varepsilon_3\right)\end{matrix}}\end{aligned} \tag{14c}$$

Actual arm resistances or their relative increments of the unbalanced bridge are not easy to reveal from measurements of input–output terminal parameters. In the general case, the set of nonlinear equations should be solved.

6 BRIDGE OPEN CIRCUIT TERMINAL PARAMETERS' LINEARIZATION

Bridge open circuit terminal parameters are related practically linearly only for small values of independent resistance increments ε_i. It is possible to obtain the linear unbalance function $f'(\varepsilon_i)$ for large values of ε_i too. In this case, increments should simultaneously be at least in two bridge arms and they are not independent. It happens when increments of the sum of resistances of neighboring arms are equal to each other, that is, $\varepsilon_{12} = \varepsilon_{34}$, or $\varepsilon_{14} = \varepsilon_{23}$. In these cases, from (6b) and (9) or from (7b) and (9) the outcomes respectively are $\varepsilon_{AB}^{\infty} = \varepsilon_{12} = \varepsilon_{\Sigma R}$ or $\varepsilon_{CD}^{\infty} = \varepsilon_{14} = \varepsilon_{\Sigma R}$ and according to the definition (8), *generalized bridge linearity conditions* could be formulated as

$$\varepsilon_1 + m\varepsilon_2 = \varepsilon_4 + m\varepsilon_3 \tag{15a}$$

or

$$\varepsilon_1 + n\varepsilon_4 = \varepsilon_2 + n\varepsilon_3 \tag{15b}$$

With every one of them, formulas of bridge terminal parameters become simpler. If condition (15a) is valid, then it is possible to find from (5) that

$$r_{21} = R_{10}\frac{n}{1+n}(\varepsilon_1 - \varepsilon_4) \tag{16a}$$

and from (6a), that

$$\varepsilon_{AB}^{\infty} = \frac{\varepsilon_1 + m\varepsilon_2}{1+m} \tag{16b}$$

In this case, output resistance R_{CD}^{∞} depends nonlinearly on increments ε_i of arm resistances.

If condition (15b) is satisfied then

$$r_{21} = R_{10}\frac{m}{1+m}(\varepsilon_1 - \varepsilon_2) \tag{17a}$$

and

$$\varepsilon_{DC}^{\infty} = \frac{\varepsilon_1 + n\varepsilon_4}{1+n} \tag{17b}$$

and now open circuit input resistance R_{AB}^{∞} nonlinearly depends on increments ε_i.

In the literature, only some particular cases of general linearity conditions (15a) and (15b) can be found, for example, for $m = 1$, $n = 1$. If each of them is to be separately satisfied, at most three increments can be independent, and the fourth one results from others according to the above formulas. It is difficult to implement such cases in practice. Furthermore, in any pair of terminal parameter formulas (16a,b) or (17a,b) three increments ε_i are present and an additional equation is needed to find all of them separately from the terminal measurements. It is not so easy because the third terminal parameter (R_{CD}^{∞} or R_{AB}^{∞}) depends on ε_i

nonlinearly. It is much easier to obtain two pairs of increments related to each other within each pair. It can be done by respectively forming the relations to common measured variables. For example, stationary resistance connected in series to the arm resistance (or parallel to arm conductance) proportionally decreases its increment. In force or pressure sensors, it is also possible to place two strain gauges in points stressed differently but of known ratio. For condition (15a), it could be

$$\varepsilon_1 = m\varepsilon_3, \quad \varepsilon_2 = m\varepsilon_4 \tag{18a}$$

or

$$\varepsilon_1 = -m\varepsilon_2, \quad \varepsilon_4 = -m\varepsilon_3 \tag{18b}$$

It is obvious that the output signal is higher if increments of neighboring arms are of the opposite signs, that is, $sign\ \varepsilon_4 = -sign\ \varepsilon_1$ and $sign\ \varepsilon_2 = -sign\ \varepsilon_1$.

In (18a) conditions, positive values of increments ε_i are limited only by the permissible dissipate power of arm resistances or by maximum voltage of the current supply source. Increment $\varepsilon_{AB}^{\infty}$ of the input resistance R_{AB}^{∞} of the unloaded bridge is now given by the formula

$$\varepsilon_{AB}^{\infty} = \frac{\varepsilon_1 + \varepsilon_4}{1 + m} \tag{19}$$

From formulas (16a), (18a), and (19) it is now possible to find increments of any arm.

As an example of the (18b) case is the bridge built by connecting two resistance potentiometers with output on their slides. Both ends of these resistances limit extreme increments and are as follows: $|\varepsilon_i| \leq 1 + m$. In this bridge, the input resistance R_{AB}^{∞} of the open output is constant and the output resistance R_{CD} nonlinearly depends on out-of-balance increments, but it should be measured instead.

Linear relationships of the bridge transmittance r_{21} and one of its terminal resistances could be used in one variable measurement to correct the influence of another variable on the sensor set or to simultaneously obtain two variables measured indirectly on bridge terminals.

As an example of the first case, it is the use of the strain gauge bridge input resistance changes to compensate temperature influences on it.

7 TERMINAL PARAMETERS OF THE DC BRIDGE OF ANY SUPPLY SOURCE AND LOAD

If in the circuit there are branches that can be considered as internal or external diagonals connected to the 4R bridge diagonals of finite equivalent resistances of values comparable to terminal open circuit resistances, then bridge terminal parameters are different from the ones in matrix $\mathbf{Z_R}$ of 4R bridge alone. Here they are called *working terminal parameters*. Any four-terminal (4T) circuit operating as the X type twoport could be substituted by the equivalent 4R bridge of arm resistances and its terminal parameters dependent now on diagonal resistances. Current to voltage transmittance (or transfer resistance) r_{21} of unloaded bridge is replaced now by *working transmittance* $T \equiv U_{DC}/J$ and open circuit terminal resistances R_{AB}^{∞}, R_{CD}^{∞} – by working terminal resistances R_{AB}, R_{CD}.

From (6) of **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**, if $Z_i = R_i$, output voltage $U_{DC} = R_L I_{DC}$ is

$$U_{DC} = J\frac{R_1R_3 - R_2R_4}{M_{UJ}\left(R_i, R_G, R_L\right)} \equiv JT \tag{20}$$

where

$$T = \frac{R_1R_3 - R_2R_4}{M_{UJ}\left(R_i, R_G, R_L\right)} \tag{20a}$$

$$M_{UJ} = \Sigma R_i + \frac{1}{R_G}(R_1 + R_2)(R_3 + R_4) + \frac{1}{R_L}(R_1 + R_4)(R_2 + R_3) + \frac{A}{R_G R_L}$$

$$A = \Sigma R_i R_j R_k = R_1R_2(R_3 + R_4) + R_3R_4(R_1 + R_2) = \ldots$$

Numerators of the sensitivity T in (20) and then the balance condition are in all cases the same as before for the bridge without diagonals. The denominator is the function of bridge resistances R_i and of diagonal resistances R_G and R_L. When $R_G \to \infty$, the second and the last addend (component of the sum) in it become negligible. It is also the same with the third one and the last one of the addends if $R_L \to \infty$. For J = *constant*, and if also together $R_G \to \infty$ and $R_L \to \infty$ then output voltage U_{DC} is the highest one and given in (5) as U_{CD}^{∞}.

Similarly it is possible to find equivalent working terminal resistances R_{AB}, R_{CD}, of the bridge. After Karandeyev (1966) they are

$$R_{AB} = \frac{R_L(R_1 + R_2)(R_3 + R_4) + A}{R_L\Sigma R_i + (R_1 + R_4)(R_2 + R_3)} \tag{21}$$

and

$$R_{DC} = \frac{R_G(R_1 + R_4)(R_2 + R_3) + A}{R_G\Sigma R_i + (R_1 + R_2)(R_3 + R_4)} \tag{22}$$

Formulas (20) to (22) are quite complex. Then, in many cases it should be more useful in practice to apply equivalent terminal working parameters of the bridge only as functions of its matrix $\mathbf{Z_R}$ elements.

From (4) in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**, formulas of the output voltage of the bridge loaded by R_L and supplied by the current or voltage source of equivalent internal resistance R_G could be obtained. They are

$$U_{DC} = J\frac{R_G R_L\, r_{21}}{\left(R_G + R_{AB}^{\infty}\right)\left(R_L + R_{CD}^{\infty}\right) - r_{21}^2} \tag{23a}$$

or after putting $J = E R_G^{-1}$:

$$U_{DC} = E\frac{R_L\, r_{21}}{\left(R_G + R_{AB}^{\infty}\right)\left(R_L + R_{CD}^{\infty}\right) - r_{21}^2} \tag{23b}$$

Formula (23a) simplified when $R_G \to \infty$ or/and $R_L \to \infty$ and formula (23b) when $R_G = 0$ or/and $R_L \to \infty$.

The equivalent source resistance R_G and load R_L are generally constant in measuring circuits. They could be variable in equivalent circuits of four-terminal (4T) tested objects and sensors, for example, Hall devices – see Chapters 6 and 7 by Warsza (1980) in the monograph by Kobus *et al.*

After applying formulas of resistances R_{AB}^{∞}, R_{CD}^{∞} and putting $R_G \equiv gR_{10} \equiv k_G R_{AB0}$ and $R_L \equiv lR_{10} \equiv k_L R_{CD0}$ it is

$$U_{DC} = J\frac{r_{21}}{\left(1 + \dfrac{1+\varepsilon_{AB}^{\infty}}{k_G}\right)\left(1 + \dfrac{1+\varepsilon_{CD}^{\infty}}{k_L}\right) - \dfrac{r_{21}^2}{R_G R_L}} \tag{24a}$$

and

$$U_{DC} = \frac{E}{R_G}\frac{r_{21}}{\left(1 + \dfrac{1+\varepsilon_{AB}^{\infty}}{k_G}\right)\left(1 + \dfrac{1+\varepsilon_{CD}^{\infty}}{k_L}\right) - \dfrac{r_{21}^2}{R_G R_L}} \tag{24b}$$

Then the output voltage depends on resistances R_G, R_L, and also on their ratios to terminal resistances of the balanced bridge given by coefficients k_G, k_L.

Working terminal resistances of the bridge within both constant diagonal resistances are given by formulas:

$$R_{AB} = R_{AB}^{\infty} - \frac{r_{21}^2}{R_{CD}^{\infty} + R_L} = R_{AB0}\left[1 + \varepsilon_{AB}^{\infty} - \frac{r_{12}^2}{mn\ R_{10}^2\left(1 + \varepsilon_{CD}^{\infty} + k_L\right)}\right] \tag{25a,b}$$

and

$$R_{CD} = R_{CD}^{\infty} - \frac{r_{21}^2}{R_{AB}^{\infty} + R_G} = R_{CD0}\left[1 + \varepsilon_{CD}^{\infty} - \frac{r_{12}^2}{mnR_{10}^2\left(1 + \varepsilon_{AB}^{\infty} + k_G\right)}\right] \tag{26a,b}$$

These resistances in balance state are equal to R_{AB0} and to R_{CD0}. Out of the balance both of them decrease with the square of transmittance r_{21}, that is, independently of its sign. Each of them also decreases on the decreasing of the bridge opposite diagonal resistances R_L or R_G.

If $R_L = 0$ or $R_G = 0$, short circuit resistances obtained are R_{AB}^0, R_{CD}^0. After comparison of (25a) and (26a) for any value of r_{21} it is

$$\frac{R_{CD}^0}{R_{CD}^{\infty}} = \frac{R_{AB}^0}{R_{AB}^{\infty}} = 1 - \frac{r_{21}^2}{R_{CD}^{\infty} R_{AB}^{\infty}} \tag{27a}$$

or

$$R_{CD}^0 R_{AB}^{\infty} = R_{AB}^0 R_{CD}^{\infty} \tag{27b}$$

Then ratios of working open circuit and short circuit terminal resistances of both ports are equal and decrease with r_{21}^2.

When $R_L = 0$, from (23a) or (24a), and (25a) two forms of current I_{DC}^0 of the bridge shortened output could be found:

$$I_{DC}^0 = \frac{U_{DC}^{\infty}}{R_{CD}} = J\frac{R_G r_{21}}{\left(R_G + R_{AB}^{\infty}\right)R_{CD}^{\infty} - r_{21}^2} = \frac{J\ r_{21}}{R_{CD0}}\frac{1}{\left(1 + \dfrac{1+\varepsilon_{AB}^{\infty}}{k_G}\right)\left(1+\varepsilon_{CD}^{\infty}\right) - \dfrac{r_{21}^2}{k_G\ mn\ R_{10}^2}} \tag{28a,b}$$

All the above formulas became simpler, in particular, cases of ideal current or voltage supply sources and of the load resistance $R_L = 0$ or $R_L = \infty$. All such cases are given in Table 2.

The output voltage of any case could be expressed similarly as U_{DC}^{∞} in formula (5), that is:

$$U_{DC} \equiv T_0 f_{UJ}(\varepsilon_i) \tag{29}$$

where

$T_0 \equiv J(R_{10}R_{30})/M_{UJ0} = E/(R_G)(R_{10}R_{30})/M_{UJ0}$ – initial sensitivity of the working output voltage of the bridge supplied by source of internal resistance $R_G > 0$ and loaded by any $R_L > 0$,

$f_{UJ}(\varepsilon_i) \equiv \Delta L(\varepsilon_i)/1 + \varepsilon_{UJ}(\varepsilon_i)$ – unbalance function of the working output voltage of the bridge.

$\Delta L(\varepsilon_i) = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4$ – numerator of above function (as for 4R bridge alone),

$\varepsilon_{UJ}(\varepsilon_i) \equiv \Delta M_{UJ}(\varepsilon_i)/M_{UJ0}$ – relative increment of its denominator,

Table 2. Bridge 4R output signals and terminal resistances of any mode of DC supply and load as functions of its $\mathbf{Z_R}$ matrix elements.

No	Bridge output signals and terminal resistances	Symbol	General case	Particular cases		
			$U_{AB} = R^{\infty}_{AB} I_{AB} - r_{21} I_{DC}$ $U_{DC} = r_{21} I_{AB} - R^{\infty}_{CD} I_{DC}$	(a) Current supply $R_G \to \infty,\ I_{AB} = J$	(b) Voltage supply $R_G \to 0,\ U_{AB} = E$	(c) Source with resistance R_G, voltage U^{∞}_{CD} as output signal $R_L \to \infty,\ I_{DC} = 0$
1	**Output voltage:** $U_{DC} = J\dfrac{R_1R_3 - R_2R_4}{M_{UJ}} \equiv T_0\dfrac{\Delta L(\varepsilon_i)}{1+\Delta M_L(\varepsilon_i)}$	U_{DC}	$J\dfrac{R_G R_L r_{21}}{(R_G + R^{\infty}_{AB})(R_L + R^{\infty}_{CD}) - r^2_{21}} = \dfrac{Jr_{21}}{\left(1+\dfrac{1+\varepsilon^{\infty}_{AB}}{k_G}\right)\left(1+\dfrac{1+\varepsilon^{\infty}_{CD}}{k_L}\right) - \dfrac{r^2_{21}}{R_G R_L}}$	$J\dfrac{R_L r_{21}}{R_L + R_{CD0}(1+\varepsilon^{\infty}_{CD})} = J\dfrac{r_{21}}{1+\dfrac{1+\varepsilon^{\infty}_{CD}}{k_L}}$	$E\dfrac{R_L r_{21}}{R_{AB0}(1+\varepsilon^{\infty}_{AB})[R_L + R_{CD0}(1+\varepsilon^{\infty}_{CD})] - r^2_{21}} = \dfrac{Er_{21}}{R_{AB0}}\dfrac{1}{(1+\varepsilon^{\infty}_{AB})\left(1+\dfrac{1+\varepsilon^{\infty}_{CD}}{k_L}\right) - \dfrac{r^2_{21}}{R_{AB0}R_L}}$	$J\dfrac{R_G r_{21}}{R_G + R_{AB0}(1+\varepsilon^{\infty}_{AB})} = J\dfrac{r_{21}}{1+\dfrac{1+\varepsilon^{\infty}_{AB}}{k_G}}$
	Initial sensitivity $T_0 \equiv J\dfrac{R_{10}R_{30}}{M_{UJ0}} = \dfrac{E}{R_G}\dfrac{R_{10}R_{30}}{M_{UJ0}}$	T_0	$J\dfrac{R_{10}mn}{(1+m)(1+n)}\dfrac{k_G k_L}{(1+k_G)(1+k_L)} = E\dfrac{m}{(1+m)^2}\dfrac{1}{(1+k_G)}\dfrac{k_L}{(1+k_L)}$	$J\dfrac{R_{10}mn}{(1+m)(1+n)}\dfrac{k_L}{1+k_L}$	$E\dfrac{m}{(1+m)^2}\dfrac{k_L}{(1+k_L)}$	$T_0 = J\dfrac{R_{10}mn}{(1+m)(1+n)}\dfrac{k_G}{1+k_G} \times E\dfrac{m}{(1+m)^2}\dfrac{1}{(1+k_G)}$
	Denominator of U_{DC} in balance	M_{UJ0}	$R_{10}\left[1+n+\dfrac{n}{g}(1+m)\right]\left[1+m+\dfrac{m}{l}(1+n)\right]$	$R_{10}(1+n)\left[1+m+\dfrac{m}{l}(1+n)\right]$	$R_{10}[g(1+n)+n(1+m)] \times\left[1+m+\dfrac{m}{l}(1+n)\right]$	$R_{10}\left[1+n+\dfrac{n}{g}(1+m)\right](1+m)$
2	**Input resistance:** In balance: $R_{AB0} = R_{10}\dfrac{n(1+m)}{(1+n)}$	R_{AB}	$R^{\infty}_{AB}\left[1 - \dfrac{r^2_{21}}{R^{\infty}_{AB}(R^{\infty}_{CD} + R_L)}\right] = R_{AB0}(1+\varepsilon^{\infty}_{AB}) - \dfrac{r^2_{21}}{R_{CD0}(1+\varepsilon^{\infty}_{CD}+k_L)}$			$R_{AB0}(1+\varepsilon^{\infty}_{AB})$
3	**Output resistance:** In balance: $R_{CD0} = R_{10}\dfrac{m(1+n)}{(1+m)}$	R_{CD}	$R^{\infty}_{CD}\left[1 - \dfrac{r^2_{21}}{R^{\infty}_{CD}(R^{\infty}_{AB} + R_G)}\right] = R_{CD0}(1+\varepsilon^{\infty}_{CD}) - \dfrac{r^2_{21}}{R_{AB0}(1+\varepsilon^{\infty}_{AB}+k_G)}$	$R_{CD0}(1+\varepsilon^{\infty}_{CD})$	$R^{\infty}_{CD} - \dfrac{r^2_{21}}{R^{\infty}_{AB}} = R^{\infty}_{CD}\left(1 - \dfrac{r^2_{21}}{R^{\infty}_{CD}R^{\infty}_{AB}}\right)$	$R_{CD0}(1+\varepsilon^{\infty}_{CD}) - \dfrac{r^2_{21}}{R_{AB0}(1+\varepsilon^{\infty}_{AB}+k_G)}$
4	**Shorted output current:** $I^0_{DC} = \dfrac{U^{\infty}_{DC}}{R_{CD}}$	I^0_{DC}	$\dfrac{Jr_{21}}{R_{CD0}}\dfrac{1}{\left(1+\dfrac{1+\varepsilon^{\infty}_{AB}}{k_G}\right)(1+\varepsilon^{\infty}_{CD}) - \dfrac{r^2_{21}}{R_G R_{CD0}}}$	$J\dfrac{r_{21}}{R_{CD0}(1+\varepsilon^{\infty}_{CD})}$	$\dfrac{Er_{21}}{mnR_{10}}\dfrac{1}{(1+\varepsilon^{\infty}_{AB})(1+\varepsilon^{\infty}_{CD}) - \dfrac{r^2_{21}}{mnR^2_{10}}}$	$J\dfrac{R_G r_{21}}{(R_G + R^{\infty}_{AB})R^{\infty}_{CD} - r^2_{21}}$

Note: Some useful relations: $E = JR_G$; $R_G \equiv gR_{10}$; $R_L \equiv lR_{10}$; $\dfrac{R_G}{R_{AB0}} \equiv k_G$; $\dfrac{R_L}{R_{CD0}} \equiv k_L$; $r_{12} = \dfrac{R_{10}mn}{(1+m)(1+n)}$; $\Delta L(\varepsilon_i) = \varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4 + \varepsilon_1\varepsilon_3 - \varepsilon_2\varepsilon_4$; $\varepsilon^{\infty}_{AB}, \varepsilon^{\infty}_{CD}$ – see Table 1a and b.

$M_{UJ} \equiv M_{UJ0} + \Delta M_{UI}(\varepsilon_i)$ – denominator of (20) expressed as a sum of its balance value and the resultant increment (sum of 14 components dependent differently on products of 6 resistances increments of bridge with diagonals – 4T circuit) – see (8) and (9) of **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**.

The working output voltage initial sensitivity T_0 is

$$T_0 = JR_{10}\frac{mn}{(1+n)(1+m)}\frac{k_G}{1+k_G}\frac{k_L}{1+k_L} \tag{30a}$$

or

$$T_0 = E\frac{m}{(1+m)^2}\frac{k_L}{(1+k_G)(1+k_L)} \tag{30b}$$

If supplied current $J = constant$, initial sensitivity $T_0 \to T_0' = JR_{10}(mn/(1+m)(1+n))$ when: $k_G \to \infty$ and $k_L \to \infty$. It is the highest one: $T_{0\ max}' = JR_{10}$ is when $m \to \infty, n \to \infty$.

For $E = constant$ $T_0 \to T_0'' = E(m)/(1+m)^2$ when $k_G \to 0, k_L \to \infty$ and is independent of n. Maximal sensitivity $T_{0\ max}'' = 1/4E$ is now when $m = 1$. It is independent of n. Particular cases are in Table 2.

After applying formula (5b) to (30a) is obtained

$$T_0 = Jt_0'\frac{k_G}{1+k_G}\frac{k_L}{1+k_L} \tag{31}$$

where: $t_0' = (R_{AB0}R_{CD0}/\sum R_{i0})$ – initial sensitivity of transmittance r_{21}.

This is the extension of formula (13) to the case of the resistance bridge with additional diagonal resistances. It relates the bridge initial working sensitivity T_0 to the product of the current J, the initial open-circuit sensitivity t_0' and coefficients of diagonal branches – on the right side.

If changes of arm immitances are given as conductance increments, then it is possible to obtain linear relations of two bridge terminal parameters in dual circuit, that is, bridge supplied from the ideal voltage source E and the output signal as the short circuited output current I_{DC}^0.

More information about unbalanced DC bridges can be found in the literature given below. Measurements of two to four variables provided by the resistance bridge, supplied classically from one current source and unconventionally by two of them connected in parallel to opposite bridge arms, are discussed in detail in Warsza (2002).

1 INTRODUCTION TO COMPUTATIONAL INTELLIGENCE

Machine intelligence dates back to 1936, when Alan Turing proposed the idea of a universal mathematics machine, a theoretical concept in the mathematical theory of computability. Turing and Emil Post independently proved that determining the decidability of mathematical propositions is equivalent to asking what sort of sequences of a finite number of symbols can be recognized by an abstract machine with a finite set of instructions.

Such a mechanism is now known as a Turing machine (Turing Machine, 2004). Turing's research paper addressed the question of machine intelligence, assessing the arguments against the possibility of creating an intelligent computing machine and suggesting answers to those arguments; it proposed the Turing test as an empirical test of intelligence (Turing, 1950).

The Turing test, called the *imitation game* by Alan Turing, measures the performance of a machine against that of a human being. The machine and a human (A) are placed in two rooms. A third person, designated the interrogator, is in a room apart from both the machine and the human. The interrogator cannot see or speak directly to either A or the machine, communicating with them solely through some text messages or even a chat window. The task of the interrogator is to distinguish between the human and the computer on the basis of questions he or she may put to both of them over the terminals. If the interrogator cannot distinguish the machine from the human, then, Turing argues, the machine may be assumed to be intelligent. In the 1960s, computers failed to pass the Turing test because of the low processing speed of the computers.

The last few decades have seen a new era of artificial intelligence (AI) focusing on the principles, theoretical aspects, and design methodology of algorithms gleaned from nature. Examples are artificial neural networks inspired by mammalian neural systems, evolutionary computation inspired by natural selection in biology, simulated annealing inspired by thermodynamics principles, and swarm intelligence inspired by the collective behavior of insects or microorganisms, and so on, interacting locally with their environment, therein causing coherent functional global patterns to emerge. These techniques have found their way into solving real-world problems in science, business, technology, commerce, and also to a great extent in measuring systems.

Computational intelligence is a well-established paradigm, where new theories with a sound biological understanding have been evolving. The current experimental systems have many of the characteristics of biological computers (brains, in other words) and are beginning to be built

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

to perform a variety of tasks that are difficult or impossible to do with conventional computers.

To name a few, we have microwave ovens, washing machines, and digital cameras that can figure out on their own what settings to use to perform their tasks optimally; they have a reasoning capability, make intelligent decisions, and learn from experience.

As usual, defining computational intelligence is not an easy task. In a nutshell, which becomes quite apparent in light of the current research pursuits, the area is heterogeneous with a combination of such technologies as neural networks, fuzzy systems, evolutionary computation, swarm intelligence, and probabilistic reasoning.

The recent trend is to integrate different components to take advantage of complementary features and to develop a synergistic system. Hybrid architectures like neuro-fuzzy systems, evolutionary-fuzzy systems, evolutionary-neural networks, evolutionary-neuro-fuzzy systems, and so on, are widely applied for real-world problem solving. In the following sections, the main functional components of computational intelligence are introduced along with their key advantages and application domains.

2 ARTIFICIAL NEURAL NETWORKS

Artificial neural networks (ANN) have been developed as generalizations of mathematical models of biological nervous systems.

In a simplified mathematical model of the neuron, the effects of the synapses are represented by connection weights that modulate the effect of the associated input signals, and the nonlinear characteristic exhibited by neurons is represented by a transfer function, which is usually the sigmoid, Gaussian, trigonometric function, and so on.

The neuron impulse is then computed as the weighted sum of the input signals, being transformed by the transfer function.

The learning capability of an artificial neuron is achieved by adjusting the weights in accordance to the chosen learning algorithm. Most applications of neural networks fall into the following categories:

- Prediction: Use input values to predict some output
- Classification: Use input values to determine the classification
- Data Association: Like classification, but it also recognizes data that contains errors
- Data conceptualization: Analyze the inputs so that grouping relationships can be inferred.

A typical multilayered neural network and an artificial neuron are illustrated in Figure 1. Each neuron is characterized by an activity level (representing the state of polarization of a neuron), an output value (representing the firing rate of the neuron), a set of input connections (representing synapses on the cell and its dendrite), a bias value (representing an internal resting level of the neuron), and a set of output connections (representing a neuron's axonal projections). Each of these aspects of the unit is represented mathematically by real numbers. Thus, each connection has an associated weight (synaptic strength), which determines the effect of the incoming input on the activation level of the unit. The weights may be positive or negative. Referring to Figure 1, the signal flow from inputs $x_1, \ldots, x_n$ is considered to be unidirectional, indicated by arrows, as is a neuron's output signal flow (O). The neuron output signal O is given by the following relationship:

$$O = f(net) = f\left(\sum_{j=1}^{n} w_j x_j\right) \tag{1}$$

where w_j is the weight vector and the function *f(net) i*s referred to as an *activation (transfer) function*. The variable net is defined as a scalar product of the weight and input vectors

$$net = w^{\mathrm{T}} x = w_1 x_1 + \cdots + w_n x_n \tag{2}$$

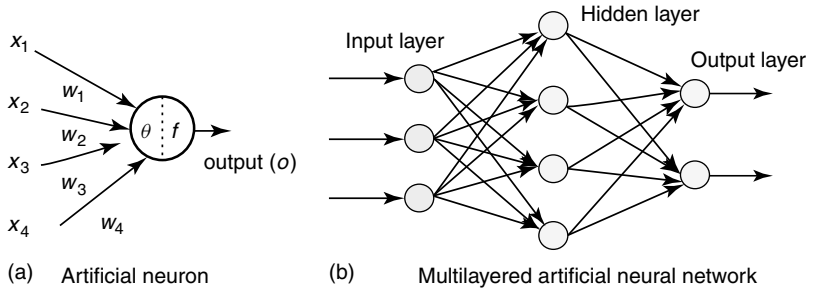

Figure 1. Architecture of an artificial neuron and a multilayered neural network.

where T is the transpose of a matrix and in the simplest case the output value O is computed as

$$O = f(net) = \begin{cases} 1 & if\ w^{\mathrm{T}}x \geq \theta \\ 0 & otherwise \end{cases} \quad (3)$$

where θ is called the *threshold level*, and this type of node is called a *linear threshold unit*.

3 NEURAL NETWORK ARCHITECTURES

The behavior of the neural network depends largely on the interaction between the different neurons. The basic architecture consists of three types of neuron layers:

1. Input
2. Hidden
3. Output.

In feed-forward networks, the signal flow is from input to output units, strictly in a feed-forward direction. The data processing can extend over multiple (layers of) units, but no feedback connections are present, that is, connections extending from outputs of units to inputs of units in the same layer or previous layers.

Recurrent networks contain feedback connections. Contrary to feed-forward networks, the dynamical properties of the network are important. In some cases, the activation values of the units undergo a relaxation process such that the network will evolve into a stable state in which these activations do not change anymore. In other applications, the changes of the activation values of the output neurons are significant, such that the dynamical behavior constitutes the output of the network.

There are several other neural network architectures (Elman network, adaptive resonance theory maps, competitive networks, etc.) depending on the properties and requirement of the application. The reader may refer to Bishop (1995) for an extensive overview of the different neural network architectures and learning algorithms.

A neural network has to be configured such that the application of a set of inputs produces the desired set of outputs. Various methods to set the strengths of the connections exist. One way is to set the weights explicitly, using a priori knowledge.

Another way is to train the neural network by feeding it, teaching patterns and letting it change its weights according to some learning rule.

The learning situations in neural networks may be classified into three distinct sorts of learning:

1. Supervised
2. Unsupervised
3. Reinforcement.

In supervised learning, an input vector is presented at the inputs together with a set of desired responses, one for each node, at the output layer. A forward pass is done and the errors or discrepancies, between the desired and actual response for each node in the output layer, are found. These are then used to determine weight changes in the net according to the prevailing learning rule.

The term 'supervised' originates from the fact that the desired signals on individual output nodes are provided by an external teacher. The best-known examples of this technique occur in the backpropagation algorithm, the delta rule, and perceptron rule.

In unsupervised learning (or self-organization), a (output) unit is trained to respond to clusters of pattern within the input. In this paradigm, the system is supposed to discover statistically salient features of the input population (Kohonen, 1988). Unlike the supervised learning paradigm, there is no a priori set of categories into which the patterns are to be classified; rather, the system must develop its own representation of the input stimuli.

Reinforcement learning is learning what to do – how to map situations to actions – so as to maximize a numerical reward signal. The learner is not told which actions to take, as in most forms of machine learning, but instead must discover which actions yield the most reward by trying them. In the most interesting and challenging cases, actions may affect not only the immediate reward but also the next situation and, through that, all subsequent rewards. These two characteristics, trial-and-error search and delayed reward, are the two most important distinguishing features of reinforcement learning.

4 FUZZY LOGIC

Zadeh (1965) introduced the concept of fuzzy logic to represent vagueness in linguistics and to further implement and express human knowledge and inference capability in a natural way. Fuzzy logic starts with the concept of a fuzzy set.

A fuzzy set is a set without a crisp, clearly defined boundary. It can contain elements with only a partial degree of membership.

A Membership Function (MF) is a curve that defines how each point in the input space is mapped to a membership value (or degree of membership) between 0 and 1. The input space is sometimes referred to as the *universe of discourse*.

Let X be the universe of discourse and x be a generic element of X. A classical set A is defined as a collection of elements or objects $x \in X$, such that each x can either belong to or not belong to the set A.

By defining a characteristic function (or membership function) on each element x in X, a classical set A can

be represented by a set of ordered pairs $(x, 0)$ or $(x, 1)$, where 1 indicates membership and 0, nonmembership.

Unlike the conventional set mentioned above, the fuzzy set expresses the degree to which an element belongs to a set. Hence, the characteristic function of a fuzzy set is allowed to have a value between 0 and 1, denoting the degree of membership of an element in a given set. If X is a collection of objects denoted generically by x, then a fuzzy set A in X is defined as a set of ordered pairs:

$$A = \{(x, \mu_A(x)) | x \in X\} \tag{4}$$

$\mu_A(x)$ is called the *membership function* of linguistic variable x in A, which maps X to the membership space M, $M = [0,1]$, where M contains only two points 0 and 1, A is crisp and μ_A is identical to the characteristic function of a crisp set.

Triangular and trapezoidal membership functions are the simplest membership functions, formed using straight lines. Some of the other shapes are Gaussian, generalized bell, sigmoidal, and polynomial-based curves. Figure 2 illustrates the shapes of two commonly used MFs. The most important thing to realize about fuzzy logical reasoning is the fact that it is a superset of standard Boolean logic.

4.1 Fuzzy logic operators

It is interesting to note the correspondence between two-valued and multivalued logic operations for the **AND, OR**, and **NOT** logical operators.

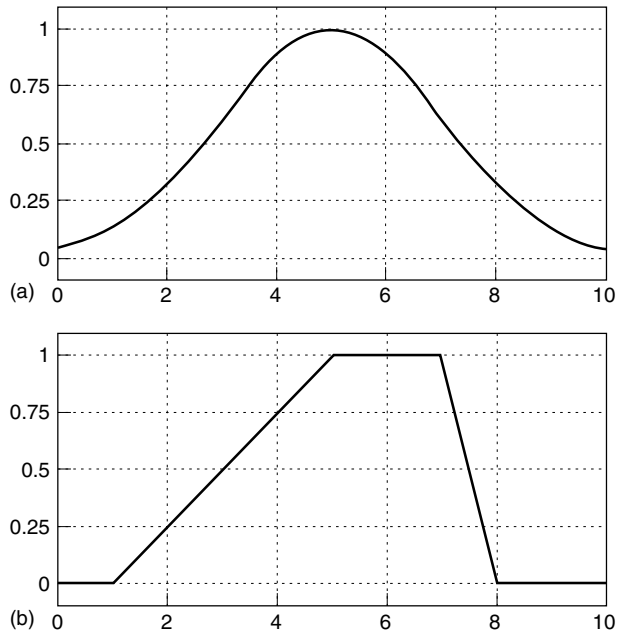

Figure 2. Membership functions; (a) Gaussian and (b) trapezoidal.

It is possible to resolve the statement A **AND** B, where A and B are limited to the range (0, 1) by using the operator minimum (A, B). Using the same reasoning, we can replace the **OR** operation with the maximum operator, so that A **OR** B becomes equivalent to maximum (A, B). Finally, the operation **NOT** A becomes equivalent to the operation 1 – A.

In fuzzy logic terms, these are popularly known as fuzzy intersection or conjunction (AND), fuzzy union or disjunction (OR), and fuzzy complement (NOT). The intersection of two fuzzy sets A and B is specified, in general, by a binary mapping T, which aggregates two membership functions as follows.

$$\mu_{A \cap B}(x) = T(\mu_A(x), \mu_B(x)) \tag{5}$$

The fuzzy intersection operator is usually referred to as *T-norm (Triangular norm) operator*. The fuzzy union operator is specified in general by a binary mapping S.

$$\mu_{A \cup B}(x) = S(\mu_A(x), \mu_B(x)) \tag{6}$$

This class of fuzzy union operators are often referred to as *T-conorm (S-norm) operators*.

5 IF-THEN RULES AND FUZZY INFERENCE SYSTEMS

The fuzzy rule base is characterized in the form of *if-then* rules in which preconditions and consequents involve linguistic variables. The collection of these fuzzy rules forms the rule base for the fuzzy logic system. Owing to their concise form, fuzzy *if-then* rules are often employed to capture the imprecise modes of reasoning that play an essential role in the human ability to make decisions in an environment of uncertainty and imprecision. A single fuzzy *if-then* rule assumes the form

$$if\ x \text{ is } A\ then\ y \text{ is } B$$

where A and B are linguistic values defined by fuzzy sets in the ranges (universes of discourse) X and Y, respectively.

The *if* part of the rule 'x is A' is called the *antecedent (precondition)* or premise, while the *then* part of the rule 'y is B' is called the *consequent* or conclusion. Interpreting an *if-then* rule involves evaluating the antecedent (*fuzzification of* the input and applying any necessary *fuzzy operators*) and then applying that result to the consequent (known as *implication*). For rules with multiple antecedents, all parts of the antecedent are calculated simultaneously and resolved to a single value using the logical operators. Similarly, all the consequents (rules with multiple consequents)

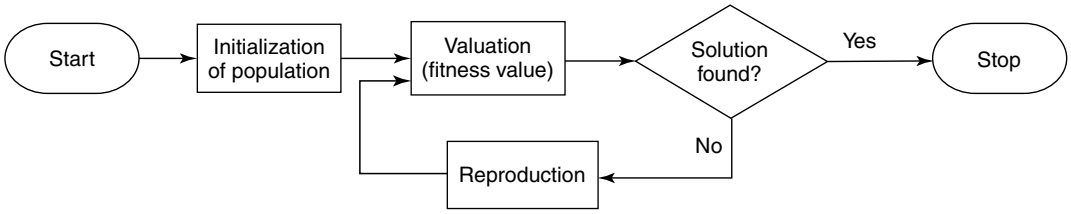

Figure 3. Flowchart of genetic algorithm iteration.

are affected equally by the result of the antecedent. The consequent specifies a fuzzy set be assigned to the output. The implication function then modifies that fuzzy set to the degree specified by the antecedent. For multiple rules, the output of each rule is a fuzzy set. The output fuzzy sets for each rule are then aggregated into a single output fuzzy set. Finally, the resulting set is defuzzified, or resolved, to a single number.

The defuzzification interface is a mapping from a space of fuzzy actions defined over an output universe of discourse into a space of nonfuzzy actions, because the output from the inference engine is usually a fuzzy set, while for most practical applications, crisp values are often required.

The three commonly applied defuzzification techniques are max-criterion, center-of-gravity, and the mean-of-maxima. The max-criterion is the simplest of these three to implement. It produces the point at which the possibility distribution of the action reaches a maximum value.

The reader can refer to Nguyen and Walker (1999) for more information related to fuzzy systems. It is typically advantageous if the fuzzy rule base is adaptive to a certain application. The fuzzy rule base is usually constructed manually or by automatic adaptation by some learning techniques using evolutionary algorithms and/or neural network learning methods (Abraham, 2001).

6 EVOLUTIONARY ALGORITHMS

Evolutionary algorithms (EA) are adaptive methods, which may be used to solve search and optimization problems, based on the genetic processes of biological organisms. Over many generations, natural populations evolve according to the principles of natural selection and 'survival of the fittest', first clearly stated by Charles Darwin in his work '*The Origin of Species*'. By mimicking this process, evolutionary algorithms are able to 'evolve' solutions to real-world problems, provided they have been suitably encoded (Fogel, 1999).

Usually grouped under the term evolutionary algorithms or evolutionary computation, we find the domains of genetic algorithms (GA) (Holland, 1975), (Goldberg, 1989); evolution strategies (Rechenberg, 1973), (Schwefel, 1977); evolutionary programming (Fogel, Owens and Walsh, 1967); genetic programming (Koza, 1992); and learning classifier systems. They all share a common conceptual base of simulating the evolution of *individual* structures via processes of *selection, mutation*, and *reproduction*. The processes depend on the perceived performance of the individual structures as defined by the environment (problem).

EA's deal with parameters of finite length, which are coded using a finite alphabet, rather than directly manipulating the parameters themselves. This means that the search is unconstrained neither by the continuity of the function under investigation nor by the existence of a derivative function. Figure 3 depicts the functional block diagram of a genetic algorithm, and the various aspects are discussed below. It is assumed that a potential solution to a problem may be represented as a set of parameters. These parameters (known as *genes*) are joined together to form a string of values (known as a *chromosome*). A gene (also referred to as a *feature, character*, or *detector*) refers to a specific attribute that is encoded in the chromosome. The particular values that the genes can take are called its *alleles*.

Encoding issues deal with representing a solution in a chromosome and, unfortunately, no one technique works best for all problems. A fitness function must be devised for each problem to be solved.

Given a particular chromosome, the fitness function returns a single numerical fitness or figure of merit, which will determine the ability of the individual that the chromosome represents.

Reproduction is the second critical attribute of GAs, where two individuals selected from the population are allowed to mate to produce an offspring, which will comprise the next generation. Having selected the parents, the offsprings are generated, typically using the mechanisms of crossover and mutation.

Selection is the survival of the fittest within GAs. It determines which individuals are to survive to the next generation. The selection phase consists of three parts.

The first part involves determination of the individual's fitness by the fitness function. A fitness function must be devised for each problem; given a particular chromosome, the fitness function returns a single numerical fitness value,

which is proportional to the ability, or utility, of the individual represented by that chromosome.

The second part involves converting the fitness function into an expected value, followed by the last part where the expected value is then converted to a discrete number of offspring.

Some of the commonly used selection techniques are roulette wheel and stochastic universal sampling. If the GA has been correctly implemented, the population will evolve over successive generations so that the fitness of the best and the average individual in each generation increases toward the global optimum.

7 INTELLIGENT PARADIGMS

7.1 Probabilistic computing

Probabilistic models are viewed as being similar to that of a game; actions are based on expected outcomes. The center of interest moves from the deterministic to probabilistic models using statistical estimations and predictions.

In the probabilistic modeling process, risk means uncertainty for which the probability distribution is known. Therefore, risk assessment means a study to determine the outcomes of decisions along with their probabilities. Decision makers often face a severe lack of definite information. Probability assessment quantifies the information gap between what is known and what needs to be known for an optimal decision. Probabilistic models are used for protection against adverse uncertainty and exploitation of propitious uncertainty (Pearl, 1997).

A good example is the probabilistic neural network (Bayesian learning) in which probability is used to represent uncertainty about the relationship being learned. Before we have seen any data, our *prior* opinions about what the true relationship might be can be expressed in a probability distribution over the network weights that define this relationship.

After we look at the data, our revised opinions are captured by a *posterior* distribution over network weights. Network weights that seemed plausible before, but which do not match the data very well, will now be seen as being much less likely, while the probability for values of the weights that do fit the data well will have increased. Typically, the purpose of training is to make predictions for future cases in which only the inputs to the network are known. The result of conventional network training is a single set of weights that can be used to make such predictions.

7.2 Swarm intelligence

Swarm intelligence is aimed at collective behavior of intelligent agents in decentralized systems. Although there is typically no centralized control dictating the behavior of the agents, local interactions among the agents often cause a global pattern to emerge (Eberhart, Shi and Kennedy, 2001).

Most of the basic ideas are derived from the real swarms in nature, which includes ant colonies, bird flocking, honeybees, bacteria and microorganisms, and so on. Ant Colony Optimization (ACO) has already been applied successfully to solve several engineering optimization problems.

Swarm models are population based and the population is initialized with a population of potential solutions. These individuals are then manipulated (optimized) over several iterations using several heuristics inspired from the social behavior of insects in an effort to find the optimal solution.

Ant colony algorithms are inspired by the behavior of natural ant colonies, in the sense that they solve their problems by multiagent cooperation using indirect communication through modifications in the environment. Ants release a certain amount of pheromone (hormone) while walking, and each ant prefers (probabilistically) to follow a direction that is rich in pheromone. This simple behavior explains why ants are able to adjust to changes in the environment, such as optimizing the shortest path to a food source or a nest. In ACO, ants use information collected during past simulations to direct their search and this information is available and modified through the environment. Recently, ACO algorithms have also been used for clustering data sets.

8 HYBRID INTELLIGENT SYSTEMS

Several adaptive hybrid intelligent systems have, in recent years, been developed for model expertise, image, and video segmentation techniques, process control, mechatronics, robotics, complicated automation tasks and so on.

Many of these approaches use the combination of different knowledge representation schemes, decision-making models, and learning strategies to solve a computational task. This integration aims at overcoming limitations of individual techniques through hybridization or fusion of various techniques.

These ideas have led to the emergence of several different kinds of intelligent system architectures. Most of the current Hybrid Intelligent Systems (HIS) consist of three essential paradigms: artificial neural networks, fuzzy inference systems, and global optimization algorithms (example, evolutionary algorithms). Nevertheless, HIS is an

Table 1. Hybrid intelligent system basic ingredients.

Methodology	Advantage
Artificial neural networks	Adaptation, learning, and approximation
Fuzzy logic	Approximate reasoning
Global optimization algorithms	Derivative free optimization

open, instead of conservative, concept, that is, it is evolving those relevant techniques together with the important advances in other new computing methods. Table 1 lists the three principal ingredients together with their advantages (Abraham, 2002).

Experience has shown that it is crucial for the design of HIS to primarily focus on the integration and interaction of different techniques rather than merge different methods to create ever-new techniques. Techniques already well understood should be applied to solve specific domain problems within the system. Their weakness must be addressed by combining them with complementary methods.

Neural networks offer a highly structured architecture with learning and generalization capabilities. The generalization ability for new inputs is then based on the inherent algebraic structure of the neural network. However, it is very hard to incorporate human a priori knowledge into a neural network. This is mainly due to the fact that the connectionist paradigm gains most of its strength from a distributed knowledge representation.

In contrast, fuzzy inference systems exhibit complementary characteristics, offering a very powerful framework for approximate reasoning as it attempts to model the human reasoning process at a cognitive level. Fuzzy systems acquire knowledge from domain experts and this is encoded within the algorithm in terms of the set of *if-then* rules. Fuzzy systems employ this rule-based approach and interpolative reasoning to respond to new inputs. The incorporation and interpretation of knowledge is straightforward, whereas learning and adaptation constitute major problems.

Global optimization is the task of finding the absolutely best set of parameters to optimize an objective function. In general, it may be possible to have solutions that are locally optimal but not globally optimal. Evolutionary computing (EC) works by simulating evolution on a computer. Such techniques could be easily used to optimize neural networks, fuzzy inference systems, and other problems.

Owing to the complementary features and strengths of different systems, the trend in the design of hybrid system is to merge different techniques into a more powerful integrated system to overcome their individual weaknesses.

9 MODELS OF HYBRID SYSTEMS

The various HIS architectures could be broadly classified into four different categories based on the systems overall architecture:

1. Stand alone
2. Transformational
3. Hierarchical hybrid
4. Integrated hybrid.

9.1 Stand-alone architecture

Stand-alone models of HIS applications consist of independent software components, which do not interact in any way. Developing stand-alone systems can have several purposes. First, they provide direct means of comparing the problem-solving capabilities of different techniques with reference to a certain application. Running different techniques in a parallel environment permits a loose approximation of integration. Stand-alone models are often used to develop a quick initial prototype while a more time-consuming application is developed. Some of the benefits are simplicity and ease of development using commercially available software packages.

9.2 Transformational hybrid architecture

In a transformational hybrid model, the system begins as one type and ends up as the other. Determining which technique is used for development and which is used for delivery is based on the desirable features that the technique offers. Expert systems and neural networks have proven to be useful transformational models. Variously, either the expert system is incapable of adequately solving the problem, or it requires the speed, adaptability, and robustness of neural network. Knowledge from the expert system is used to set the initial conditions and training set for neural network. Transformational hybrid models are often quick to develop and ultimately require maintenance on only one system. Most of the developed models are just application oriented.

9.3 Hierarchical hybrid architectures

The architecture is built in a hierarchical fashion, associating a different functionality with each layer. The overall functioning of the model will depend on the correct functioning of all the layers. A possible error in one of the layers will directly affect the desired output.

9.4 Integrated hybrid architectures

These models include systems, which combine different techniques into one single computational model. They share data structures and knowledge representations. Another approach is to put the various techniques on a side-by-side basis and focus on their interaction in the problem-solving task. This method might allow integrating alternative techniques and exploiting their mutuality. The benefits of fused architecture include robustness, improved performance, and increased problem-solving capabilities. Finally, fully integrated models can provide a full range of capabilities such as adaptation, generalization, noise tolerance, and justification. Fused systems have limitations caused by the increased complexity of the intermodule interactions, and specifying, designing, and building fully integrated models is complex.

10 SUMMARY

Artificial intelligence is the study of intelligent behavior. Its ultimate goal is a theory of intelligence that accounts for the behavior of naturally occurring intelligent entities, and this guides the creation of artificial entities capable of intelligent behavior. The stagnation of artificial intelligence during the 1970s and 1980s does not have much bearing on the likelihood of artificial intelligence to succeed in the future, since we know that the cause responsible for stagnation (mainly due to insufficient hardware resources) is no longer present. More detail of the various methods introduced here is found in **Article 129, Artificial Neural Networks, Volume 2**; **Article 130, Rule-based Expert Systems, Volume 2**; and **Article 131, Evolutionary Computation, Volume 2**.

1 INTRODUCTION TO ARTIFICIAL NEURAL NETWORKS

A general introduction to artificial intelligence methods of measuring signal processing is given in **Article 128, Nature and Scope of AI Techniques, Volume 2**.

The human brain provides proof of the existence of massive neural networks that can succeed at those cognitive, perceptual, and control tasks in which humans are successful. The brain is capable of computationally demanding perceptual acts (e.g. recognition of faces, speech) and control activities (e.g. body movements and body functions). The advantage of the brain is its effective use of massive parallelism, the highly parallel computing structure, and the imprecise information-processing capability. The human brain is a collection of more than 10 billion interconnected neurons. Each neuron is a cell (Figure 1) that uses biochemical reactions to receive, process, and transmit information.

Treelike networks of nerve fibers called *dendrites* are connected to the cell body or soma, where the cell nucleus is located. Extending from the cell body is a single long fiber called the *axon*, which eventually branches into strands and substrands, and are connected to other neurons through synaptic terminals or synapses.

The transmission of signals from one neuron to another at synapses is a complex chemical process in which specific transmitter substances are released from the sending end of the junction. The effect is to raise or lower the electrical potential inside the body of the receiving cell. If the potential reaches a threshold, a pulse is sent down the axon and the cell is 'fired'.

Artificial neural networks (ANN) have been developed as generalizations of mathematical models of biological nervous systems. A first wave of interest in neural networks (also known as *connectionist models* or *parallel distributed processing*) emerged after the introduction of simplified neurons by McCulloch and Pitts (1943).

The basic processing elements of neural networks are called *artificial neurons*, or *simply neurons* or *nodes*. In a simplified mathematical model of the neuron, the effects of the synapses are represented by connection weights that modulate the effect of the associated input signals, and the nonlinear characteristic exhibited by neurons is represented by a transfer function. The neuron impulse is then computed as the weighted sum of the input signals, transformed by the transfer function. The learning capability of an artificial neuron is achieved by adjusting the weights in accordance to the chosen learning algorithm.

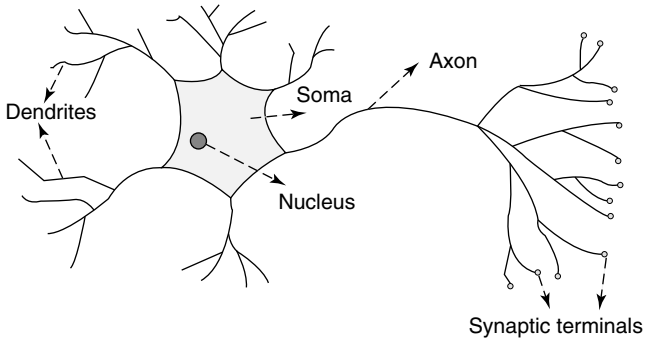

Figure 1. Mammalian neuron.

A typical artificial neuron and the modeling of a multilayered neural network are illustrated in Figure 2. Referring to Figure 2, the signal flow from inputs $x_1, \ldots, x_n$ is considered to be unidirectional, which are indicated by arrows, as is a neuron's output signal flow (O). The neuron output signal O is given by the following relationship:

$$O = f(net) = f\left(\sum_{j=1}^{n} w_j x_j\right) \tag{1}$$

where w_j is the weight vector, and the function *f(net)* is referred to as an activation (transfer) function. The variable *net* is defined as a scalar product of the weight and input vectors,

$$net = w^{\mathrm{T}} x = w_1 x_1 + \cdots + w_n x_n \tag{2}$$

where T is the transpose of a matrix, and, in the simplest case, the output value O is computed as

$$O = f(net) = \begin{cases} 1 & if\ w^{\mathrm{T}} x \geqslant \theta \\ 0 & otherwise \end{cases} \tag{3}$$

where θ is called the threshold level; and this type of node is called a *linear threshold unit*.

2 NEURAL NETWORK ARCHITECTURES

The basic architecture consists of three types of neuron layers: input, hidden, and output layers. In feed-forward networks, the signal flow is from input to output units, strictly in a feed-forward direction. The data processing can extend over multiple (layers of) units, but no feedback connections are present. Recurrent networks contain feedback connections. Contrary to feed-forward networks, the dynamical properties of the network are important. In some cases, the activation values of the units undergo a relaxation process such that the network will evolve to a stable state in which these activations do not change anymore. In other applications, the changes of the activation values of the output neurons are significant, such that the dynamical behavior constitutes the output of the network. There are several other neural network architectures (Elman network, adaptive resonance theory maps, competitive networks, etc.), depending on the properties and requirement of the application. The reader can refer to Bishop (1995) for an extensive overview of the different neural network architectures and learning algorithms.

A neural network has to be configured such that the application of a set of inputs produces the desired set of outputs. Various methods to set the strengths of the connections exist. One way is to set the weights explicitly, using a priori knowledge. Another way is to train the neural network by feeding it teaching patterns and letting it change its weights according to some learning rule. The learning situations in neural networks may be classified into three distinct sorts. These are supervised learning, unsupervised learning, and reinforcement learning. In supervised learning, an input vector is presented at the inputs together with a set of desired responses, one for each node, at the output layer. A forward pass is done, and the errors or discrepancies between the desired and actual response for each node in the output layer are found. These are then used to determine weight changes in the net according to the prevailing learning rule. The term *supervised* originates from the fact that the desired signals on individual output nodes are provided by an external teacher.

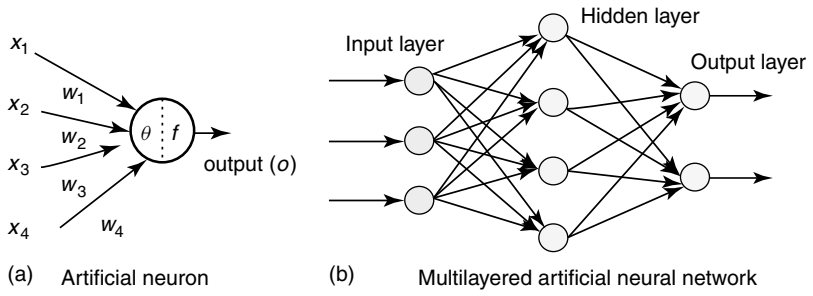

Figure 2. Architecture of an artificial neuron and a multilayered neural network.

The best-known examples of this technique occur in the backpropagation algorithm, the delta rule, and the perceptron rule. In unsupervised learning (or self-organization), a (output) unit is trained to respond to clusters of pattern within the input. In this paradigm, the system is supposed to discover statistically salient features of the input population. Unlike the supervised learning paradigm, there is no a priori set of categories into which the patterns are to be classified; rather, the system must develop its own representation of the input stimuli. Reinforcement learning is learning what to do – how to map situations to actions – so as to maximize a numerical reward signal. The learner is not told which actions to take, as in most forms of machine learning, but instead must discover which actions yield the most reward by trying them. In the most interesting and challenging cases, actions may affect not only the immediate reward, but also the next situation and, through that, all subsequent rewards. These two characteristics, trial-and-error search and delayed reward are the two most important distinguishing features of reinforcement learning.

3 NEURAL NETWORK LEARNING

3.1 Hebbian learning

The learning paradigms discussed above result in an adjustment of the weights of the connections between units, according to some modification rule. Perhaps the most influential work in connectionism's history is the contribution of Hebb (1949), where he presented a theory of behavior based, as much as possible, on the physiology of the nervous system.

The most important concept to emerge from Hebb's work was his formal statement (known as *Hebb's postulate*) of how learning could occur. Learning was based on the modification of synaptic connections between neurons. Specifically, when an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased. The principles underlying this statement have become known as *Hebbian Learning*. Virtually, most of the neural network learning techniques can be considered as a variant of the Hebbian learning rule. The basic idea is that if two neurons are active simultaneously, their interconnection must be strengthened. If we consider a single layer net, one of the interconnected neurons will be an input unit and one an output unit. If the data are represented in bipolar form, it is easy to express the desired weight update as

$$w_i(new) = w_i(old) + x_i o,$$

where o is the desired output for

$$i = 1 \text{ to } n(\text{inputs}).$$

Unfortunately, plain Hebbian learning continually strengthens its weights without bound (unless the input data is properly normalized).

3.2 Perceptron learning rule

The perceptron is a single layer neural network whose weights and biases could be trained to produce a correct target vector when presented with the corresponding input vector. The training technique used is called the *perceptron-learning rule*. Perceptrons are especially suited for simple problems in pattern classification.

Suppose we have a set of learning samples consisting of an input vector x and a desired output $d(k)$. For a classification task, the $d(k)$ is usually $+1$ or -1. The perceptron-learning rule is very simple and can be stated as follows:

1. Start with random weights for the connections.
2. Select an input vector x from the set of training samples.
3. If output $y_k \neq d(k)$ (the perceptron gives an incorrect response), modify all connections w_i according to: $\delta w_i = \eta(d_k - y_k)x_i$; ($\eta =$ learning rate).
4. Go back to step 2.

Note that the procedure is very similar to the Hebb rule; the only difference is that when the network responds correctly, no connection weights are modified.

4 BACKPROPAGATION LEARNING

The simple perceptron is just able to handle linearly separable or linearly independent problems. By taking the partial derivative of the error of the network with respect to each weight, we will learn a little about the direction the error of the network is moving.

In fact, if we take the negative of this derivative (i.e. the rate change of the error as the value of the weight increases) and then proceed to add it to the weight, the error will decrease until it reaches a local minima. This makes sense because if the derivative is positive, this tells us that the error is increasing when the weight is increasing. The obvious thing to do then is to add a negative value to the weight and vice versa if the derivative is negative. Because the taking of these partial derivatives and then applying them to each of the weights takes place, starting from the output layer to hidden layer weights, then the hidden layer to input layer weights (as it turns out, this is necessary since

changing these set of weights requires that we know the partial derivatives calculated in the layer downstream), this algorithm has been called the *backpropagation algorithm*.

A neural network can be trained in two different modes: online and batch modes. The number of weight updates of the two methods for the same number of data presentations is very different.

The online method weight updates are computed for each input data sample, and the weights are modified after each sample.

An alternative solution is to compute the weight update for each input sample, but store these values during one pass through the training set which is called an *epoch*.

At the end of the epoch, all the contributions are added, and only then the weights will be updated with the composite value. This method adapts the weights with a cumulative weight update, so it will follow the gradient more closely. It is called the *batch-training mode*.

Training basically involves feeding training samples as input vectors through a neural network, calculating the error of the output layer, and then adjusting the weights of the network to minimize the error.

The average of all the squared errors (E) for the outputs is computed to make the derivative easier. Once the error is computed, the weights can be updated one by one. In the batched mode variant, the descent is based on the gradient ∇E for the total training set

$$\Delta w_{ij}(n) = -\eta^* \frac{\delta E}{\delta w_{ij}} + \alpha^* \Delta w_{ij}(n-1) \qquad (4)$$

where η and α are the learning rate and momentum respectively.

The momentum term determines the effect of past weight changes on the current direction of movement in the weight space. A good choice of both η and α are required for the training success and the speed of the neural-network learning.

It has been proven that backpropagation learning with sufficient hidden layers can approximate any nonlinear function to arbitrary accuracy. This makes backpropagation learning neural network a good candidate for signal prediction and system modeling.

5 TRAINING AND TESTING NEURAL NETWORKS

The best training procedure is to compile a wide range of examples (for more complex problems, more examples are required), which exhibit all the different characteristics of the problem.

To create a robust and reliable network, in some cases, some noise or other randomness is added to the training data to get the network familiarized with noise and natural variability in real data.

Poor training data inevitably leads to an unreliable and unpredictable network. Usually, the network is trained for a prefixed number of epochs or when the output error decreases below a particular error threshold.

Special care is to be taken not to overtrain the network. By overtraining, the network may become too adapted in learning the samples from the training set, and thus may be unable to accurately classify samples outside of the training set.

Figure 3 illustrates the classification results of an overtrained network. The task is to correctly classify two patterns X and Y. Training patterns are shown by '●' and test patterns by '♣'. The test patterns were not shown during the training phase.

As shown in Figure 3 (left side), each class of test data has been classified correctly, even though they were not seen during training. The trained network is said to have good generalization performance. Figure 3 (right side) illustrates some misclassification of the test data. The network initially learns to detect the global features of the input and, as a consequence, generalizes very well. But after prolonged training, the network starts to recognize individual input/output pairs rather than settling for weights that generally describe the mapping for the whole training set (Fausett, 1994).

5.1 Choosing the number of neurons

The number of hidden neurons affects how well the network is able to separate the data. A large number of hidden neurons will ensure correct learning, and the network is able to correctly predict the data it has been trained on, but its performance on new data, its ability to generalize, is compromised. With too few hidden neurons, the network may be unable to learn the relationships amongst the data and the error will fail to fall below an acceptable level. Thus, selection of the number of hidden neurons is a crucial decision.

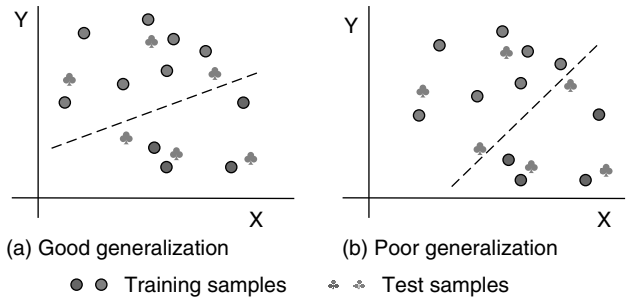

Figure 3. Illustration of generalization performance.

5.2 Choosing the initial weights

The learning algorithm uses a steepest descent technique, which rolls straight downhill in weight space until the first valley is reached. This makes the choice of initial starting point in the multidimensional weight space critical. However, there are no recommended rules for this selection except trying several different starting weight values to see if the network results are improved.

5.3 Choosing the learning rate

Learning rate effectively controls the size of the step that is taken in multidimensional weight space when each weight is modified. If the selected learning rate is too large, then the local minimum may be overstepped constantly, resulting in oscillations and slow convergence to the lower error state. If the learning rate is too low, the number of iterations required may be too large, resulting in slow performance.

6 HIGHER ORDER LEARNING ALGORITHMS

Backpropagation (BP) often gets stuck at a local minimum mainly because of the random initialization of weights. For some initial weight settings, BP may not be able to reach a global minimum of weight space, while for other initializations the same network is able to reach an optimal minimum.

A long recognized bane of analysis of the error surface and the performance of training algorithms is the presence of multiple stationary points, including multiple minima.

Empirical experience with training algorithms show that different initialization of weights yield different resulting networks. Hence, multiple minima not only exist, but there may be huge numbers of them.

In practice, there are four types of optimization algorithms that are used to optimize the weights. The first three methods, gradient descent, conjugate gradients, and quasi-Newton, are general optimization methods whose operation can be understood in the context of minimization of a quadratic error function.

Although the error surface is surely not quadratic, for differentiable node functions, it will be so in a sufficiently small neighborhood of a local minimum, and such an analysis provides information about the behavior of the training algorithm over the span of a few iterations and also as it approaches its goal.

The fourth method of Levenberg and Marquardt is specifically adapted to the minimization of an error function that arises from a squared error criterion of the form we are assuming. A common feature of these training algorithms is the requirement of repeated efficient calculation of gradients. The reader can refer to Bishop (1995) for an extensive coverage of higher-order learning algorithms.

Even though artificial neural networks are capable of performing a wide variety of tasks, in practice, sometimes, they deliver only marginal performance. Inappropriate topology selection and learning algorithm are frequently blamed. There is little reason to expect that one can find a uniformly best algorithm for selecting the weights in a feedforward artificial neural network. This is in accordance with the no free lunch theorem, which explains that for any algorithm, any elevated performance over one class of problems is exactly paid for in performance over another class (Macready and Wolpert, 1997).

The design of artificial neural networks using evolutionary algorithms has been widely explored. Evolutionary algorithms are used to adapt the connection weights, network architecture, and so on, according to the problem environment.

A distinct feature of evolutionary neural networks is their adaptability to a dynamic environment. In other words, such neural networks can adapt to an environment as well as changes in the environment. The two forms of adaptation, evolution and learning in evolutionary artificial neural networks, make their adaptation to a dynamic environment much more effective and efficient than the conventional learning approach. Refer to Abraham (2004) for more technical information related to evolutionary design of neural networks.

7 DESIGNING ARTIFICIAL NEURAL NETWORKS

To illustrate the design of artificial neural networks, the Mackey-Glass chaotic time series (Box and Jenkins, 1970) benchmark is used. The performance of the designed neural network is evaluated for different architectures and activation functions. The Mackey-Glass differential equation is a chaotic time series for some values of the parameters $x(0)$ and τ.

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = \frac{0.2x(t-\tau)}{1+x^{10}(t-\tau)} - 0.1\ x(t). \tag{5}$$

We used the value $x(t-18)$, $x(t-12)$, $x(t-6)$, $x(t)$ to predict $x(t+6)$. Fourth order Runge-Kutta method was used to generate 1000 data series. The time step used in the method is 0.1 and initial condition were $x(0) = 1.2$, $\tau =$

Table 1. Training and test performance for Mackey-Glass Series for different architectures.

Hidden neurons	Root mean-squared error	
	Training data	Test data
14	0.0890	0.0880
16	0.0824	0.0860
18	0.0764	0.0750
20	0.0452	0.0442
24	0.0439	0.0437

17, $x(t) = 0$ for $t < 0$. The first 500 data sets were used for training and remaining data for testing.

7.1 Network architecture

A feed-forward neural network with four input neurons, one hidden layer and one output neuron is used. Weights were randomly initialized and the learning rate and momentum are set at 0.05 and 0.1 respectively. The numbers of hidden neurons are varied (14, 16, 18, 20, 24) and the generalization performance is reported in Table 1. All networks were trained for an identical number of stochastic updates (2500 epochs).

7.2 Role of activation functions

The effect of two different node activation functions in the hidden layer, log-sigmoidal activation function LSAF and tanh-sigmoidal activation function TSAF), keeping 24 hidden neurons for the backpropagation learning algorithm, is illustrated in Figure 4. Table 2 summarizes the empirical results for training and generalization for the two node transfer functions. The generalization looks better with TSAF.

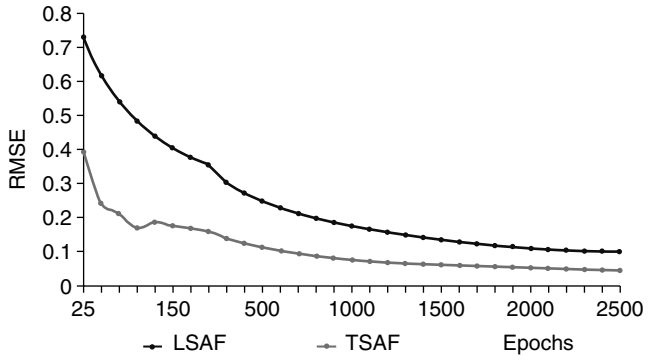

Figure 4. Convergence of training for different node transfer function.

Table 2. Mackey-Glass time series: training and generalization performance for different activation functions.

Activation function	Root mean-squared error	
	Training	Test
TSAF	0.0439	0.0437
LSAF	0.0970	0.0950

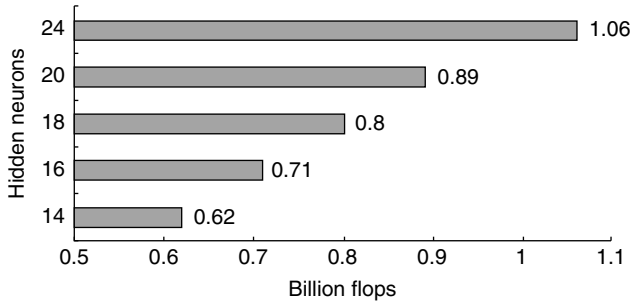

Figure 5. Computational complexity for different architectures.

Figure 5 illustrates the computational complexity in billion flops for different numbers of hidden neurons. At present, neural network design relies heavily on human experts who have sufficient knowledge about the different aspects of the network and the problem domain. As the complexity of the problem domain increases, manual design becomes more difficult.

8 SELF-ORGANIZING FEATURE MAP AND RADIAL BASIS FUNCTION NETWORK

8.1 Self-organizing feature map

Self-organizing Feature Maps SOFM is a data visualization technique proposed by Kohonen (1988), which reduces the dimensions of data through the use of self-organizing neural networks.

A SOFM learns the categorization, topology, and distribution of input vectors. SOFM allocate more neurons to recognize parts of the input space where many input vectors occur and allocate fewer neurons to parts of the input space where few input vectors occur. Neurons next to each other in the network learn to respond to similar vectors.

SOFM can learn to detect regularities and correlations in their input and adapt their future responses to that input accordingly. An important feature of the SOFM learning

algorithm is that it allows neurons that are neighbors to the winning neuron to be output values. Thus, the transition of output vectors is much smoother than that obtained with competitive layers, where only one neuron has an output at a time.

The problem that data visualization attempts to solve is that humans simply cannot visualize high-dimensional data. The way SOFM goes about reducing dimensions is by producing a map of usually 1 or 2 dimensions, which plot the similarities of the data by grouping similar data items together (data clustering). In this process, SOFM accomplish two things, they reduce dimensions and display similarities.

It is important to note that while a self-organizing map does not take long to organize itself so that neighboring neurons recognize similar inputs, it can take a long time for the map to finally arrange itself according to the distribution of input vectors.

8.2 Radial basis function network

The Radial Basis Function (RBF) network is a three-layer feed-forward network that uses a linear transfer function for the output units and a nonlinear transfer function (normally the Gaussian) for the hidden layer neurons (Chen, Cowan and Grant, 1991). Radial basis networks may require more neurons than standard feed-forward backpropagation networks, but often they can be designed with lesser time. They perform well when many training data are available.

Much of the inspiration for RBF networks has come from traditional statistical pattern classification techniques. The input layer is simply a fan-out layer and does no processing. The second or hidden layer performs a nonlinear mapping from the input space into a (usually) higher dimensional space whose activation function is selected from a class of functions called basis functions.

The final layer performs a simple weighted sum with a linear output. Contrary to BP networks, the weights of the hidden layer basis units (input to hidden layer) are set using some clustering techniques. The idea is that the patterns in the input space form clusters. If the centers of these clusters are known, then the Euclidean distance from the cluster center can be measured. As the input data moves away from the connection weights, the activation value reduces. This distance measure is made nonlinear in such a way that for input data close to a cluster center gets a value close to 1. Once the hidden layer weights are set, a second phase of training (usually backpropagation) is used to adjust the output weights.

9 RECURRENT NEURAL NETWORKS AND ADAPTIVE RESONANCE THEORY

9.1 Recurrent neural networks

Recurrent networks are the state of the art in nonlinear time series prediction, system identification, and temporal pattern classification. As the output of the network at time t is used along with a new input to compute the output of the network at time $t + 1$, the response of the network is dynamic (Mandic and Chambers, 2001).

Time Lag Recurrent Networks (TLRN) are multilayered perceptrons extended with short-term memory structures that have local recurrent connections. The recurrent neural network is a very appropriate model for processing temporal (time-varying) information.

Examples of temporal problems include time-series prediction, system identification, and temporal pattern recognition. A simple recurrent neural network could be constructed by a modification of the multilayered feed-forward network with the addition of a 'context layer'. The context layer is added to the structure, which retains information between observations. At each time step, new inputs are fed to the network. The previous contents of the hidden layer are passed into the context layer. These then feed back into the hidden layer in the next time step. Initially, the context layer contains nothing, so the output from the hidden layer after the first input to the network will be the same as if there is no context layer. Weights are calculated in the same way for the new connections from and to the context layer from the hidden layer.

The training algorithm used in TLRN (backpropagation through time) is more advanced than standard backpropagation algorithm. Very often, TLRN requires a smaller network to learn temporal problems when compared to MLP that use extra inputs to represent the past samples. TLRN is biologically more plausible and computationally more powerful than other adaptive models such as the hidden Markov model.

Some popular recurrent network architectures are the Elman recurrent network in which the hidden unit activation values are fed back to an extra set of input units and the Jordan recurrent network in which output values are fed back into hidden units.

9.2 Adaptive resonance theory

Adaptive Resonance Theory (ART) was initially introduced by Grossberg (1976) as a theory of human information processing. ART neural networks are extensively used for

supervised and unsupervised classification tasks and function approximation.

There exist many different variations of ART networks today (Carpenter and Grossberg, 1998). For example, ART1 performs unsupervised learning for binary input patterns, ART2 is modified to handle both analog and binary input patterns, and ART3 performs parallel searches of distributed recognition codes in a multilevel network hierarchy. Fuzzy ARTMAP represents a synthesis of elements from neural networks, expert systems, and fuzzy logic.

10 SUMMARY

This section presented the biological motivation and fundamental aspects of modeling artificial neural networks. Performance of feed-forward artificial neural networks for a function approximation problem is demonstrated. Advantages of some specific neural network architectures and learning algorithms are also discussed.

1 PROBLEM SOLVING USING HEURISTICS

A general introduction to artificial intelligence methods of measurement signal processing is given in **Article 128, Nature and Scope of AI Techniques, Volume 2**.

Problem solving is the process of finding a solution when the path leading to that solution is uncertain. Even though we are familiar with several problem-solving techniques, in the real world, sometimes many problems cannot be solved by a technique we are familiar with.

Surprisingly, for some complicated problems, no straightforward solution technique is known at all. For these problems, heuristic solution techniques may be the only alternative. A heuristic can be simplified as a strategy that is powerful and general, but not absolutely guaranteed to provide best solutions.

Heuristic methods are very problem specific. Previous experience and some general rules – often called *rules of thumb* – could help find good heuristics easier. Humans use heuristics a great deal in their problem solving. Of course, if the heuristic does fail, it is necessary for the problem solver to either pick another heuristic, or know that it is appropriate to give up.

Choosing random solutions, adopting greedy approaches, evolving the basic heuristics for finding better heuristics are just some of the popular approaches used in heuristic problem solving (Michalewicz and Fogel, 1999).

Heuristic problem solving involves finding a set of rules, or a procedure, that finds satisfactory solutions to a specific problem. A good example is finding one's way through a maze. To make the way toward the final goal, a step-by-step movement is necessary. Very often false moves are made but in most cases we solve the problem without much difficulty. For the maze problem, a simple heuristic rule could be '*choose the direction that seems to make progress*'. Another good example is the job shop scheduling problem wherein the task is to schedule J_n independent jobs, where $n = \{1, 2, \ldots .N\}$ on R_m heterogeneous resources and $m = \{1, 2, \ldots ., M\}$, with an objective of minimizing the completion time of all the jobs and utilizing all the resources effectively.

Each job J_n has processing requirement P_j cycles and resource R_m has speed of S_i cycles/unit time. Any job J_n has to be processed in resource R_m, until completion. If C_j is the completion time and the last job j finishes processing, then we define $C_{\max} = \max\{C_j, j = 1, \ldots, N\}$, the make-span and ΣC_j, as the flow-time.

The task is to find an optimal schedule that optimizes the flow-time and make-span. Some simple heuristic rules to achieve this are by scheduling the Shortest Job on the Fastest Resource (SJFR), which would minimize ΣC_j or by

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

scheduling the Longest Job on the Fastest Resource (LJFR), which would minimize $C_{\max}$.

Minimizing ΣC_j asks that the average job finishes quickly, at the expense of the largest job taking a long time, whereas minimizing $C_{\max}$, asks that no job takes too long, at the expense of most jobs taking a long time.

In summary, minimization of $C_{\max}$ will result in maximization of ΣC_j, which makes the problem more interesting.

By contrast, algorithms are straightforward procedures that are guaranteed to work every time for they are fully determinate and time invariant. For example, certain daily routine tasks could be formulated in a strict algorithm format (example, starting up an automobile). However, for a 'problem solver' to be more adaptive, novel elements or new circumstances must be introduced. Many real-world problems cannot be reduced to algorithms, which leads us to the quest to find more powerful techniques.

2 WHAT ARE RULE-BASED SYSTEMS?

Conventional problem-solving computer programs make use of well-structured algorithms, data structures, and crisp reasoning strategies to find solutions. For the difficult problems with which expert systems are concerned, it may be more useful to employ heuristics: strategies that often lead to the correct solution, but that also sometimes fail.

Conventional rule-based expert systems, use human expert knowledge to solve real-world problems that normally would require human intelligence. Expert knowledge is often represented in the form of *rules* or as *data* within the computer.

Depending upon the problem requirement, these rules and data can be recalled to solve problems. Rule-based expert systems have played an important role in modern intelligent systems and their applications in strategic goal setting, planning, design, scheduling, fault monitoring, diagnosis and so on.

With the technological advances made in the last decade, today's users can choose from dozens of commercial software packages having friendly graphic user interfaces (Ignizio, 1991). Conventional computer programs perform tasks using a decision-making logic containing very little knowledge other than the basic algorithm for solving that specific problem. The basic knowledge is often embedded as part of the programming code, so that as the knowledge changes, the program has to be rebuilt. Knowledge-based expert systems collect the small fragments of human know-how into a knowledge base, which is used to reason through a problem, using the knowledge that is appropriate. An important advantage here is that within the domain of the knowledge base, a different problem can be solved using the same program without reprogramming efforts. Moreover, expert systems could explain the reasoning process and handle levels of confidence and uncertainty, which conventional algorithms do not handle (Giarratano and Riley, 1989). Some of the important advantages of expert systems are as follows:

- ability to capture and preserve irreplaceable human experience;
- ability to develop a system more consistent than human experts;
- minimize human expertise needed at a number of locations at the same time (especially in a hostile environment that is dangerous to human health);
- solutions can be developed faster than human experts.

The basic components of an expert system are illustrated in Figure 1. The knowledge base stores all relevant information, data, rules, cases, and relationships used by the expert system. A knowledge base can combine the knowledge of multiple human experts. A rule is a conditional statement that links given conditions to actions or outcomes. A frame is another approach used to capture and store knowledge in a knowledge base. It relates an object or item to various facts or values. A frame-based representation is ideally suited for object-oriented programming techniques. Expert systems making use of frames to store knowledge are also called *frame-based expert systems*.

The purpose of the inference engine is to seek information and relationships from the knowledge base and to provide answers, predictions, and suggestions in the way a human expert would. The inference engine must find the right facts, interpretations, and rules and assemble them correctly. Two types of inference methods are commonly used – Backward chaining is the process of starting with conclusions and working backward to the supporting facts. Forward chaining starts with the facts and works forward to the conclusions.

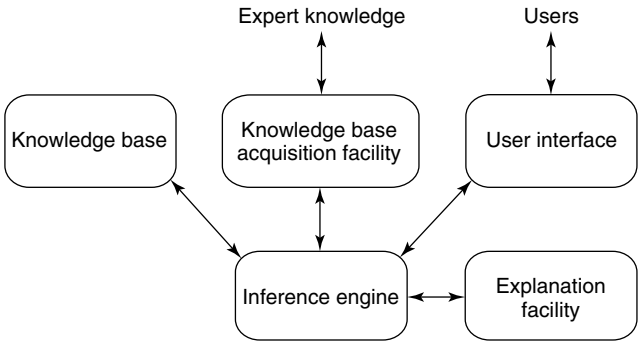

Figure 1. Architecture of a simple expert system.

The explanation facility allows a user to understand how the expert system arrived at certain results. The overall purpose of the knowledge acquisition facility is to provide a convenient and efficient means for capturing and storing all components of the knowledge base.

Very often specialized user interface software is used for designing, updating, and using expert systems. The purpose of the user interface is to ease use of the expert system for developers, users, and administrators.

3 INFERENCE ENGINE IN RULE-BASED SYSTEMS

A rule-based system consists of *if-then rules*, a bunch of *facts*, and an *interpreter* controlling the application of the rules, given the facts.

These *if-then* rule statements are used to formulate the conditional statements that comprise the complete knowledge base. A single *if-then* rule assumes the form 'if x is A then y is B' and the if-part of the rule 'x is A' is called the *antecedent* or *premise*, while the then-part of the rule 'y is B' is called the *consequent* or *conclusion*. There are two broad kinds of inference engines used in rule-based systems: *forward chaining* and *backward chaining* systems.

In a *forward chaining* system, the initial facts are processed first, and keep using the rules to draw new conclusions given those facts. In a *backward chaining* system, the hypothesis (or solution/goal) we are trying to reach is processed first, and keep looking for rules that would allow to conclude that hypothesis. As the processing progresses, new subgoals are also set for validation. Forward chaining systems are primarily data-driven, while backward chaining systems are goal-driven. Consider an example with the following set of *if-then* rules

Rule 1: *If A and C then Y*
Rule 2: *If A and X then Z*
Rule 3: *If B then X*
Rule 4: *If Z then D*

If the task is to prove that D is true, given A and B are true. According to *forward chaining*, start with Rule 1 and go on downward till a rule that fires is found. Rule 3 is the only one that fires in the first iteration. After the first iteration, it can be concluded that A, B, and X are true. The second iteration uses this valuable information. After the second iteration, Rule 2 fires adding Z is true, which in turn helps Rule 4 to fire, proving that D is true. Forward chaining strategy is especially appropriate in situations where data are expensive to collect, but few in quantity. However, special care is to be taken when these rules are constructed, with the preconditions specifying as precisely as possible when different rules should fire.

In the backward chaining method, processing starts with the desired goal, and then attempts to find evidence for proving the goal. Returning to the same example, the task to prove that D is true would be initiated by first finding a rule that proves D. Rule 4 does so, which also provides a subgoal to prove that Z is true. Now Rule 2 comes into play, and as it is already known that A is true, the new subgoal is to show that X is true. Rule 3 provides the next subgoal of proving that B is true. But that B is true is one of the given assertions. Therefore, it could be concluded that X is true, which implies that Z is true, which in turn also implies that D is true. Backward chaining is useful in situations where the quantity of data is potentially very large and where some specific characteristic of the system under consideration is of interest. If there is not much knowledge what the conclusion might be, or there is some specific hypothesis to test, forward chaining systems may be inefficient. In principle, we can use the same set of rules for both forward and backward chaining. In the case of backward chaining, since the main concern is with matching the conclusion of a rule against some goal that is to be proved, the 'then' (consequent) part of the rule is usually not expressed as an action to take but merely as a state, which will be true if the antecedent part(s) are true (Donald, 1986).

4 EXPERT SYSTEM DEVELOPMENT

Steps in the expert systems development process include determining the actual requirements, knowledge acquisition, constructing expert system components, implementing results, and formulating a procedure for maintenance and review.

Knowledge acquisition is the most important element in the development of expert system (Niwa, Sasaki and Ihara, 1988). Knowledge could be obtained by interviewing domain experts and/or learning by experience.

Very often people express knowledge as natural language (spoken language), or using letters or symbolic terms. There exist several methods to extract human knowledge. Cognitive Work Analysis (CWA) and the Cognitive Task Analysis (CTA) provide frameworks to extract knowledge.

The CWA is a technique to analyze, design, and evaluate the human computer interactive systems (Vicente, 1999).

The CTA is a method to identify cognitive skill, mental demands, and needs to perform task proficiency (Militallo and Hutton, 1998). This focuses on describing the representation of the cognitive elements that defines goal generation and decision-making. It is a reliable method for extracting

human knowledge because it is based on the observations or an interview.

Most expert systems are developed using specialized software tools called *shells*. These shells come equipped with an inference mechanism (backward chaining, forward chaining, or both), and require knowledge to be entered according to a specified format.

One of the most popular shells widely used throughout the government, industry, and academia is the CLIPS (CLIPS, 2004). CLIPS is an expert system tool that provides a complete environment for the construction of rule- and/or object-based expert systems. CLIPS provides a cohesive tool for handling a wide variety of knowledge with support for three different programming paradigms: rule-based, object-oriented, and procedural. CLIPS is written in C for portability and speed and has been installed on many different operating systems without code changes.

5 FUZZY EXPERT SYSTEMS

The world of information is surrounded by uncertainty and imprecision. The human reasoning process can handle inexact, uncertain, and vague concepts in an appropriate manner. Usually, the human thinking, reasoning, and perception process cannot be expressed precisely. These types of experiences can rarely be expressed or measured using statistical or probability theory. Fuzzy logic provides a framework to model uncertainty, the human way of thinking, reasoning, and the perception process. Fuzzy systems were first introduced by Zadeh (1965).

A fuzzy expert system is simply an expert system that uses a collection of fuzzy membership functions and rules, instead of Boolean logic, to reason about data (Schneider *et al.,* 1996). The rules in a fuzzy expert system are usually of a form similar to the following:

If A is *low* and B is *high* then $X = medium$

where A and B are input variables, X is an output variable. Here low, high, and medium are fuzzy sets defined on A, B, and X respectively. The antecedent (the rule's premise) describes to what degree the rule applies, while the rule's consequent assigns a membership function to each of one or more output variables.

Let X be a space of objects and x be a generic element of X. A classical set A, $A \subseteq X$, is defined as a collection of elements or objects $x \in X$, such that x can either belong or not belong to the set A. A fuzzy set A in X is defined as a set of ordered pairs

$$A = \{(x, \mu_A(x)) | x \in X\} \tag{1}$$

where $\mu_A(x)$ is called the *membership function* (MF) for the fuzzy set A. The MF maps each element of X to a membership grade (or membership value) between zero and one. Obviously (1) is a simple extension of the definition of a classical set in which the characteristic function is permitted to have any values between zero and one.

The intersection of two fuzzy sets A and B is specified in general by a function T: [0,1] × [0,1] → [0,1], which aggregates two membership grades as follows:

$$\mu_{A \cap B}(x) = T(\mu_A(x), \mu_B(x)) = \mu_A(x) \bar{*} \mu_B(x) \tag{2}$$

where $\bar{*}$ is a binary operator for the function T. This class of fuzzy intersection operators are usually referred to as *T-norm operators* (Jang, Sun and Mizutani, 1997). Four of the most frequently used T-norm operators are

$$\text{Minimum: } T_{\min}(a, b) = \min(a, b) = a \wedge b \tag{3}$$

$$\text{Algebraic product: } T_{\text{ap}}(a, b) = ab \tag{4}$$

$$\text{Bounded product: } T_{\text{bp}}(a, b) = 0 \vee (a + b - 1) \tag{5}$$

$$\text{Drastic product: } T_{\text{dp}}(a, b) = \begin{cases} a, & if\ b = 1 \\ b, & if\ a = 1 \\ 0, & if\ a, b < 1 \end{cases} \tag{6}$$

Like intersection, the fuzzy union operator is specified in general by a function S: [0,1] × [0,1] → [0,1], which aggregates two membership grades as follows:

$$\mu_{A \cup B}(x) = S(\mu_A(x), \mu_B(x)) = \mu_A(x) \mp \mu_B(x) \tag{7}$$

where $\mp$ is the binary operator for the function S. This class of fuzzy union operators are often referred to as *T-conorm* (or *S-norm*) operators (Jang, Sun and Mizutani, 1997). Four of the most frequently used T-conorm operators are

$$\text{Maximum: } S_{\max}(a, b) = \max(a, b) = a \vee b \tag{8}$$

$$\text{Algebraic sum: } S_{\text{as}}(a, b) = a + b - ab \tag{9}$$

$$\text{Bounded sum: } S_{\text{bs}}(a, b) = 1 \wedge (a + b) \tag{10}$$

$$\text{Drastic sum: } S_{\text{ds}}(a, b) = \begin{cases} a, & if\ b = 0 \\ b, & if\ a = 0 \\ 1, & if\ a, b > 0 \end{cases} \tag{11}$$

Both the intersection and union operators retain some properties of the classical set operation. In particular, they are associative and commutative.

Figure 2 illustrates the basic architecture of a fuzzy expert system. The main components are a fuzzification interface, a fuzzy rule base (knowledge base), an inference engine (decision-making logic), and a defuzzification interface. The input variables are fuzzified whereby the membership functions defined on the input variables are applied to their actual values, to determine the degree of truth for each rule antecedent. Fuzzy *if-then* rules and fuzzy reasoning are the backbone of fuzzy expert systems, which are the most

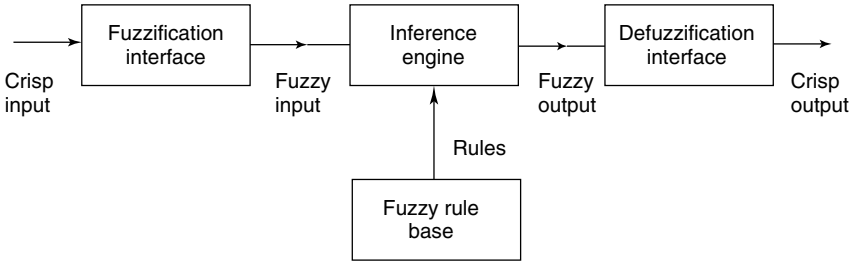

Figure 2. Basic architecture of a fuzzy expert system.

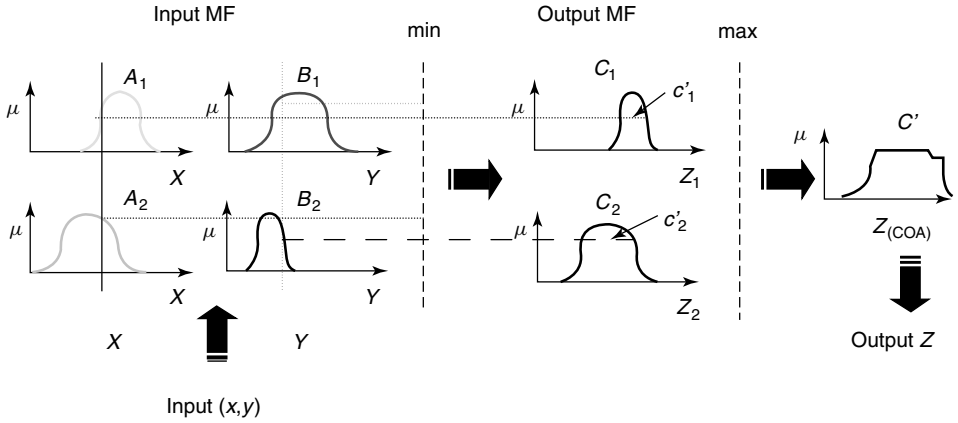

Figure 3. Mamdani fuzzy inference system using min and max for T-norm and T-conorm operators.

important modeling tools based on fuzzy set theory. The fuzzy rule base is characterized in the form of *if-then* rules in which the antecedents and consequents involve linguistic variables. The collection of these fuzzy rules forms the rule base for the fuzzy logic system. Using suitable inference procedure, the truth value for the antecedent of each rule is computed, and applied to the consequent part of each rule. This results in one fuzzy subset to be assigned to each output variable for each rule. Again, by using suitable composition procedure, all the fuzzy subsets assigned to each output variable are combined together to form a single fuzzy subset for each output variable. Finally, defuzzification is applied to convert the fuzzy output set to a crisp output.

The basic fuzzy inference system can take either fuzzy inputs or crisp inputs, but the outputs it produces are always fuzzy sets. The defuzzification task extracts the crisp output that best represents the fuzzy set. With crisp inputs and outputs, a fuzzy inference system implements a nonlinear mapping from its input space to output space through a number of fuzzy *if-then* rules.

In what follows, the two most popular fuzzy inference systems are introduced that have been widely deployed in various applications. The differences between these two fuzzy inference systems lie in the consequents of their fuzzy rules, and thus their aggregation and defuzzification procedures differ accordingly.

According to Mamdani, fuzzy inference system (Mamdani and Assilian, 1975) – see Figure 3 – the rule antecedents and consequents are defined by fuzzy sets and has the following structure:

$$if\ x\ is\ A_1\ and\ y\ is\ B_1\ then\ z_1 = C_1^{'} \tag{12}$$

There are several defuzzification techniques. The most widely used defuzzification technique uses the centroid of area method as follows

$$\text{Centroid of area } Z_{\text{COA}} = \frac{\int_Z \mu_A(z)\, z\, \mathrm{d}z}{\int_Z \mu_A(z)\, \mathrm{d}z} \tag{13}$$

where $\mu_A(z)$ is the aggregated output MF.

Takagi and Sugeno (1985) proposed an inference scheme in which the conclusion of a fuzzy rule is constituted by a weighted linear combination of the crisp inputs rather than a fuzzy set. A basic Takagi–Sugeno fuzzy inference system is illustrated in Figure 4 and the rule has the following structure

$$if\ x\ is\ A_1\ and\ y\ is\ B_1,\ then\ z_1 = p_1 x + q_1 y + r_1 \tag{14}$$

where p_1, q_1, and r_1 are linear parameters. TSK Takagi–Sugeno Kang fuzzy controller usually needs a smaller

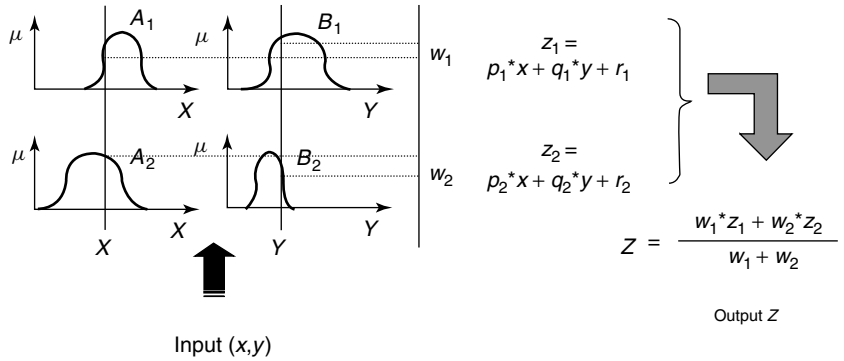

Figure 4. Takagi–Sugeno fuzzy inference system using a min or product as T-norm operator.

number of rules, because their output is already a linear function of the inputs rather than a constant fuzzy set.

6 MODELING FUZZY EXPERT SYSTEMS

Fuzzy expert system modeling can be pursued using the following steps.

- Select relevant input and output variables. Determine the number of linguistic terms associated with each input/output variable. Also, choose the appropriate family of membership functions, fuzzy operators, reasoning mechanism, and so on.
- Choose a specific type of fuzzy inference system (for example, Mamdani, Takagi–Sugeno etc.). In most cases, the inference of the fuzzy rules is carried out using the 'min' and 'max' operators for fuzzy intersection and union.
- Design a collection of fuzzy *if-then* rules (knowledge base). To formulate the initial rule base, the input space is divided into multidimensional partitions and then actions are assigned to each of the partitions.

In most applications, the partitioning is achieved using one-dimensional membership functions using fuzzy *if-then* rules as illustrated in Figure 5. The consequent parts of the rule represent the actions associated with each partition. It is evident that the MFs and the number of rules are tightly related to the partitioning.

7 ILLUSTRATION OF FUZZY EXPERT SYSTEM DESIGN

This section illustrates the development of a reactive power prediction model using Mamdani and Takagi–Sugeno fuzzy inference expert systems. The MatLab™ fuzzy logic toolbox was used to simulate the various experiments (Fuzzy Logic Tool Box, 2004).

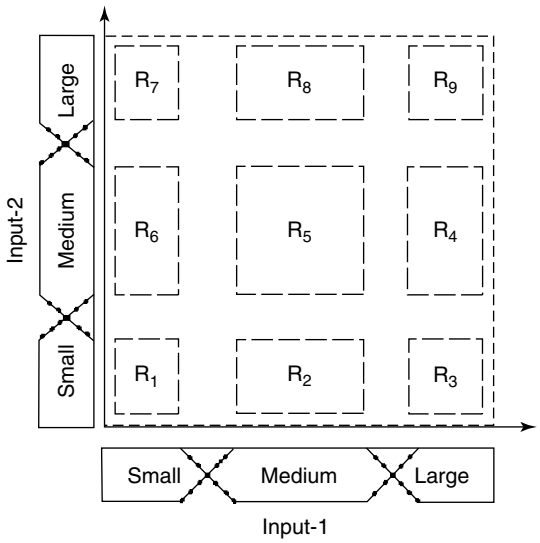

Figure 5. Example showing how the two-dimensional spaces are partitioned using three trapezoidal membership functions per input dimension. A simple if-then rule will appear as *If input-1 is medium and input 2 is large, then rule* R_8 *is fired*.

The task is to develop a fuzzy expert system to forecast the reactive power (P) at time $t + 1$ by knowing the load current (I) and voltage (V) at time t. The experiment system consists of two stages: developing the fuzzy expert system, and performance evaluation using the test data. The model has two in–out variables (V and I) and one output variable (P). Training and testing data sets were extracted randomly from the master dataset. Sixty percent of data was used for training and the remaining 40% for testing (Abraham and Khan, 2003).

7.1 Design and experiments: fuzzy expert systems

First, the effects of (a) shape and quantity of membership functions (b) T-norm and T-conorm operators (c) defuzzification methods and (d) inference method for

designing the fuzzy expert system is analyzed. Experiments were carried out using four different settings using the same rule base.

Experiment 1 (To evaluate the effect on the number of membership functions) The following settings were used for designing the expert system

1. Two triangular membership functions (MFs) for each input variable and four triangular MFs for the output variable (power). Using the grid partitioning method (Figure 5), four *if-then* rules were developed.
2. Three triangular MFs for each input variable and nine triangular MFs for the output variable (power). The rule base consisted of nine *if-then* rules.

'min' and 'max' were used as T-norm and T-conorm operators and the centroid method of defuzzification for Mamdani inference method and weighted average defuzzification method for Takagi–Sugeno Fuzzy Inference System (FIS). The developed fuzzy inference systems using Mamdani and Takagi–Sugeno models are depicted in Figures 6 to 9. Table 1 summarizes the training and testing Root Mean Squared Error (RMSE) values.

Experiment 2 (To evaluate the effect of shape of membership functions) For the Mamdani FIS, three Gaussian MFs for each input variable and nine Gaussian MFs for the output variable were used. The rule base consisted of nine *if-then* rules. 'min' and 'max' as T-norm and T-conorm operators, and the centroid method of defuzzification for Mamdani FIS and the weighted average defuzzification method for Takagi–Sugeno FIS were also used. The developed fuzzy inference systems using Mamdani and Takagi–Sugeno models are depicted in Figures 10 and 11. Table 2 summarizes the training and testing RMSE values.

Experiment 3 (To evaluate the effect of fuzzy operators) For Mamdani FIS, three Gaussian MFs for each input variable and nine Gaussian MFs for the output variable were used. The rule base consisted of nine *if-then* rules. T-norm and T-conorm operators were 'product' and 'sum' and the centroid method of defuzzification for Mamdani FIS, and weighted average defuzzification method for Takagi–Sugeno FIS were used. Table 3 summarizes the training and testing RMSE values.

Experiment 4 (To evaluate the effect of defuzzification operators) For the Mamdani FIS, three Gaussian MFs for each input variable and nine Gaussian MFs for the output variable were used. The rule base consisted of nine *if-then* rules. T-norm and T-conorm operators were 'product' and 'sum' and the following defuzzification operators were tested for Mamdani FIS.

Table 1. Empirical comparison of fuzzy inference systems and quantity of Membership Functions (MFs).

No. of MFs	Mamdani FIS		Takagi – Sugeno FIS	
	Root mean squared error			
	Training	Test	Training	Test
2	0.401	0.397	0.024	0.023
3	0.348	0.334	0.017	0.016

Table 2. Empirical comparison of fuzzy inference systems using Gaussian MFs.

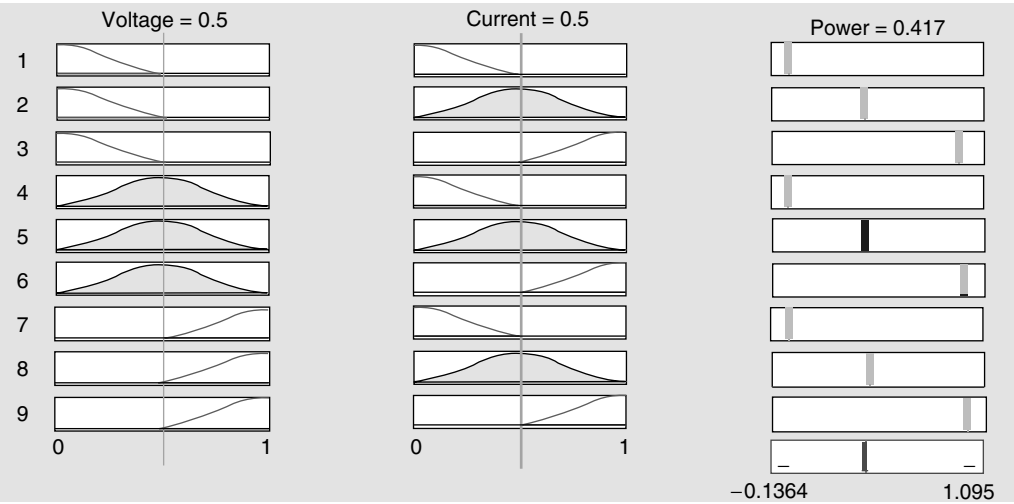

Figure 11. Takagi–Sugeno fuzzy inference system using three Gaussian MFs for input variables.

Table 3. Empirical comparison of fuzzy inference systems for different fuzzy operators.

Mamdani FIS		Takagi – Sugeno FIS	
Root mean squared error			
Training	Test	Training	Test
0.221	0.219	0.019	0.018

- Centroid
- Bisector of Area (BOA)
- Mean of Maximum (MOM)
- Smallest of Maximum (SOM).

For the Takagi–Sugeno FIS, the weighted sum and weighted average defuzzification methods were used. Table 4 summarizes the training and testing of RMSE values.

Discussions of Results and Problem Solution As depicted in Table 1, when the number of input MFs were increased from two to three, the RMSE values reduced regardless of the inference system used. However, when the shape of the MF was changed to Gaussian, RMSE values for Mamdani FIS decreased but the RMSE values for Takagi–Sugeno FIS increased (Table 2). Using Gaussian MFs, when the T-norm and T-conorm operators were changed to 'product' and 'sum' (instead of 'min' and 'max') both the inference methods performed better (Table 3). Finally, the selection of an ideal defuzzification operator also has a direct influence in the performance of FIS as shown in Table 4.

Table 4. Empirical comparison of fuzzy inference systems for different defuzzification operators.

Mamdani FIS			Takagi–Sugeno FIS		
Defuzzification	RMSE		Defuzzification	RMSE	
	Training	Test		Training	Test
Centroid	0.221	0.0219	Weighted sum	0.019	0.018
MOM	0.230	0.232	Weighted average	0.085	0.084
BOA	0.218	0.216			
SOM	0.229	0.232			

The design of the rule base (number of rules and how the inputs and outputs are related) is also very important for the good performance of FIS. The role of weighting factors emphasizing the importance of certain rules also bears a prominent role for the overall performance. When the input/output dimensions become larger, manual design becomes tedious and sometimes could even lead to poor design and implementation.

8 ADAPTATION OF FUZZY INFERENCE SYSTEMS

Expert knowledge is often the main source to design the fuzzy expert systems. Figure 12 illustrates the various parameters and components that need to be adapted for controlling a process. According to the performance measure of the problem environment, the membership functions, rule bases, and the inference mechanism are to be adapted (Abraham, 2002).

Neural network learning, self-organizing maps and clustering methods could be used to generate rules. Gradient descent and its variants could be applied to fine-tune the parameters of parameterized input/output membership functions and fuzzy operators (Abraham, 2001). Adaptation of fuzzy inference systems using evolutionary computation techniques has been widely explored. Evolutionary Computation (EC) is a population based adaptive method, which may be used to solve optimization problems, based on the genetic processes of biological organisms (Michalewicz and Fogel, 1999).

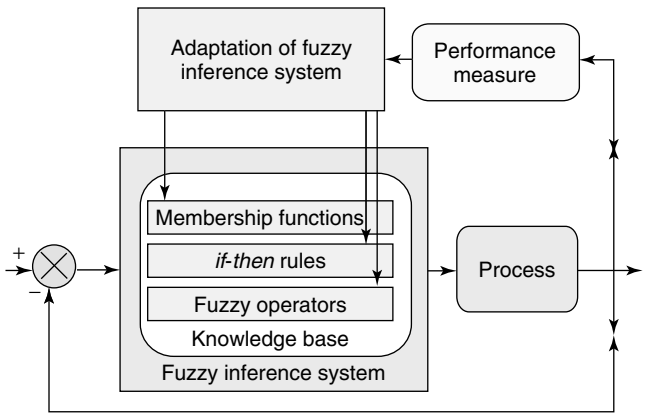

Figure 12. Adaptation of fuzzy inference systems.

Over many generations, natural populations evolve according to the principles of natural selection and 'survival of the fittest', first clearly stated by Charles Darwin in '*On the Origin of Species*'. By mimicking this process, EC could 'evolve' solutions to real-world problems, if they have been suitably encoded (problem representation is called *chromosome*). Automatic adaptation of membership functions is popularly known as *self tuning* and the chromosome encodes parameters of trapezoidal, triangle, logistic, hyperbolic-tangent, Gaussian membership functions, and so on. Evolutionary search of fuzzy rules can be carried out using three approaches. In the first method (Michigan approach), the fuzzy knowledge base is adapted as a result of antagonistic roles of competition and cooperation of fuzzy rules.

The second method (Pittsburgh approach), evolves a population of knowledge bases rather than individual fuzzy rules. Reproduction operators serve to provide a new combination of rules and new rules.

The third method (iterative rule learning approach), is very much similar to the first method with each chromosome representing a single rule, but contrary to the Michigan approach, only the best individual is considered to form part of the solution, discarding the remaining chromosomes of the population. The evolutionary learning process builds up the complete rule base through an iterative learning process (Cordón *et al*., 2001).

9 SUMMARY

Rule-based expert systems have been applied in a vast number of application areas. An important advantage of the fuzzy expert system is that the knowledge is expressed as easy-to-understand linguistic rules. If we have data, the fuzzy expert system can be taught using neural network

learning, EC, or other adaptation techniques. It is to be expected that the number of applications will grow considerably in the future now that success is clearly proven for these methods.

1 INTRODUCTION AND BIOLOGICAL MOTIVATION

A general introduction to artificial intelligence methods of measurement signal processing is given in **Article 128, Nature and Scope of AI Techniques, Volume 2**.

In nature, evolution is mostly determined by natural selection or different individuals competing for resources in the environment. Those individuals that are better are more likely to survive and propagate their genetic material. The encoding for genetic information (genome) is done in a way that admits asexual reproduction, which results in offspring that are genetically identical to the parent. Sexual reproduction allows some exchange and reordering of chromosomes, producing offspring that contain a combination of information from each parent. This is the recombination operation, which is often referred to as *crossover* because of the way strands of chromosomes cross over during the exchange. The diversity in the population is achieved by mutation operation.

Evolutionary algorithms are ubiquitous nowadays, having been successfully applied to numerous problems from different domains, including optimization, automatic programming, signal processing, bioinformatics, social systems, and so on. In many cases, the mathematical function, which describes the problem, is not known, and the values at certain parameters are obtained from simulations. In contrast to many other optimization techniques, an important advantage of evolutionary algorithms is they can cope with multimodal functions.

Usually found grouped under the term evolutionary computation or evolutionary algorithms (Bäck, 1996), are the domains of genetic algorithms (GA) (Holland, 1975), evolution strategies (Rechenberg, 1973; Schwefel, 1977), evolutionary programming (Fogel, Owens and Walsh, 1966), and genetic programming (Koza, 1992).

These all share a common conceptual base of simulating the evolution of *individual* structures via processes of *selection*, recombination, and mutation *reproduction*, thereby producing better solutions. The processes depend on the perceived performance of the individual structures as defined by the problem.

A population of candidate solutions (for the optimization task to be solved) is initialized. New solutions are created by applying reproduction operators (crossover and/or mutation). The fitness (how good the solutions are) of the resulting solutions is evaluated and suitable selection strategy is then applied to determine which solutions will be maintained into the next generation. The procedure is then iterated, as illustrated in Figure 1.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

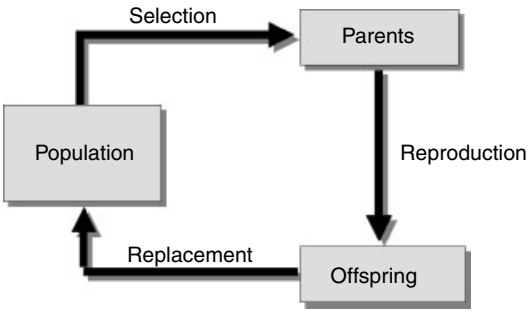

Figure 1. Flow chart of an evolutionary algorithm.

A primary advantage of evolutionary computation is that it is conceptually simple.

The procedure may be written as the difference equation:

$$x(t+1) = s\{v[x(t)]\} \tag{1}$$

where $x(t)$ is the population at time t under a representation x, v is a random variation (reproduction) operator, and s is the selection operator (Fogel, 1999).

1.1 Advantages of evolutionary algorithms

Following are some of the advantages of using evolutionary algorithms while compared to other global optimization techniques (Fogel, 1999).

1. Evolutionary algorithm performance is representation independent in contrast to other numerical techniques, which might be applicable for only continuous values or other constrained sets.
2. Evolutionary algorithms offer a framework such that it is comparably easy to incorporate prior knowledge about the problem. Incorporating such information focuses the evolutionary search, yielding a more efficient exploration of the state space of possible solutions.
3. Evolutionary algorithms can also be combined with more traditional optimization techniques. This may be as simple as the use of a gradient minimization after primary search with an evolutionary algorithm (e.g. fine tuning of weights of an evolutionary neural network) or it may involve simultaneous application of other algorithms (e.g. hybridizing with simulated annealing or Tabu search to improve the efficiency of basic evolutionary search).
4. The evaluation of each solution can be handled in parallel and only selection (which requires at least pair-wise competition) requires some serial processing. Implicit parallelism is not possible in many global optimization algorithms like simulated annealing and Tabu search.
5. Traditional methods of optimization are not robust to the dynamic changes in the problem of the environment and often require a complete restart in order to provide a solution (e.g. dynamic programming). In contrast, evolutionary algorithms can be used to adapt solutions to changing circumstance.
6. Perhaps, the greatest advantage of evolutionary algorithms comes from the ability to address problems for which there are no human experts. Although human expertise should be used when it is available, it often proves less than adequate for automating problem-solving routines.

2 GENETIC ALGORITHMS

A typical flowchart of a genetic algorithm is depicted in Figure 2. One iteration of the algorithm is referred to as a *generation*. The basic GA is very generic, and there are many aspects that can be implemented differently according to the problem (e.g. representation of solution (chromosomes), type of encoding, selection strategy, type of crossover and mutation operators, etc.). In practice, GAs are implemented by having arrays of bits or characters to represent the chromosomes. The individuals in the population

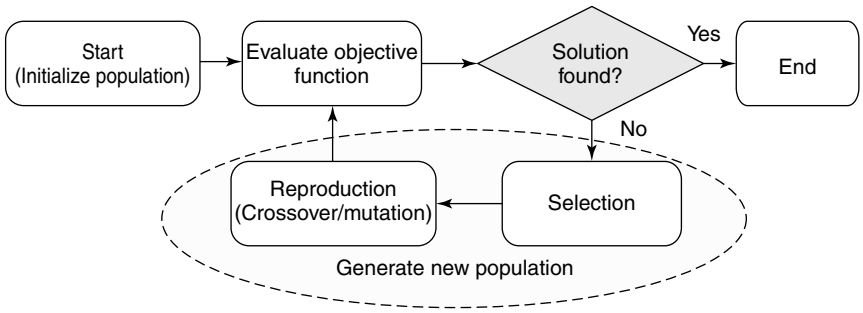

Figure 2. Flow chart of basic genetic algorithm iteration.

then go through a process of simulated evolution. Simple bit manipulation operations allow the implementation of crossover, mutation, and other operations. The number of bits for every gene (parameter) and the decimal range in which they decode are usually the same, but nothing precludes the utilization of a different number of bits or range for every gene.

When compared to other evolutionary algorithms, one of the most important GA feature is its focus on fixed-length character strings, although variable-length strings and other structures have been used.

2.1 Encoding and decoding

In a typical application of GAs, the given problem is transformed into a set of genetic characteristics (parameters to be optimized) that will survive in the best possible manner in the environment. For example, optimizing a function

$$\min f(x_1, x_2) = (x_1 - 5)^2 + (x_2 - 2)^2 \text{for} - 3 \leq x_1 3 \leq; \\ -8 \leq x_2 8 \leq \quad (2)$$

The parameters of the search are identified as x_1 and x_2, which are called the *phenotypes* in evolutionary algorithms. In genetic algorithms, the *phenotypes* (parameters) are usually converted to *genotypes* by using a coding procedure. Knowing the ranges of x_1 and x_2, each variable is to be represented using a suitable binary string. This representation using binary coding makes the parametric space independent of the type of variables used. The genotype (chromosome) should in some way contain information about solution, which is also known as *encoding*. GAs use a binary string encoding, as shown below.

Chromosome A: 110110111110100110110

Chromosome B: 11011110101010011110

Each bit in the chromosome strings can represent some characteristic of the solution. There are several types of encoding (e.g. direct integer or real numbers encoding), which directly depends on the problem.

Permutation encoding can be used in ordering problems, such as the traveling salesman problem (TSP) or task-ordering problem. In permutation encoding, every chromosome is a string of numbers, which represents numbers in a sequence. A chromosome using permutation encoding for a 9-city TSP problem will appear as follows:

Chromosome A: 4 5 3 2 6 1 7 8 9

Chromosome B: 8 5 6 7 2 3 1 4 9

The chromosome represents the order in which the salesman will visit the cities. Special care is taken to ensure that the strings represent real sequences after crossover and mutation. Floating-point representation is very useful for numeric optimization (e.g. for encoding the weights of a neural network).

It should be noted that in many recent applications, more sophisticated genotypes are appearing (e.g. chromosome can be a tree of symbols or a combination of a string and a tree, some parts of the chromosome are not allowed to evolve, etc.).

3 SCHEMA THEOREM

Theoretical foundations of evolutionary algorithms can be partially explained by the schema theorem (Holland, 1975), which relies on the concept of schemata. Schemata are templates that partially specify a solution (more strictly, a solution in the genotype space). If genotypes are strings built using symbols from an alphabet A, schemata are strings whose symbols belong to $A \cup (*)$. This extra-symbol $(*)$ must be interpreted as a wildcard, being loci occupied by it, called *undefined*. A chromosome is said to match a schema if they agree in the defined positions.

For example, the string 10011010 matches the schemata 1******* and **011*** among others but does not match *1*11*** because they differ in the second gene (the first defined gene in the schema).

A schema can be viewed as a hyperplane in a k-dimensional space, representing a set of solutions with common properties. Obviously, the numbers of solutions that match a schema H depend on the number of defined positions in it. Another related concept is the *defining-length* of a schema, defined as the distance between the first and the last defined positions in it.

The GA works by allocating strings to best schemata exponentially through successive generations, this being the selection mechanism mainly responsible for this behavior. On the other hand, the crossover operator is responsible for exploring new combinations of the present schemata in order to get the fittest individuals. Finally, the purpose of the mutation operator is to introduce fresh genotypic material in the population.

4 SELECTION AND REPRODUCTION

Individuals for producing offspring are chosen using a selection strategy after evaluating the fitness value of each individual in the selection pool. Each individual in the selection pool receives a reproduction probability

depending on its own fitness value and the fitness value of all other individuals in the selection pool. This fitness is used for the actual selection step afterwards. Some of the popular selection schemes are discussed below.

4.1 Roulette-wheel selection

The simplest selection scheme is the roulette-wheel selection, also called *stochastic sampling with replacement*. This technique is analogous to a roulette wheel with each slice proportional in size to the fitness. The individuals are mapped to contiguous segments of a line such that each individual's segment is equal in size to its fitness. A random number is generated and the individual whose segment spans the random number is selected. The process is repeated until the desired number of individuals is obtained. As illustrated in Figure 3, chromosome 1 has the highest probability for being selected since it has the highest fitness.

4.2 Rank-based fitness assignment

In rank-based fitness assignment, the population is sorted according to the objective values. The fitness assigned to each individual depends only on the position of the objective values in the individual's rank. Ranking introduces a uniform scaling across the population.

4.3 Tournament selection

In tournament selection, a number of individuals are chosen randomly from the population and the best individual from this group is selected as the parent. This process is repeated as often until there are sufficient individuals to choose. These selected parents produce uniformly random offspring. The tournament size will often depend on the problem, population size, and so on. The parameter for tournament selection is the tournament size. Tournament size takes values ranging from two to the total number of individuals in the population.

4.4 Elitism

When creating a new population by crossover and mutation, there is a big chance that we will lose the best chromosome. Elitism is the name of the method that first copies the best chromosome (or a few best chromosomes) to the new population. The rest is done in the classical way. Elitism can very rapidly increase performance of GA because it prevents losing the best-found solution.

4.5 Genetic operators

Crossover and mutation are two basic operators of GA. Performance of GA depends very much on the genetic operators. Type and implementation of operators depends on encoding and also on the problem. There are many ways of doing crossover and mutation. In this section, we will demonstrate some of the popular methods, with some examples and suggestions as to how to do it for different encoding schemes.

4.6 Crossover

Crossover selects genes from parent chromosomes and creates a new offspring. The simplest way to do this is to choose randomly some crossover point and everything before this point is copied from the first parent and then, everything after a crossover point is copied from the second parent. A single point crossover is illustrated as follows (| is the crossover point):

Chromosome A: 11011|00100110110

Chromosome B: 11011|11000011110

Offspring A: 11011|11000011110

Offspring B: 11011|00100110110

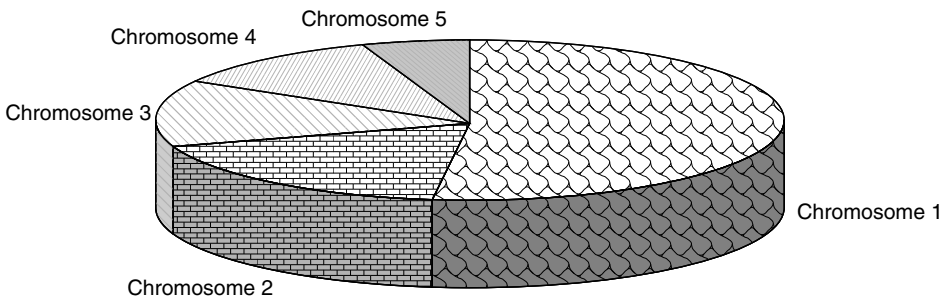

Figure 3. Roulette-wheel selection.

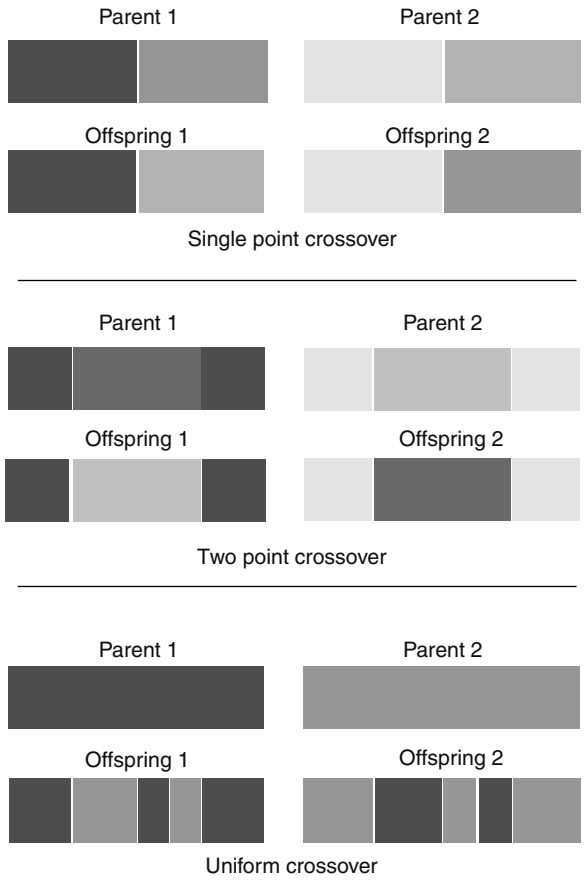

Figure 4. Types of crossover operators.

As illustrated in Figure 4, there are several crossover techniques. In a uniform crossover, bits are randomly copied from the first or the second parent. Specific crossover made for a specific problem can improve the GA performance.

4.7 Mutation

After crossover operation, mutation takes place. Mutation randomly changes the new offspring. For binary encoding, mutation is performed by changing a few randomly chosen bits from 1 to 0 or from 0 to 1. Mutation depends on the encoding as well as the crossover. For example, when we are encoding permutations, mutation could be exchanging two genes. A simple mutation operation is illustrated as follows:

Chromosome A: 1101111000011110

Chromosome B: 1101100100110110

Offspring A: 1100111000011110

Offspring B: 1101101100110110

For many optimization problems, there may be multiple, equal, or unequal optimal solutions. Sometimes, a simple GA cannot maintain stable populations at different optima of such functions. In the case of unequal optimal solutions, the population invariably converges to the global optimum. Niching helps to maintain subpopulations near global and local optima. A niche is viewed as an organism's environment and a species as a collection of organisms with similar features. Niching helps to maintain subpopulations near global and local optima by introducing a controlled competition among different solutions near every local optimal region. Niching is achieved by a sharing function, which creates subdivisions of the environment by degrading an organism's fitness proportional to the number of other members in its neighborhood. The amount of sharing contributed by individuals to their neighbor is determined by their proximity in the decoded parameter space (phenotypic sharing) based on a distance measure (Goldberg, 1989).

5 GA DEMONSTRATIONS

5.1 Rastrigin function

The Rastrigin function is a typical example of nonlinear multimodal function. It was first proposed by Rastrigin (Törn and Zilinskas, 1989) as a two-dimensional function and has later been generalized. This function is a fairly difficult problem due to its large search space and its large number of local minima. Rastrigin's function is defined as

$$F(x) = 10n + \sum_{i=1}^{n} x_i^2 - 10\cos(2\pi x_i), -5.12 \leq x_i \leq 5.12 \tag{3}$$

The function has just one global minimum, which occurs at the origin where the value of the function is 0. At any local minimum other than [0, 0], the value of Rastrigin's function is greater than 0. The farther the local minimum is from the origin, the larger the value of the function is at that point. Figure 5 illustrates the surface of the function for two input variables.

A real-value representation was used to encode the two input variables. The following parameters were used for the GA experiments.

- Mutation: 0.05, crossover: 0.90
- Population size: 20, number of iterations: 50, selection method: Roulette-wheel selection.

Figure 6 illustrates how the best fitness values were evolved during the 50 generations. As evident after 30 generations, the GA algorithm has succeeded in finding the best optimal solution.

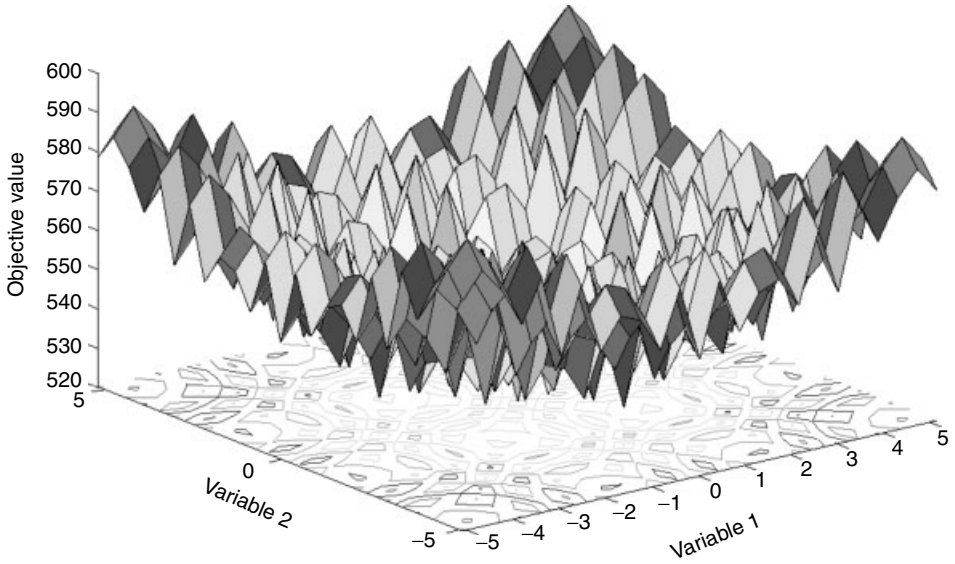

Figure 5. Rastrigin's function for two variables.

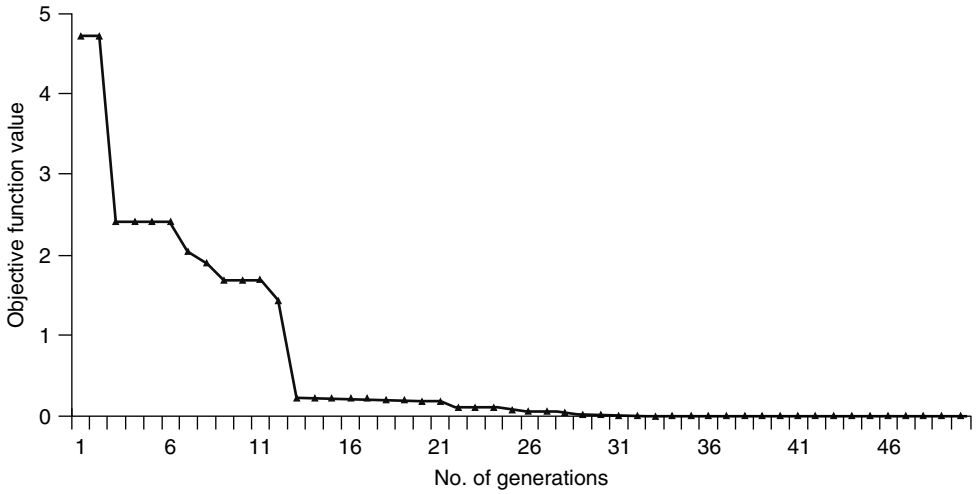

Figure 6. GA learning during the 50 generations.

5.2 Peaks function

Peaks function is a function of two variables, obtained by translating and scaling Gaussian distributions (Jang, Sun and Mizutani, 1997).

$$F(x, y) = 3(1-x)^2 \exp(-(x^2) - (y+1)^2) - 10\left(\frac{x}{5 - x^3 - y^5}\right) \exp(-x^2 - y^2) - \tfrac{1}{3}\exp(-(x+1)^2 - y^2) \quad \text{for } -3 \le x \le 3 \quad \text{and} \quad -3 \le y \le 3 \tag{4}$$

The Peak function surface is plotted in Figure 7, and the task is to find the optimum value (maximum) for the given range of x and y values. Using a population size of 30, the genetic algorithm was run for 25 iterations. Each input variable was represented using 8 bit. Crossover and mutation rates were set as 0.9 and 0.1 respectively.

Figure 8(a), (b), and (c), illustrate the convergence of the solutions on a contour plot of the surface. After 10 iterations, almost all the solutions were near the optimal point.

6 EVOLUTION STRATEGIES

Evolution strategy (ES) was developed by Rechenberg (1973) and Schwefel (1977). ES tends to be used for

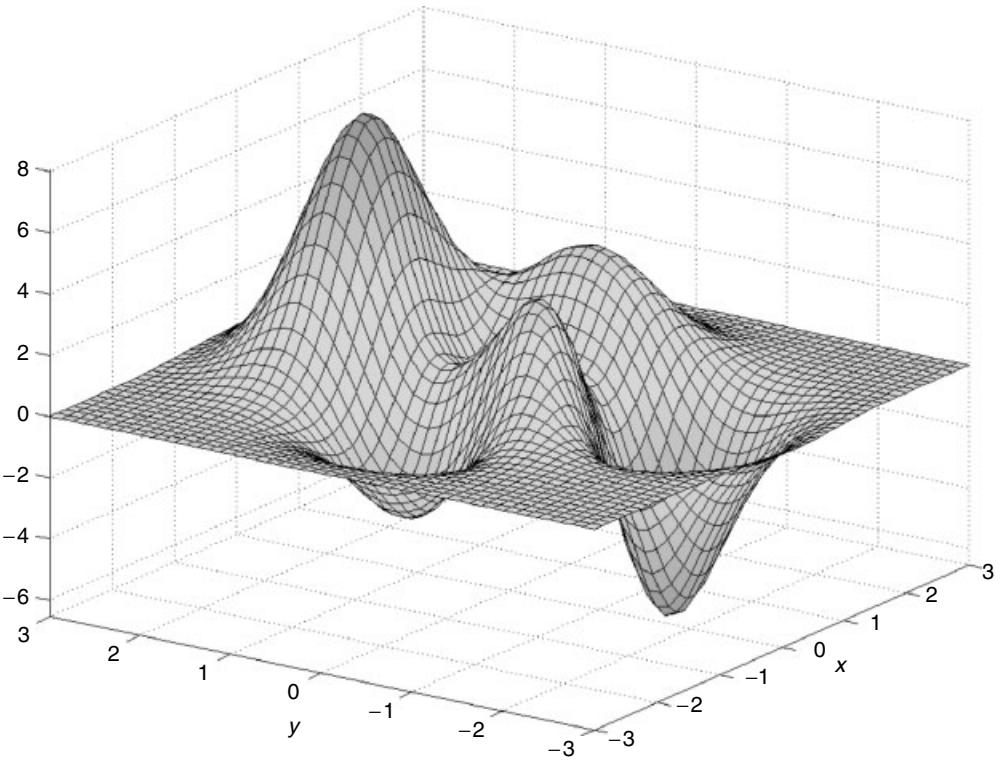

Figure 7. Surface of Peaks function.

empirical experiments that are difficult to model mathematically. The system to be optimized is actually constructed and ES is used to find the optimal parameter settings.

Evolution strategies merely concentrate on translating the fundamental mechanisms of biological evolution for technical optimization problems. The parameters to be optimized are often represented by a vector of real numbers (object parameters – o_p). Another vector of real numbers defines the strategy parameters (s_p), which controls the mutation of the objective parameters. Both object and strategic parameters form the data structure for a single individual.

A population P of n individuals could be described as follows:

$$P = (c_1, c_2, \ldots, c_{n-1}, c_n) \tag{5}$$

where the ith chromosome c_i is defined as: $c_i = (o_p, s_p)$

$$o_p = (o_1, o_2, \ldots, o_{n-1}, o_n) \quad \text{and}$$

$$s_p = (s_1, s_2, \ldots, s_{n-1}, s_n) \tag{6}$$

6.1 Mutation in evolution strategies

The mutation operator is defined as component-wise addition of normal distributed random numbers. Both the objective parameters and the strategy parameters of the chromosome are mutated. Objective parameter vector is calculated as follows:

$$o_{p(mut)} = o_p + N_0(s_p) \tag{7}$$

where $N_0(s_i)$ is the Gaussian distribution of mean value 0 and standard deviation s_i.

Usually, the strategy parameters mutation step size is done by adapting the standard deviation s_i. This may be done (for example) as follows:

$$s_{p(mut)} = ({s_1}^* A_1, {s_2}^* A_2, \ldots, {s_{n-1}}^* A_{n-1}, {s_n}^* A_n) \tag{8}$$

where A_i is randomly chosen from α or $1/\alpha$, depending on the value of equally distributed random variable E of [0,1]

$$A_i = \alpha \quad \text{if} \quad E < 0.5$$

$$A_i = \frac{1}{\alpha} \quad \text{if} \quad E \geq 0.5 \tag{9}$$

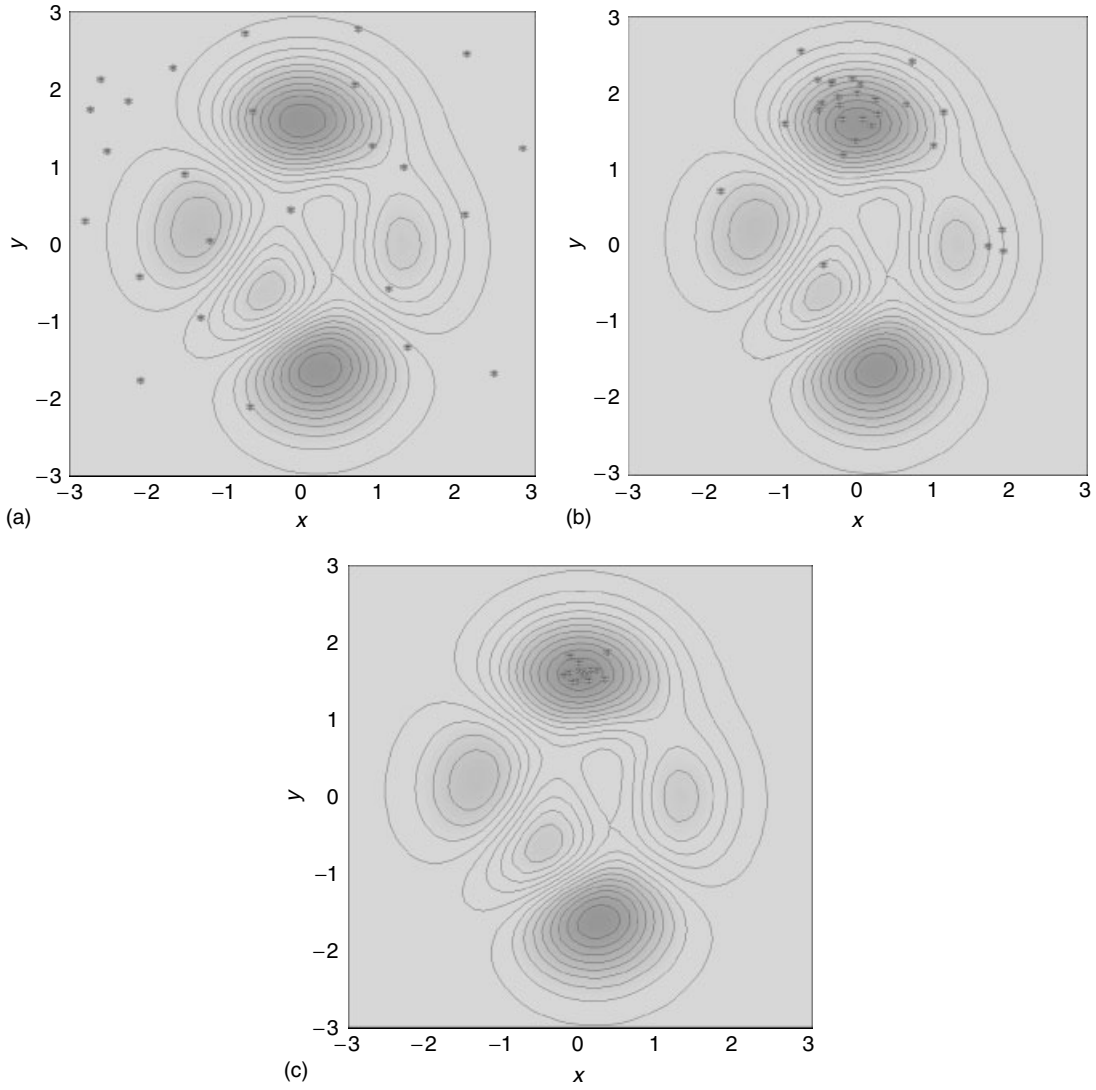

Figure 8. Convergence of solutions (a) generation 0; (b) after 5 generations; (c) after 20 generations (solution points are marked with *).

α is usually referred to as *strategy parameters adaptation value*.

6.2 Crossover (recombination) in evolution strategies

For two chromosomes $c_1 = (o_{p(c1)}, s_{p(c1)})$ and $c_2 = (o_{p(c2)}, s_{p(c2)})$, the crossover operator x is defined as follows:

$$\begin{aligned} R(c_1, c_2) &= c = (o_p, s_p) \\ \text{with } o_{p(i)} &= (o_{p(c1),i} | o_{p(c2),i}) \\ \text{and } s_{p(i)} &= (s_{p(c1),i} | s_{p(c2),i}) \end{aligned} \tag{10}$$

By defining $o_{p(i)}$ and $s_{p(i)} = (x|y)$, a value is randomly assigned for either x or y (50% selection probability for x and y).

6.3 Controlling the evolution

Let P be the number of parents in generation 1 and let C be the number of children in generation i. There are basically four different types of evolution strategies: P,C; $P + C$; $P/R, C$; and $P/R + C$, as discussed below. They mainly differ in how the parents for the next generation are selected and in the usage of crossover operators.

6.3.1 P,C *strategy*

The P parents produce C children, using mutation. Fitness values are calculated for each of the C children and the best P children become next-generation parents. The best individuals of C children are sorted by their fitness value and the first P individuals are selected to be next-generation parents ($C \geq P$).

6.3.2 P + C *strategy*

The P parents produce C children, using mutation. Fitness values are calculated for each of the C children and the best P individuals of both parents and children become next-generation parents. Children and parents are sorted by their fitness value and the first P individuals are selected to be next-generation parents.

6.3.3 P/R, C *strategy*

The P parents produce C children, using mutation and crossover. Fitness values are calculated for each of the C children and the best P children become next-generation parents. The best individuals of C children are sorted by their fitness value and the first P individuals are selected to be next-generation parents ($C \geq P$). Except for the usage of crossover operator, this is exactly the same as P,C strategy.

6.3.4 P/R + C *strategy*

The P parents produce C children, using mutation and recombination. Fitness values are calculated for each of the C children and the best P individuals of both parents and children become next-generation parents. Children and parents are sorted by their fitness value and the first P individuals are selected to be next-generation parents. Except for the usage of crossover operator, this is exactly the same as $P + C$ strategy.

7 EVOLUTIONARY PROGRAMMING

The book *Artificial Intelligence Through Simulated Evolution* by Fogel, Owens and Walsh (1966) is the landmark publication for evolutionary programming (EP). In this book, finite state automata are evolved to predict symbol strings generated from Markov processes and nonstationary time series (AI–FAQ-Genetic). The basic evolutionary programming method involves the following steps:

1. Choose an initial population (possible solutions at random). The number of solutions in a population is highly relevant to the speed of optimization, but no definite answers are available as to how many solutions are appropriate (other than > 1).
2. New offspring are created by mutation. Each offspring solution is assessed by computing its fitness. Typically, a stochastic tournament is held to determine the N solutions to be retained for the population of solutions. It should be noted that, typically, evolutionary programming method does not use any crossover as a genetic operator.

7.1 Evolutionary programming versus genetic algorithms

1. GA is implemented by having arrays of bits or characters to represent the chromosomes. In EP, there are no such restrictions for the representation. In most cases, the representation follows from the problem.
2. EP typically uses an adaptive mutation operator in which the severity of mutations is often reduced as the global optimum is approached, while GAs use a prefixed mutation operator. Among the schemes to adapt the mutation step size, the most widely studied is the 'meta-evolutionary' technique in which the variance of the mutation distribution is subject to mutation by a fixed variance mutation operator that evolves along with the solution.

7.2 Evolutionary programming versus evolution strategies

1. When implemented to solve real-valued function optimization problems, both typically operate on the real values themselves and use adaptive reproduction operators.
2. EP typically uses stochastic tournament selection, while ES typically uses deterministic selection.
3. EP does not use crossover operators, while ES (P/R, C and $P/R + C$ strategies) crossover. However, the effectiveness of the crossover operators depends on the problem at hand.

8 GENETIC PROGRAMMING

The genetic programming (GP) technique provides a framework for automatically creating a working computer program from a high-level statement of the problem (Koza, 1992).

Genetic programming achieves this goal of automatic programming by genetically breeding a population of computer programs, using the principles of Darwinian natural selection and biologically inspired operations. The operations include most of the techniques discussed in the previous sections. The main difference between GP and GA is the representation of the solution. GP creates computer programs in the LISP or scheme computer languages as the solution. LISP is an acronym for LISt Processor and was developed in the late 1950s (History of LISP, 2004). Unlike most languages, LISP is usually used as an interpreted language. This means that, unlike compiled languages, an interpreter can process and respond directly to programs written in LISP.

The main reason for choosing LISP to implement GP is because of the advantage that the programs and data have the same structure, which could provide easy means for manipulation and evaluation.

In GP, the individual population members are not fixed-length character strings that encode possible solutions to the problem at hand, they are programs that, when executed, are the candidate solutions to the problem. These programs are expressed in genetic programming as parse trees rather than as lines of code. For example, the simple program '$a + b * c$' would be represented as shown in Figure 9. The terminal and function sets are also important components of genetic programming. The terminal and function sets are the alphabets of the programs to be made. The terminal set consists of the variables and constants of the programs (e.g. A, B, and C in Figure 9).

The most common way of writing down a function with two arguments is the infix notation. That is, the two arguments are connected with the operator symbol between them as follows.

$$A + B$$

A different method is the prefix notation. Here, the operator symbol is written down first, followed by its required arguments.

$$+AB$$

While this may be a bit more difficult or just unusual for human eyes, it opens some advantages for computational uses. The computer language LISP uses symbolic expressions (or S-expressions) composed in prefix notation. Then, a simple S-expression could be

$$(operator, argument),$$

where *operator* is the name of a function and *argument* can be either a constant or a variable or another symbolic expression, as shown below.

$$(operator, argument\,(operator, argument)$$
$$(operator, argument))$$

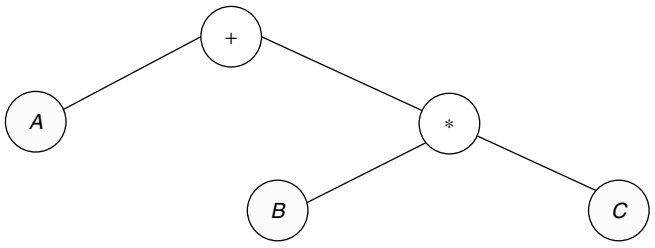

Figure 9. A simple tree structure of GP.

9 GENETIC PROGRAMMING BASICS

A parse tree is a structure that develops the interpretation of a computer program. Functions are written down as nodes and their arguments as leaves. A subtree is the part of a tree that is under an inner node of this tree, as illustrated in Figure 10. If this tree is cut out from its parent, the inner node becomes a root node and the subtree is a valid tree of its own.

There is a close relationship between these parse trees and S-expression; in fact, these trees are just another way of writing down expressions. While functions will be the nodes of the trees (or the operators in the S-expressions) and can have other functions as their arguments, the leaves will be formed by terminals, that is, symbols that may not be further expanded. Terminals can be variables, constants, or specific actions that are to be performed. The process of selecting the functions and terminals that are needed or are useful for finding a solution to a given problem is one of the key steps in GP. Evaluation of these structures is straightforward. Beginning at the root node, the values of all subexpressions (or subtrees) are computed, descending the tree down to the leaves. GP procedure could be summarized as follows:

- generate an initial population of random compositions of the functions and terminals of the problem;
- compute the fitness values of each individual in the population;
- using some selection strategy and suitable reproduction operators, produce offsprings;
- iterate the procedure until the required solution is found or the termination conditions have been reached (specified number of generations).

The creation of an offspring from the crossover operation is accomplished by deleting the crossover fragment of the first parent and then inserting the crossover fragment of the second parent. The second offspring is produced in a symmetric manner. A simple crossover operation is illustrated in Figure 11. In GP, the crossover operation is

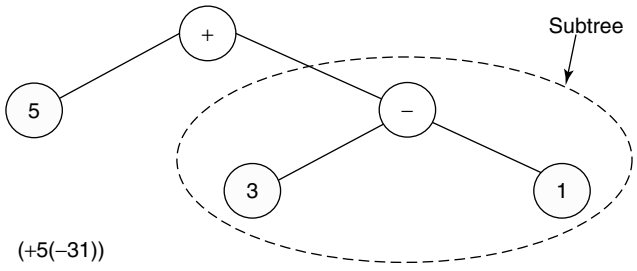

Figure 10. Illustration of a parse tree and a subtree.

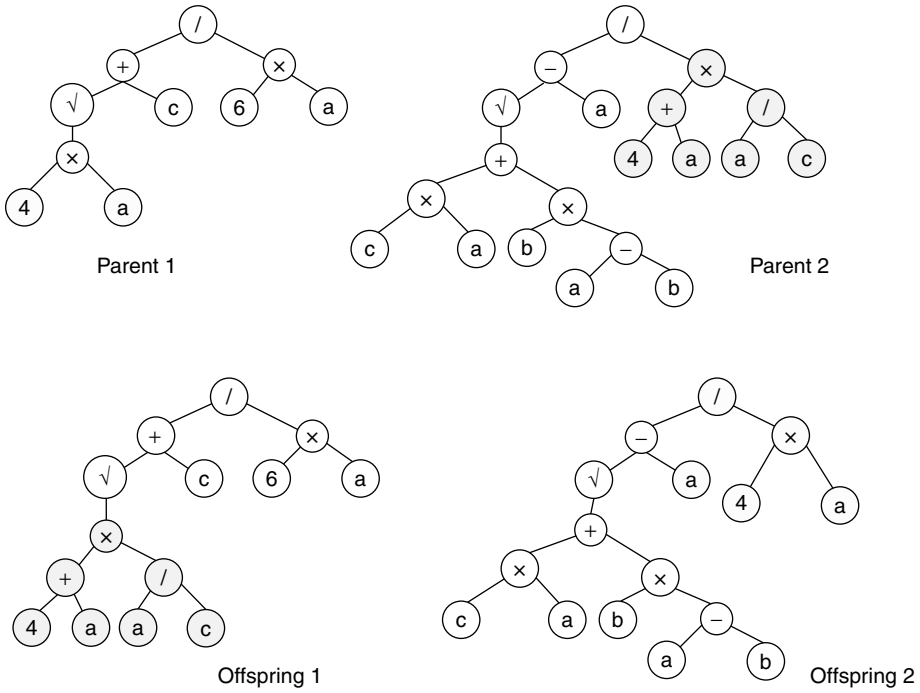

Figure 11. Illustration of crossover operator.

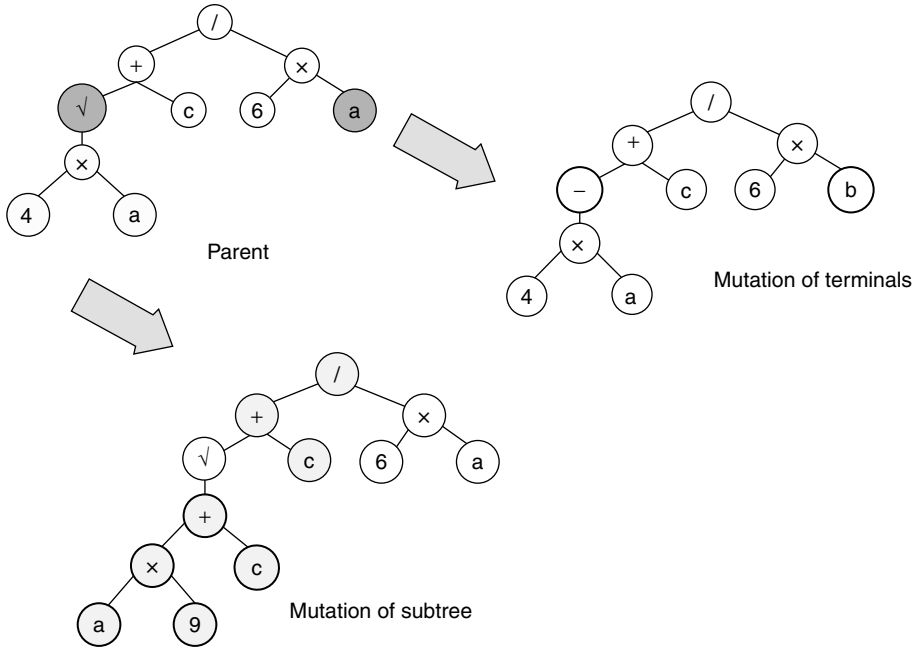

Figure 12. Illustration of mutation operator in GP.

implemented by taking randomly selected subtrees in the individuals and exchanging them.

Mutation is another important feature of genetic programming. Two types of mutations are commonly used. The simplest type is to replace a function or a terminal by another function or a terminal respectively. In the second kind, an entire subtree can replace another subtree. Figure 12 explains the concepts of mutation.

GP requires data structures that are easy to handle and evaluate and are robust to structural manipulations. These are among the reasons why the class of S-expressions was chosen to implement GP. The set of functions and terminals

that will be used in a specific problem has to be chosen carefully. If the set of functions is not powerful enough, a solution may be very complex or may not be found at all. Like in any evolutionary computation technique, the generation of the first population of individuals is important for successful implementation of GP. Some of the other factors that influence the performance of the algorithm are the size of the population, percentage of individuals that participate in the crossover/mutation, maximum depth for the initial individuals and the maximum allowed depth for the generated offspring, and so on. Some specific advantages of genetic programming are that no analytical knowledge is needed and still accurate results could be obtained. GP approach does scale with the problem size. GP does impose restrictions on how the structure of solutions should be formulated.

10 SUMMARY

This article presents the biological motivation and fundamental aspects of evolutionary algorithms and its constituents, namely, genetic algorithm, evolution strategies, evolutionary programming, and genetic programming. Performance of genetic algorithms is demonstrated using two function optimization problems. Important advantages of evolutionary computation as compared to classical optimization techniques are also discussed.

1 INTRODUCTION

Data acquisition systems (DAS) interface between the real world of physical parameters, which are analog, and the artificial world of digital computation and control. With current emphasis on digital systems, the interfacing function has become an important one; digital systems are used widely because complex circuits are low cost, accurate, and relatively simple to implement. In addition, there is rapid growth in the use of microcomputers to perform difficult digital control and measurement functions.

Computerized feedback control systems are used in many different industries today in order to achieve greater productivity in our modern industrial societies. Industries that presently employ such automatic systems include steel making, food processing, paper production, oil refining, chemical manufacturing, textile production, cement manufacturing, and others.

The devices that perform the interfacing function between analog and digital worlds are analog-to-digital (A/D) and digital-to-analog (D/A) converters, which together are known as *data converters*. Some of the specific applications in which data converters are used include data telemetry systems, pulse code modulated communications, automatic test systems, computer display systems, video signal processing systems, data logging systems, and sampled data control systems. In addition, every laboratory digital multimeter or digital panel meter contains an A/D converter.

2 BASIC DATA ACQUISITION SYSTEM

Besides A/D and D/A converters, data acquisition and distribution systems may employ one or more of the following circuit functions:

- transducers,
- amplifiers,
- filters,
- nonlinear analog functions,
- analog multiplexers,
- sample-holds.

The interconnection of these components is shown in the diagram of the data acquisition portion of a computerized feedback control system in Figure 1.

The input to the system is a physical parameter such as temperature, pressure, flow, acceleration, and position, which are analog quantities. The parameter is first converted into an electrical signal by means of a transducer; once in electrical form, all further processing is done by electronic circuits.

Next, an amplifier boosts the amplitude of the transducer output signal to a useful level for further processing (*see also* **Article 133, Amplifiers and Filters for DAS, Volume 3**). Transducer outputs may be microvolt or millivolt level signals, which are then amplified to 1 to 10 V levels. Furthermore, the transducer output may be a high-impedance signal, a differential signal with common-mode noise, a current output, a signal superimposed on a high

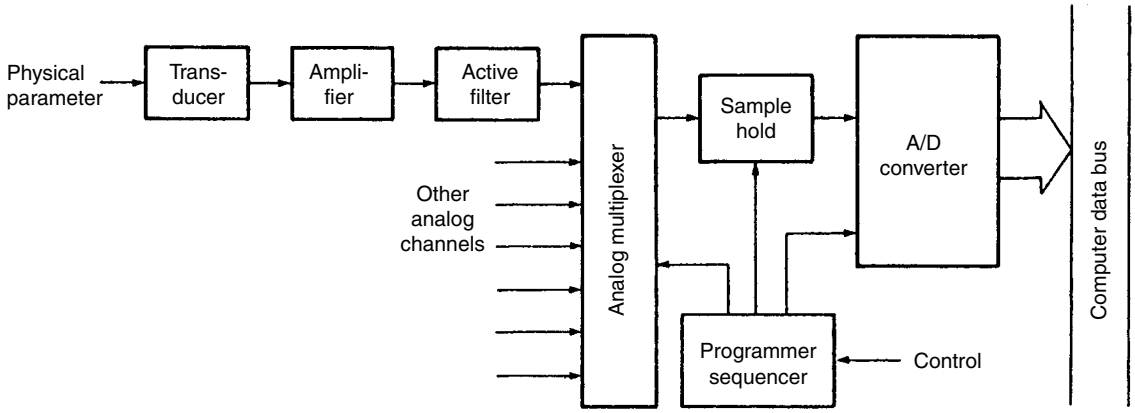

Figure 1. Data acquisition system. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

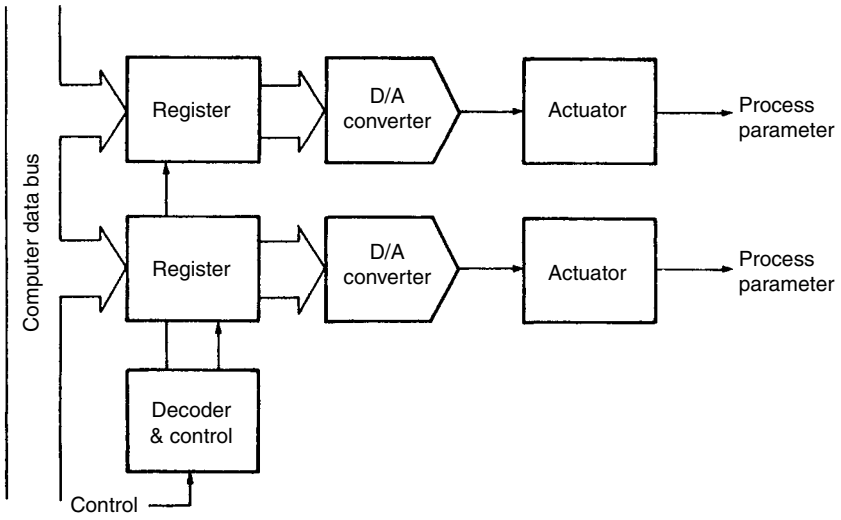

Figure 2. Data distribution system. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

voltage, or a combination of these. The amplifier, in order to convert such signals into a high-level voltage, may be one of several specialized types.

The amplifier is frequently followed by a low-pass active filter that reduces high-frequency signal components, unwanted electrical interference noise, or electronic noise from the signal (*see also* **Article 133, Amplifiers and Filters for DAS, Volume 3**). The amplifier is sometimes also followed by a special nonlinear analog function circuit that performs a nonlinear operation on the high-level signal. Such operations include squaring, multiplication, division, rms conversion, log conversion, or linearization.

The processed analog signal next goes to an analog multiplexer, which switches sequentially between a number of different analog input channels (*see also* **Article 134, Analog Multiplexers, Volume 3**). Each input is in turn connected to the output of the multiplexer for a specified period of time by the multiplexer switch. During this connection time, a sample-hold circuit acquires the signal voltage and then holds its value while an A/D converter converts the value into digital form. The resultant digital word goes to a computer data bus or to the input of a digital circuit.

Thus the analog multiplexer, together with the sample-hold, time shares the A/D converter with a number of analog input channels (*see also* **Article 135, Sample-hold Circuits, Volume 3**). The timing and control of the complete DAS is done by a digital circuit called a *programmer-sequencer*, which in turn is under the control of the computer. In some cases, the computer itself may control the entire DAS.

While this is perhaps the most commonly used DAS configuration, there are alternative ones. Instead of multiplexing high-level signals, low-level multiplexing

is sometimes used with the amplifier following the multiplexer. In such cases, just one amplifier is required, but its gain may have to be changed from one channel to the next during multiplexing. Another method is to amplify and convert the signal into digital form at the transducer location and send the digital information in serial form to the computer. Here, the digital data must be converted to parallel form and then multiplexed onto the computer data bus.

3 BASIC DATA DISTRIBUTION SYSTEM

The data distribution portion of a feedback control system, illustrated in Figure 2, is the reverse of the data acquisition system. The computer, based on the inputs of the data acquisition system, must close the loop on a process and control it by means of output control functions. These control outputs are in digital form and must, therefore, be converted into analog form in order to drive the process. The conversion is accomplished by a series of D/A converters as shown (also often called DAC's). Each D/A converter is coupled to the computer data bus by means of a register, which stores the digital word until the next update. The registers are activated sequentially by a decoder and control circuit, which is under computer control.

The D/A converter outputs then drive actuators that directly control the various process parameters such as temperature, pressure, and flow. Thus, the loop is closed on the process and the result is a complete automatic process control system under computer control.

1 OPERATIONAL AND INSTRUMENTATION AMPLIFIERS

The front end of a data acquisition system extracts the desired analog signal from a physical parameter by means of a transducer and then amplifies and filters it. An amplifier and filter are critical components in this initial signal processing. The amplifier must perform one or more of the following functions: boost the signal amplitude, buffer the signal, convert a signal current into a voltage, or extract a differential signal from common-mode noise.

To accomplish these functions, requires a variety of different amplifier types. The most popular type of electronic amplifier is an operational amplifier (opamp), which is a general purpose gain block having differential inputs. The opamp may be connected in many different closed-loop configurations to make it provide a range of functions; a few are shown in Figure 1. The gain and bandwidth of the circuits shown depend on the external resistors connected around the amplifier. An operational amplifier is a good choice in general where a single-ended signal is to be amplified, buffered, or converted from current to voltage.

In the case of differential signal processing, the instrumentation amplifier is a better choice since it maintains high impedance at both its differential inputs and the gain is set by a precision resistor located elsewhere in the amplifier circuit. One type of instrumentation amplifier circuit is shown in Figure 2. Notice that no gain-setting resistors are connected to either of the input terminals. Instrumentation amplifiers have the following important characteristics:

- high impedance differential inputs;
- low input offset voltage drift;
- low input bias currents;
- gain easily set by means of one or two external resistors;
- high common-mode rejection ratio.

2 COMMON-MODE REJECTION PRINCIPLE AND APPLICATION

The common-mode rejection ratio CMRR is an important parameter of differential amplifiers. An ideal differential input amplifier responds only to the voltage difference between its input terminals and does not respond at all to any voltage that is common to both input terminals (common-mode voltage). In nonideal amplifiers, however, the common-mode input signal causes some output response even though small compared to the response to a differential input signal.

The common-mode rejection ratio is defined as the ratio of differential and common-mode responses. The CMRR of an amplifier is the ratio of differential voltage gain to common-mode voltage gain and is generally expressed in dB:

$$\mathrm{CMRR} = 20 \log_{10} \left(\frac{A_{\mathrm{D}}}{A_{\mathrm{CM}}} \right) \tag{1}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

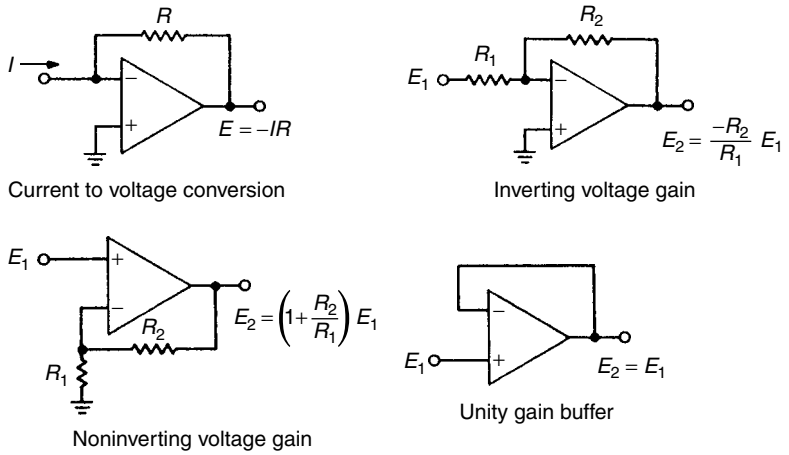

Figure 1. Operational amplifier configurations. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

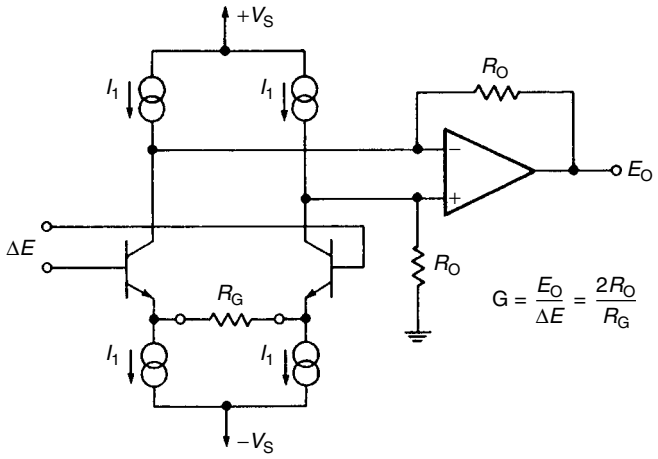

Figure 2. Simplified instrumentation amplifier circuit. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

where A_D is differential voltage gain and A_{CM} is common-mode voltage gain. CMRR is a function of frequency and, therefore, also a function of the impedance balance between the two amplifier's input terminals. At even moderate frequencies, CMRR can be significantly degraded by small unbalances in the source series resistance and shunt capacitance.

3 SPECIALIZED AMPLIFIERS USED IN DAS

There are several other special amplifiers that are useful in conditioning the input signal in a data acquisition system.

An isolation amplifier is used to amplify a differential signal, which is superimposed on a very high common-mode voltage, perhaps of several hundred or even of several thousand volts. The isolation amplifier has the characteristics of an instrumentation amplifier with a very high common-mode input voltage capability. Another special amplifier, the chopper stabilized amplifier, is used to accurately amplify microvolt level signals to the required amplitude. This amplifier employs a special switching stabilizer, which gives extremely low input offset voltage drift. Another useful device, the electrometer amplifier, has ultralow input bias currents, generally less than one picoampere and is used to convert extremely small signal currents into a high-level voltage.

4 FILTERS FOR USE WITH DAS

A low-pass filter frequently follows the signal processing amplifier to reduce signal noise. Low-pass filters are used for the following reasons: to reduce man-made electrical interference noise, to reduce electronic noise, and to limit the bandwidth of the analog signal to less than half the sampling frequency in order to eliminate frequency folding. When used for the last reason, the filter is called a *presampling filter* or an *antialiasing filter* (*see also* **Article 138, Sampling Theory Relevant to DAS, Volume 3**).

Man-made electrical noise is generally periodic, as, for example, in power line interference, and is sometimes reduced by means of a special filter such as a notch filter. Electronic noise, on the other hand, is random noise with noise power proportional to bandwidth and is present in transducer resistances, circuit resistances, and in amplifiers themselves. It is reduced by limiting the bandwidth of the

system to the minimum required to pass the desired signal components (*see also* **Article 181, Amplitude Modulated Signals: The Lock-in Amplifier, Volume 3**; **Article 180, Bandwidth Reduction of Baseband DC Signals, Volume 3**; **Article 179, Input Connections; Grounding and Shielding, Volume 3**; **Article 176, Signals and Signal-to-noise Ratio, Volume 3**; **Article 178, Noise Matching and Preamplifier Selection, Volume 3**; and **Article 121, Signals in the Presence of Noise, Volume 2**).

Grounding and shielding of amplifiers is an important topic in amplifier design – *see* **Article 177, Grounding and Shielding, Volume 3**.

No filter does a perfect job of eliminating noise or other undesirable frequency components, and therefore the choice of a filter is always a compromise. Ideal filters, frequently used as analysis examples, have flat passband response with infinite attenuation at the cutoff frequency, but are mathematical filters only and not physically realizable.

In practice, the systems engineer has a choice of cutoff frequency and attenuation rate. The attenuation rate and resultant phase response depend on the particular filter characteristic and the number of poles in the filter function. Some of the more popular filter characteristics used include the Butterworth, Chebyshev, Bessel, and elliptic alternatives. In making this choice, the effect of overshoot and nonuniform phase delay must be carefully considered. Figure 3 illustrates some practical low-pass filter response characteristics (*see also* **Article 125, Outline of Purpose of Analog Data Filters, Volume 2**).

Passive RLC filters are seldom used in signal processing applications today chiefly due to the undesirable characteristics of inductors. Active filters are generally used now since they permit the filter characteristics to be accurately set by precision and stable resistors and capacitors. Inductors, with their undesirable saturation and temperature drift characteristics, are thereby eliminated. Also, because active filters use operational amplifiers, the problems of insertion loss and output loading are also eliminated.

Filters are often implemented in digital form. These are based on the analog design concepts but the digitization, which introduced sampling issues, increases the complexity of operation considerably. Fortunately, the user is buffered from the mathematics and usually can work from data sheets to select hardware and software settings for the IC modules provided.

1 ANALOG MULTIPLEXER OPERATION

Analog multiplexers are the circuits that time-share an analog-to-digital (A/D) converter among a number of different analog channels. Since the A/D converter in many cases is the most expensive component in a data acquisition system, multiplexing analog inputs to the A/D converter is an economical approach. Usually, the analog multiplexer operates in a sample-hold circuit (*see also* **Article 135, Sample-hold Circuits, Volume 3**), which holds the required analog voltage long enough for A/D conversion.

As shown in Figure 1, an analog multiplexer consists of an array of parallel electronic switches connected to a common output line. Only one switch is turned on at a time. Popular switch configurations include 4, 8, and 16 channels that are connected in single single-ended or dual differential configurations.

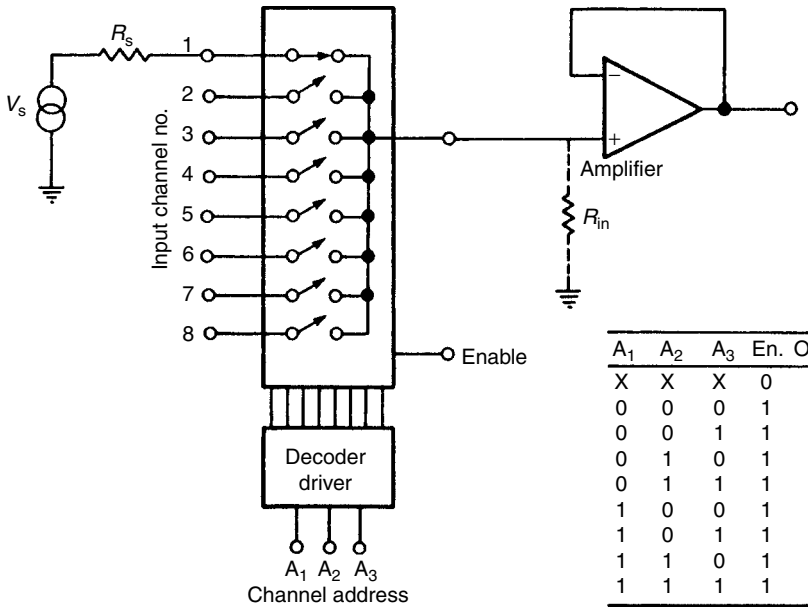
The multiplexer also contains a decoder-driver circuit that decodes a binary input word and turns on the appropriate switch. This circuit interfaces with standard TTL inputs and drives the multiplexer switches with the proper control voltages. For the 8-channel analog multiplexer shown, a one-of-eight decoder circuit is used.

Most analog multiplexers today employ the CMOS switch circuits based on the one shown in Figure 2. A CMOS driver controls the gates of the parallel-connected P-channel and N-channel MOSFETs. Both switches turn on together with the parallel connection giving relatively uniform on-resistance over the required analog input voltage range. The resulting on-resistance may vary from about 50 Ω to 2 kΩ depending on the multiplexer; this resistance increases with temperature.

2 ANALOG MULTIPLEXER CHARACTERISTICS

Because of the series resistance, it is common practice to operate an analog multiplexer into a very high load resistance such as the input of a unity gain buffer amplifier shown in Figure 1. The load impedance must be large compared with the switch on-resistance and any series source resistance in order to maintain high transfer accuracy. Transfer error is the input to output error of the multiplexer with the source and load connected; error is expressed as a percent of input voltage.

Transfer errors of 0.1 to 0.01% or less are required in most data acquisition systems. This is readily achieved by using operational amplifier buffers with typical input impedances from 10^8 to 10^{12} Ω. Many sample-hold circuits also have very high input impedances.



Another important characteristic of analog multiplexers is break-before-make switching. There is a small time delay between disconnection from the previous channel and connection to the next channel, which assures that two adjacent input channels are never instantaneously connected together.

Settling time is another important specification for analog multiplexers; it is the same definition given for amplifiers

except that it is measured from the time the channel is switched on. Throughput rate is the highest rate at which a multiplexer can switch from channel to channel with the output settling to its specified accuracy. Crosstalk is the ratio of output voltage to input voltage with all channels connected in parallel and off; it is generally expressed as an input to output attenuation ratio in decibels.

As shown in the representative equivalent circuit of Figure 3, analog multiplexer switches have a number of leakage currents and capacitances associated with their operation. These parameters are specified on data sheets and must be considered in the operation of the devices. Leakage currents, generally in picoamperes at room temperature, become troublesome only at high temperatures. Capacitances affect crosstalk and settling time of the multiplexer.

3 ANALOG MULTIPLEXER APPLICATIONS

Analog multiplexers are employed in two basic types of operation; low level and high level. In high-level multiplexing, the most popular type, the analog signal is amplified to the 1 to 10 V range ahead of the multiplexer. This has the advantage of reducing the effects of noise on the signal during the remaining analog processing. In low-level multiplexing, the signal is amplified after multiplexing; therefore, great care must be exercised in handling the low-level signal up to the multiplexer. Low-level multiplexers generally use two-wire differential switches in order to minimize noise pickup. Reed relays, because of essentially zero series

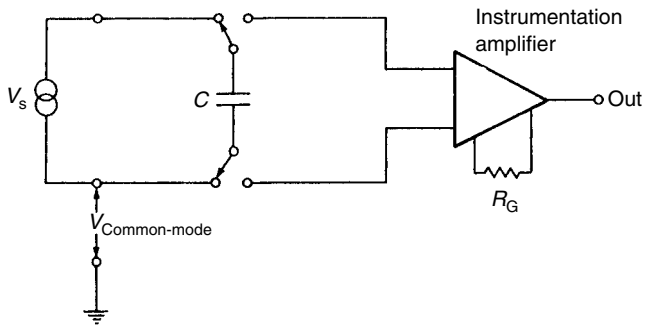

Figure 4. Flying-capacitor multiplexer switch. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

resistance and absence of switching spikes are frequently employed in low-level multiplexing systems. They are also useful for high common-mode voltages.

A useful specialized analog multiplexer is the flying-capacitor type. This circuit, shown as a single channel in Figure 4 has differential inputs and is particularly useful with high common-mode voltages. The capacitor connects first to the differential analog input, charging up to the input voltage, and is then switched to the differential output, which goes to a high input impedance instrumentation amplifier. The differential signal is, therefore, transferred to the amplifier input without the common mode voltage and is then further processed up to A/D conversion.

In order to realize large numbers of multiplexed channels, it is possible to connect analog multiplexers in parallel using the enable input to control each device. This is called *single-level multiplexing*. The output of several multiplexers can also be connected to the inputs of another to expand the number of channels; this method is *double-level multiplexing*.

1 ROLE AND OPERATION OF SAMPLE-HOLD CIRCUIT IN DAS

Sample-hold circuits are the devices that store analog information and reduce the aperture time of an analog-to-digital (A/D) converter (*see also* **Article 138, Sampling Theory Relevant to DAS, Volume 3**; **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**).

A sample hold is simply a voltage-memory device in which an input voltage is acquired and then stored on a high quality capacitor. A popular circuit is shown in Figure 1.

A_1 is an input buffer amplifier with a high input impedance so that the source, which may be an analog multiplexer (*see also* **Article 134, Analog Multiplexers, Volume 3**), is not loaded. The output of A_1 must be capable of driving the hold capacitor with stability and enough drive current to charge it rapidly. S is an electronic switch, generally field effect transistor, FET, which is rapidly switched on or off by a driver circuit that interfaces with transistor transistor logic (TTL) inputs.

C is a capacitor with low leakage and low dielectric absorption characteristics; it is a polystyrene, polycarbonate, polypropylene, or Teflon type. In the case of hybrid sample holds, the metal oxide semiconductor, MOS type capacitor is frequently used.

A_2 is the output amplifier that buffers the voltage on the hold capacitor. It must, therefore, have extremely low input bias current, and for this reason a FET input amplifier is required.

There are two modes of operation for a sample hold: sample mode or tracking mode, when the switch is closed; and hold mode, when the switch is open. Sample holds are usually operated in one of two basic ways. The device can continuously track the input signal and be switched into the hold mode only at certain specified times, spending most of the time in tracking mode. This is the case for a sample hold being employed as a deglitcher at the output of a digital-to-analog (D/A) converter, for example, *see* **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**.

Alternatively, the device can stay in the hold mode most of the time and go to the sample mode just to acquire a new input signal level. This is the case for a sample hold used in a data acquisition system following the multiplexer (*see also* **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**).

2 SAMPLE-HOLD UNIT AS A DATA RECOVERY FILTER

A common application for sample-hold circuits is in data recovery, or signal reconstruction, filters. The problem is to reconstruct a train of analog samples into the original signal; when used as a recovery filter, the sample hold is known as a *zero-order hold*. It is a useful filter because it fills in the space between samples, providing data smoothing.

As with other filter circuits, the gain and phase components of the transfer function are of interest. By an analysis

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

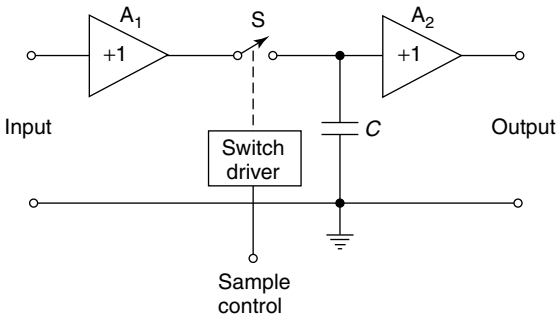

Figure 1. Popular sample-hold circuit. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

based on the impulse response of a sample hold and use of the Laplace transform, the transfer function is found to be

$$G_0(f) = \frac{1}{f_s} \frac{\sin\left(\dfrac{\pi \times f}{f_s}\right)}{\dfrac{\pi \times f}{f_s}} e^{\left(-j\frac{\pi \times f}{f_s}\right)} \qquad (1)$$

where f_s is the sampling frequency. This function contains the familiar $(\sin x)/x$ term plus a phase term, both of which are plotted in Figure 2.

The sample hold is, therefore, a low-pass filter with a cutoff frequency slightly less than $f_s/2$ and a linear phase that results in a constant delay time of $T/2$, where T is the time between samples. Notice that the gain function also has significant response lobes beyond f_s. For this reason, a sample-hold reconstruction filter is frequently followed by another conventional low-pass filter.

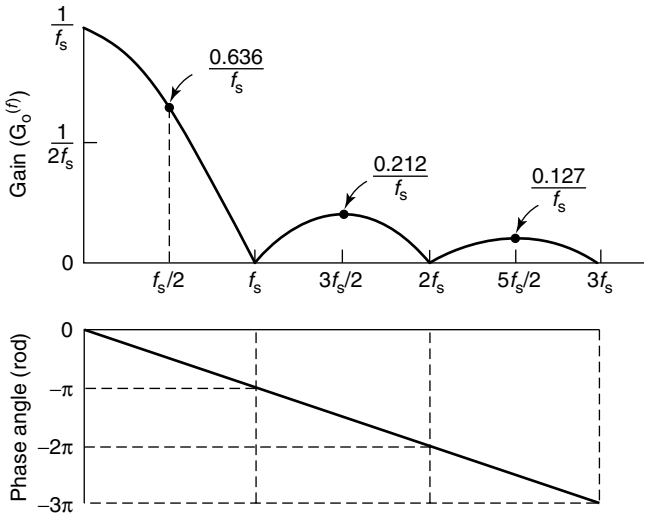

Figure 2. Gain and phase components of zero-order hold transfer function. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

3 SPECIALIZED SAMPLE-HOLD CIRCUITS

In addition to the basic circuit of Figure 1, several other sample-hold circuit configurations are frequently used. Figure 3 shows two such circuits that are closed-loop circuits as contrasted with the open-loop circuit of Figure 1. Figure 3(a) uses an operational integrator and another amplifier to make a fast, accurate inverting sample hold. A buffer amplifier is sometimes added in front of this circuit to give high input impedance. Figure 3(b) shows a high input impedance, noninverting sample-hold circuit.

The circuit in Figure 1, although generally not as accurate as those in Figure 3, can be used with a diode-bridge switch to realize ultrafast acquisition sample holds.

4 SAMPLE-HOLD CHARACTERISTICS

A number of parameters are important in characterizing sample-hold performance. Probably the most important of these is the acquisition time. The definition is similar to the definition of settling time for an amplifier (*see also* **Article 133, Amplifiers for DAS, Volume 3**). It is the time required, after the sample command is given, for the hold capacitor to charge to a full-scale

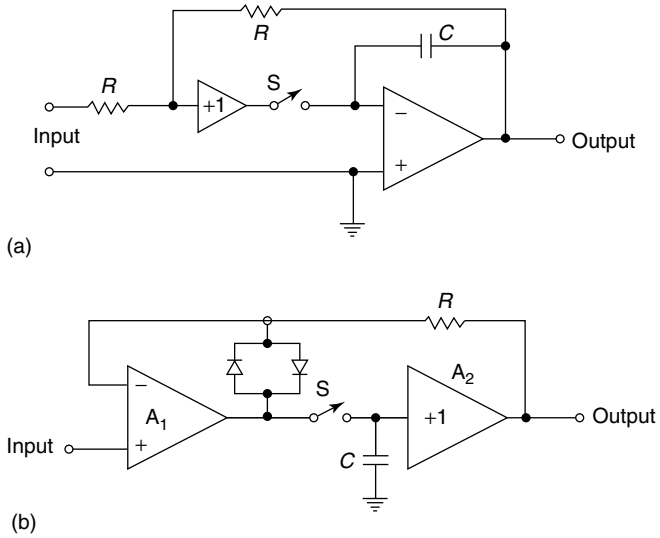

Figure 3. Accurate closed-loop sample-hold circuits: (a) inverting and (b) noninverting. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

voltage change and remain within a specified error band around final value.

Several hold-mode specifications are also important. Hold-mode droop is the output voltage change per unit time when the sample switch is open. This droop is caused by the leakage currents of the capacitor and switch, and the output amplifier bias current. Hold-mode feedthrough is the percentage of input signal transferred to the output when the sample switch is open. It is measured with a sinusoidal input signal and caused by capacitive coupling.

The most critical phase of sample-hold operation is the transition from the sample mode to the hold mode. Several important parameters characterize this transition. Sample-to-hold offset or step error is the change in output voltage from the sample mode to the hold mode, with a constant input voltage. It is caused by the switch still transferring some charge onto the hold capacitor as it turns off.

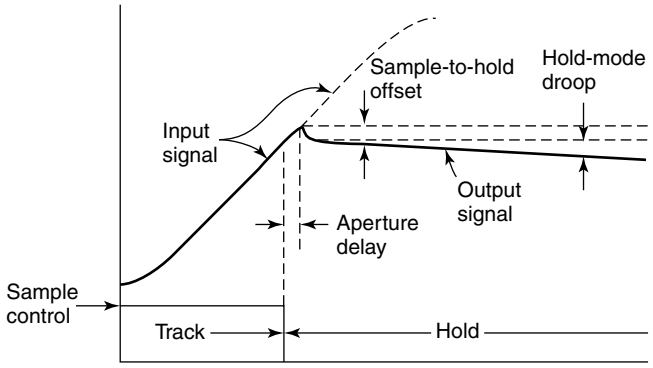

Figure 4. Some sample-hold characteristics. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

Aperture delay is the time elapsed from the hold command to when the switch actually opens; it is generally much less than a microsecond.

Aperture uncertainty or aperture jitter is the time variation, from sample-to-sample, of the aperture delay. It is the limit on how precise is the point in time of opening the switch. Aperture uncertainty is the time used to determine the aperture error due to rate of change of the input signal (*see also* **Article 138, Sampling Theory Relevant to DAS, Volume 3**).

Several of the above specifications are illustrated in the diagram of Figure 4.

Sample-hold circuits are simple in concept, but generally difficult to fully understand and apply. Their operation is full of subtleties, and they must, therefore, be carefully selected and then tested in a given application. Their simplicity is a strong reason they are not always supplanted by a digital storage device alternative.

FURTHER READING

The general principles of DAS are found explained in various titles. As the sample and hold device is usually needed in a DAS, the general titles usually cover them.

136: Quantizing Theory Relevant to DAS

Gerd Wöstenkühler
Hochschule Harz, Wernigerode, Germany

1 Quantizer Transfer Function 949
2 Quantizer Resolution and Error 949
Further Reading 950

1 QUANTIZER TRANSFER FUNCTION

The nonlinear transfer function shown in Figure 1 is that of an ideal quantizer with eight output states; with output code words assigned, it is also that of a 3-bit A/D converter. The eight output states are assigned the sequence of binary numbers from 000 through to 111. The analog input range for this quantizer is 0 to +10 V.

There are several important points concerning the transfer function of Figure 1.

First, the resolution of the quantizer is defined as the number of output states expressed in bits; in this case it is a simple 3-bit quantizer.

The number of output states for a binary coded quantizer is 2^n, where n is the number of bits. Thus, an 8-bit quantizer has 256 output states and a 12-bit quantizer has 4096 output states.

As shown in the diagram, there are $2^n - 1$ analog decision points (or threshold levels) in the transfer function. These points are at voltages of +0.625, +1.875, +3.125, +4.375, +5.625, +6.875, and +8.125 V. The decision points must be precisely set in a quantizer in order to divide the analog voltage range into the correct quantizer values.

The voltages 0.00, +1.25, +2.50, +3.75, +5.00, +6.25, +7.50, and +8.75 V are the center points of each output code word. The analog decision point voltages are precisely halfway between the code word center points. The quantizer staircase function is the best approximation that can be made to a straight line drawn through the origin and full-scale point; notice that the line passes through all of the code word center points.

2 QUANTIZER RESOLUTION AND ERROR

At any part of the input range of the quantizer, there is a small range of analog values within which the same output code word is produced. This small range is the voltage difference between any two adjacent decision points and is known as the *analog quantization size*, or *quantum*, Q. In Figure 1, the quantum is 1.25 V and is found in general by dividing the full-scale analog range by the number of output states. Thus,

$$Q = \frac{\text{FSR}}{2^n} \tag{1}$$

where FSR is the full-scale range, or 10 V in this case. Q is the smallest analog difference that can be resolved, or distinguished, by the quantizer. In the case of a 12-bit quantizer, the quantum is much smaller and is found to be

$$Q = \frac{\text{FSR}}{2^n} = \frac{10\,\text{V}}{4096} = 2.44\,\text{mV} \tag{2}$$

If the quantizer input is moved through its entire range of analog values and the difference between output and input is taken, a sawtooth error function results, as shown in Figure 1. This function is called the *quantizing error* and it is the irreducible error that results from the quantizing process. It can be reduced only by increasing the number of output states (or the resolution) of the quantizer, thereby

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

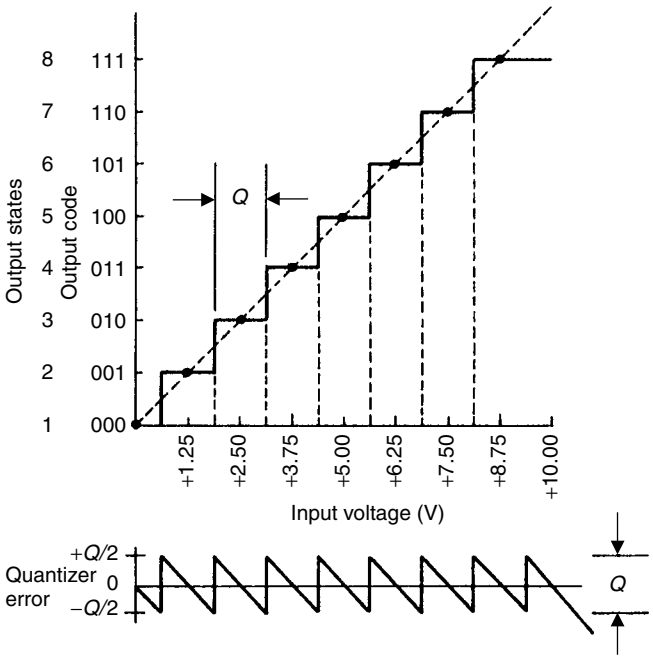

Figure 1. Transfer function and error of ideal 3-bit quantizer. (*Source*: reproduced by permission of Sydenham, P.H. (1983) *Handbook of Measurement Science*, Volume 1 Theoretical Fundamentals. John Wiley & Sons Ltd., Chichester.)

making the quantization finer and the system increasingly sophisticated.

For a given analog input value of the quantizer, the output error will vary anywhere from 0 to $\pm Q/2$; the error is zero only at analog values corresponding to the code center points. This error is also frequently called *quantization uncertainty* or *quantization noise*.

The quantizer output can be thought of as the analog input with quantization noise added to it. The noise has a peak-to-peak value of Q but, as with other types of noise, the average value is zero. Its rms value, however, is useful in analysis and can be computed from the triangular waveshape to be $Q/(2 \times \sqrt{3})$.

137: Coding for Data Converters

Gerd Wöstenkühler
Hochschule Harz, Wernigerode, Germany

1 Natural Binary Code 951
2 Other Binary Codes 952
3 Popular Bipolar Codes Used in Data Converters 953
4 Binary Coded Decimal (BCD) Codes 953
Further Reading 954

1 NATURAL BINARY CODE

Analog-to-digital (A/D) and digital-to-analog (D/A) converters interface with digital systems by means of an appropriate digital code. While there are many possible codes to select, a few standard ones are almost exclusively used with data converters.

The most popular code is natural binary, or straight binary, which is used in its fractional form to represent a number

$$N = a_1 2^{-1} + a_2 2^{-2} + a_3 2^{-3} + \cdots + a_n 2^{-n} \qquad (1)$$

where each coefficient a assumes a value of zero or one. N has a value between zero and one (*see also* **Article 33, Coding Theory and its Application to Measurement, Volume 1**).

A binary fraction is normally written as 0.110101, but with data converter codes, the decimal point is omitted and the code word is written as 110101. This code word represents a fraction of the full-scale value of the converter and has no other numerical significance.

The binary code word 110101, therefore, represents the decimal fraction

$$\begin{aligned}(1 \times 0.5) + (1 \times 0.25) + (0 \times 0.125) + (1 \times 0.0625) \\ + (0 \times 0.03125) + (1 \times 0.015625) \\ = 0.828125 \text{ or } 82.8125\% \end{aligned} \qquad (2)$$

of full scale for the converter. If full scale is +10 V, then the code word represents +8.28125 V. The natural binary code belongs to a class of codes known as *positive-weighted codes* since each coefficient has a specific weight none of which is negative.

The leftmost bit has the most weight, 0.5 of full scale, and is called the *most significant bit* (MSB); the rightmost bit has the least weight, 2^{-n} of full scale, and is, therefore, called the *least significant bit* (LSB). The bits in a code word are numbered left to right from 1 to n.

The LSB has the same analog equivalent value as Q (*see* **Article 136, Quantizing Theory Relevant to DAS, Volume 3**), namely,

$$\text{LSB(analog value)} = \frac{\text{FSR}}{2^n} \qquad (3)$$

Table 1 is a useful summary of the resolution, number of states, LSB weights, and dynamic range (DR) for data converters from 1 to 20 bits resolution.

The dynamic range of a data converter in decibels (dB) is found as follows:

$$\begin{aligned}\text{DR} &= 20 \times \log 2^n = 20 \times n \times \log 2 \approx 20 \times n \times 0.301 \\ &= 6.02 \times n \end{aligned} \qquad (4)$$

where DR is dynamic range, n is the number of bits, and 2^n is the number of states of the converter. Since 6.02 dB corresponds to a factor of 2, it is simply necessary to multiply the resolution of a converter in bits by 6.02. A 12-bit converter, for example, has a dynamic range of 72.24 dB.

Source: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.

An important point to notice is that the maximum value of the digital code, namely all 1's, does not correspond with analog full scale, but rather with one LSB less than full scale, or FS $(1-2^{-n})$. Therefore, a 12-bit converter with a 0 to +10 V analog range has a maximum code of 1111 1111 1111 and a maximum analog value of $+10\,\text{V}\ (1-2^{-12}) \approx +9.99756\,\text{V}$. In other words, the maximum analog value of the converter, corresponding to all 1's in the code, never quite reaches the point defined as analog full scale.

2 OTHER BINARY CODES

Several other binary codes are used with A/D and D/A converters in addition to straight binary. These codes are offset binary, two's complement, binary coded decimal (BCD), and their complemented versions. Each code has a specific advantage in certain applications. BCD coding, for example, is used where digital displays must be interfaced such as in digital panel meters and digital multimeters. Two's complement coding is used for computer arithmetic logic operations, and offset binary coding is used with bipolar analog measures.

Not only the digital codes are standardized with data converters but also the analog voltage ranges. Most converters use unipolar voltage ranges of 0 to +5 V and 0 to +10 V although some devices use the negative ranges 0 to −5 V and 0 to −10 V. The standard bipolar voltage ranges are ±2.5 V, ±5 V, and ±10 V. Many converters offered are pin-programmable between these various ranges.

Table 2 shows straight binary and complementary binary codes for a unipolar 8-bit converter with a 0 to +10 V analog FS range. The maximum analog value of the converter is +9.961 V, or one LSB less than +10 V. Note that the LSB size is 0.039 V as shown near the bottom of the table. The complementary binary coding used in some converters is simply the logic complement of straight binary.

When A/D and D/A converters are used in bipolar operation, the analog range is offset by half scale, or by the MSB value. The result is an analog shift of the converter transfer function as shown in Figure 1. Notice for this 3-bit A/D converter transfer function that the code 000 corresponds with −5 V; 100 with 0 V; and 111 with +3.75 V. Since the

Table 2. Binary coding for 8-bit unipolar converters.

[a]Sign magnitude binary has two code words for zero as shown here:
0+ 1000 0000
0− 0000 0000.

output coding is the same as before the analog shift, it is now appropriately called *offset binary coding*.

3 POPULAR BIPOLAR CODES USED IN DATA CONVERTERS

Table 3 shows the offset binary code together with complementary offset binary, two's complement, and sign-magnitude binary codes. These are the most popular codes employed in bipolar data converters.

The two's complement code has the characteristic that the sum of the positive and negative codes for the same analog magnitude always produces all zeros and a carry. This characteristic makes the two's complement code useful in arithmetic computations. Notice that the only difference between two's complement and offset binary is the complementing of the MSB. In bipolar coding, the MSB becomes the sign bit.

The sign-magnitude binary code, infrequently used, has identical code words for equal magnitude analog values except that the sign bit is different. As shown in Table 3, this code has two possible code words for zero: 1000 0000 or 0000 0000. The two are usually distinguished as 0+ and 0−, respectively. Because of this characteristic, the code has maximum analog values of ±(FS − 1 LSB) and reaches neither analog +FS nor −FS.

4 BINARY CODED DECIMAL (BCD) CODES

Table 4 shows BCD coding and complementary BCD coding for a three-decimal digit data converter. These are the codes used with integrating type A/D converters employed in digital panel meters, digital multimeters, and other

decimal display applications. Here 4 bits are used to represent each decimal digit. BCD is a positive-weighted code but is relatively inefficient since in each group of 4 bits, only 10 out of a possible 16 states are utilized (*see also* **Article 33, Coding Theory and its Application to Measurement, Volume 1**).

The LSB analog value (or quantum, Q) for BCD is

$$\text{LSB(analog value)} = Q = \frac{\text{FSR}}{10^d} \tag{5}$$

where FSR is the full-scale range and d is the number of decimal digits. For example, if there are three digits and the FSR is 10 V, the LSB value is

$$\text{LSB(analog value)} = \frac{10\text{V}}{10^3} = 0.01\text{V} = 10\,\text{mV} \tag{6}$$

BCD coding is frequently used with an additional over-range bit, which has a weight equal to full scale and produces a 100% increase in range for the A/D converter. Thus, for a converter with a decimal full scale of 999, an over-range bit provides a new full scale of 1999, twice that of the previous one. In this case, the maximum output code is 1 1001 1001 1001. The additional range is commonly

referred to as $\frac{1}{2}$ digit, and the resolution of the A/D converter in this case is $3\frac{1}{2}$ digits.

Likewise, if this range is again expanded by 100%, a new full scale of 3999 results and is called $3\frac{3}{4}$ digits resolution. Here, two over-range bits have been added and the full-scale output code is 11 1001 1001 1001. When BCD coding is used for bipolar measurements, another bit, a sign bit, is added to the code and the result is sign-magnitude BCD coding.

1 APERTURE TIME

Conversion time is frequently referred to as *aperture time*. In general, aperture time refers to the time uncertainty (or time window) in making a measurement and results in an amplitude uncertainty (or error) in the measurement if the signal is changing during this time.

As shown in Figure 1, the input signal to the analog-to-digital (A/D) converter changes by ΔV during the aperture time t_a in which the conversion is performed. The error can be considered as an amplitude error or a time error; the two are related as follows:

$$\Delta V = t_a \frac{dV(t)}{dt} \tag{1}$$

where $dV(t)/dt$ is the rate of change with time of the input signal.

It should be noted that ΔV represents the maximum error due to signal change, since the actual error depends on how the conversion is done. At some point in time within t_a, the signal amplitude corresponds exactly with the output code word produced.

For the specific case of a sinusoidal input signal, the maximum rate of change occurs at the zero crossing of the waveform, and the amplitude error is

$$\Delta V = t_a \frac{d}{dt}(A \sin(\omega t))_{t=0} = t_a A \omega \tag{2}$$

The resultant error as a fraction of the peak-to-peak full-scale value is

$$\varepsilon = \frac{\Delta V}{2A} = \pi f t_a \tag{3}$$

As an example from this result, the aperture time required to digitize a 1 kHz signal to 10-bits resolution can be found. The resolution required is one part in 2^{10} or approximately 0.001.

$$t_a = \frac{\varepsilon}{\pi f} \approx \frac{0.001}{3.14 \times 10^3} \approx 320 \times 10^{-9} \tag{4}$$

The result is a required aperture time of just 320 ns! A 1 kHz signal is not a particularly fast one, yet it is difficult to find a 10-bit A/D converter to perform this kind of conversion at a reasonable price! Fortunately, there is a relatively simple and inexpensive way around this dilemma by using a sample-hold circuit.

2 SAMPLE-HOLDS AND APERTURE ERROR

A sample-hold circuit samples the signal voltage and then stores it on a capacitor for the time required to perform the A/D conversion. The aperture time of the A/D converter is, therefore, greatly reduced by the much shorter aperture time of the sample-hold circuit. In turn, the aperture time of the sample-hold is a function of its bandwidth and the switching time.

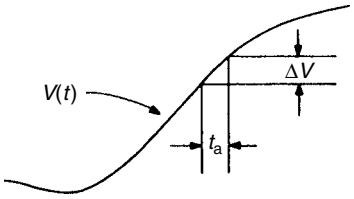

Figure 1. Aperture time and amplitude uncertainty. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

Figure 2 is a useful graph of (4). It gives the aperture time required for converting sinusoidal signals to a maximum error less than one part in 2^n where n is the resolution of the converter in bits. The peak-to-peak value of the sinusoid is assumed to be the full-scale range of the A/D converter. The graph is useful for selecting a sample-hold by aperture time or an A/D converter by conversion time.

3 SAMPLED-DATA SYSTEM AND SAMPLING THEOREM

In data acquisition and distribution systems, and other sampled-data systems, analog signals are sampled on a periodic basis as illustrated in Figure 3. The train of sampling pulses in Figure 3(b) represents a fast-acting switch, which connects to the analog signal for a very short time and then disconnects for the remainder of the sampling period.

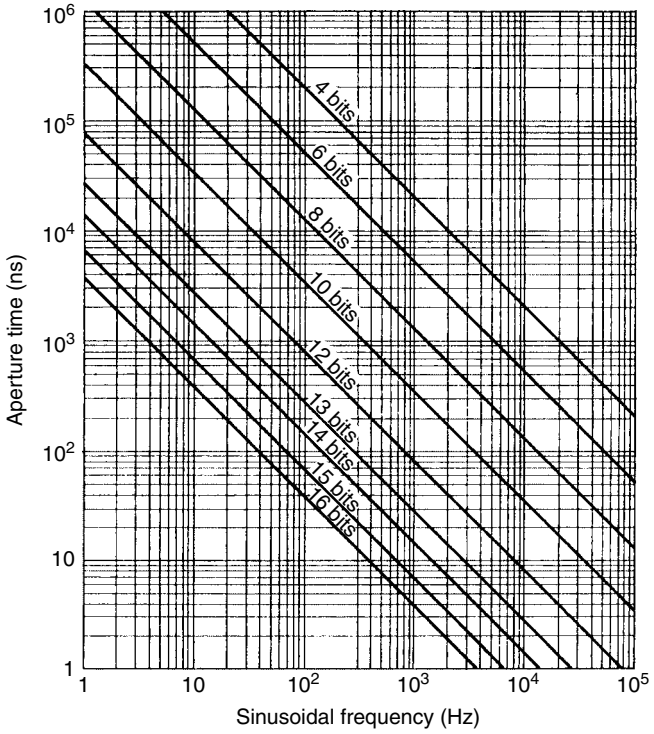

Figure 2. Graph of aperture error for sinusoidal signals. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

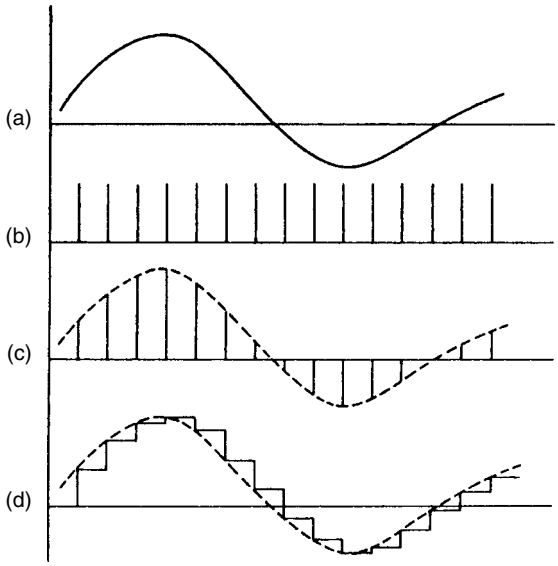

Figure 3. Signal sampling: (a) signal, (b) sampling pulses, (c) sampled signal, and (d) sampled and held signal. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

The result of the fast-acting sampler is identical with the result of multiplying the analog signal by a train of sampling pulses of unity amplitude, giving the modulated pulse train of Figure 3(c). The amplitude of the original signal is preserved in the modulation envelope of the pulses. If the switch-type sampler is replaced by a switch and capacitor (a sample-hold circuit), then the amplitude of each sample is stored between the samples and a reasonable reconstruction of the original analog signal results, as shown in Figure 3(d).

A common use of sampling is in the efficient use of data processing equipment and data transmission facilities. A single data transmission link, for example, can be used to transmit many different analog channels on a sampled, time-multiplexed basis, whereas it would be uneconomical to devote a complete transmission link to the continuous transmission of a single signal.

Likewise, a data acquisition and distribution system is used to measure and control the many parameters of a process control system by sampling the parameters and by updating the control inputs periodically. In data conversion systems, it is common to use a single, expensive A/D converter of high speed and precision, and then multiplex a number of analog inputs into it.

An important fundamental question to answer about sampled-data systems is this: 'How often must I sample an analog signal in order not to lose information from it'? It is obvious that all useful information can be extracted if a slowly varying signal is sampled at a rate such that little or no change takes place between samples. Equally obvious is the fact that the information is being lost if there is a significant change in signal amplitude between samples.

The answer to the question is contained in the well-known sampling theorem, which may be stated as follows: if a continuous bandwidth-limited signal contains no frequency components higher than f_c, then the original signal can be recovered without distortion if it is sampled at a rate of at least $2f_c$ samples per second.

4 FREQUENCY FOLDING AND ALIASING

The sampling theorem can be demonstrated by the frequency spectra illustrated in Figure 4. Figure 4(a) shows the frequency spectrum of a continuous bandwidth-limited analog signal with frequency components out to f_c. When this signal is sampled at a rate f_s, the modulation process shifts the original spectrum out to $\ldots, -3f_s, -2f_s, -f_s, f_s, 2f_s, 3f_s, \ldots$, in addition to the one at the origin. A portion of this resultant spectrum is shown in Figure 4(b).

If the sampling frequency f_s is not high enough, part of the spectrum centered about f_s will fold over into the original signal spectrum. This undesirable effect is called *frequency folding*. In the process of recovering the original signal, the folded part of the spectrum causes distortion in the recovered signal, which cannot be eliminated by filtering the recovered signal.

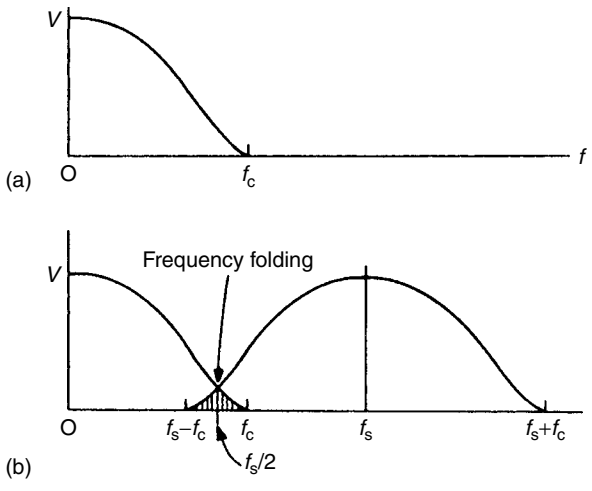

Figure 4. Frequency spectra demonstrating the sampling theorem: (a) continuous signal spectrum and (b) sampled signal spectrum. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

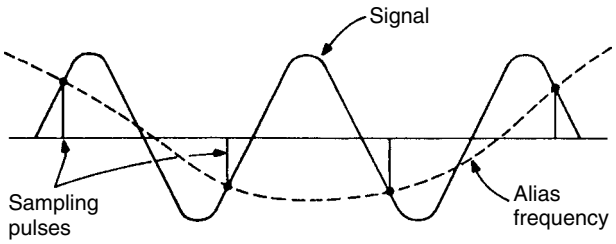

Figure 5. Alias frequency caused by inadequate sampling rate. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

From Figure 4, if the sampling rate is increased such that $f_s - f_c > f_c$, then the two spectra are separated and the original signal can be recovered without distortion. This demonstrates the results of the sampling theorem that $f_s > 2f_c$. Frequency folding can be eliminated in two ways: first, by using a high enough sampling rate, and second, by filtering the signal before sampling to limit its bandwidth to $f_s/2$.

It must be appreciated that in practice there is always some frequency folding present owing to high-frequency signal components, noise, and nonideal presample filtering. The effect must be reduced to negligible amounts for a particular application by using a sufficiently high sampling rate. The required rate, in fact, may be much higher than the minimum indicated by the sampling theorem.

The effect of an inadequate sampling rate on a sinusoid is illustrated in Figure 5; an alias frequency in the recovered signal results (*see also* **Article 31, Discrete Signal Theory, Volume 1**). In this case, sampling at a rate slightly less than twice per cycle gives the low-frequency sinusoid shown by the dotted line in the recovered signal. This alias frequency can be significantly different from the original frequency. From the figure, it is easy to see that if the sinusoid is sampled at least twice per cycle, as required by the sampling theorem, the original frequency is preserved.

1 COUNTER TYPE A/D CONVERTER

Analog-to-digital (A/D) converters, also called ADCs or encoders, employ a variety of different circuit techniques to implement the conversion function. As with digital-to-analog (D/A) converters, however, relatively few of the many originally devised circuits are widely used today. Of the various techniques available, the choice depends on the resolution and speed required.

One of the simplest A/D converters is the counter, or servo type. This circuit employs a digital counter to control the input of a D/A converter (*see also* **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**). Clock pulses are applied to the counter and the output of the D/A is stepped up one LSB (least significant bit) at a time. A comparator compares the D/A output with the analog input and stops the clock pulses when they are equal. The counter output is then the converted digital word.

While this converter is simple, it is also relatively slow. An improvement on this technique is shown in Figure 1 and is known as a *tracking A/D converter*, a device commonly used in control systems. Here an up/down counter controls the DAC, and the clock pulses are directed to the pertinent counter input depending on whether the D/A output must increase or decrease to reach the analog input voltage.

The obvious advantage of the tracking A/D converter is that it can continuously follow the input signal and give updated digital output data if the signal does not change too rapidly. Also, for small input changes, the conversions can be quite fast. The converter can be operated in either the track or hold modes by a digital input control.

2 SUCCESSIVE-APPROXIMATION A/D CONVERTERS

By far, the most popular A/D conversion technique in general use for moderate to high-speed applications is the successive-approximation type A/D. This method falls into a class of techniques known as *feedback type A/D converters*, to which the counter type also belongs. In both cases, a D/A converter (*see also* **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**) is in the feedback loop of a digital control circuit, which changes its output until it equals the analog input. In the case of the successive-approximation converter, the DAC is controlled in an optimum manner to complete a conversion in just n steps, where n is the resolution of the converter in bits.

The operation of this converter is analogous to weighing an unknown on a laboratory balance scale using standard weights in a binary sequence such as $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, . . . , $\frac{1}{2^n}$ kg. The correct procedure is to begin with the largest standard weight and proceed in order down to the smallest one.

The largest weight is placed on the balance pan first; if it does not tip, the weight is left on and the next largest weight is added. If the balance does tip, the weight is removed and the next one added. The same procedure is used for

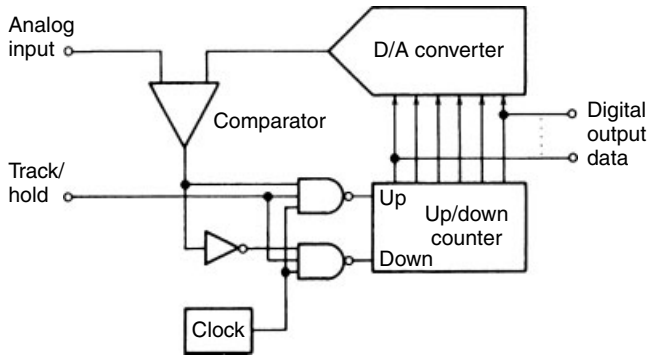

Figure 1. Tracking-type A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

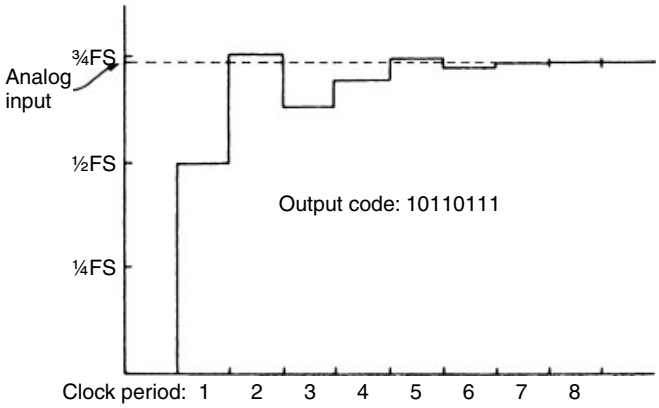

Figure 3. D/A output for 8-bit successive-approximation conversion. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

the next largest weight and so on down to the smallest. After the *n*th standard weight has been tried and a decision made, the weighing is finished. The total of the standard weights remaining on the balance is the closest possible approximation to the unknown.

In the successive-approximation A/D converter illustrated in Figure 2, a successive-approximation register (SAR) controls the D/A converter by implementing the weighing logic just described. The SAR first turns on the MSB (most significant bit) of the DAC and the comparator tests this output against the analog input. A decision is made by the comparator to leave the bit on or turn it off after which bit 2 is turned on and a second comparison is made. After *n* comparisons, the digital output of the SAR indicates all those bits that remain on and produce the desired digital code. The clock circuit controls the timing of the SAR. Figure 3 shows the D/A converter output during a typical conversion.

The conversion efficiency of this technique means that high-resolution conversions can be made in a very short time. For example, it is possible to perform a 10-bit conversion in 1 μs or less. Of course, the speed of the internal circuitry, in particular the D/A and comparator, are critical for high-speed performance.

3 PARALLEL (FLASH) A/D CONVERTERS

For ultrafast conversions required in video signal processing and radar applications where up to 8-bits resolution is required, a different technique is employed; it is known as the *parallel* (also *flash*, or *simultaneous*) method and is illustrated in Figure 4. This circuitry employs $2^n - 1$ analog comparators to directly implement the quantizer transfer function of an A/D converter.

The comparator trip-points are spaced 1 LSB apart by the series resistor chain and voltage reference. For a given analog input voltage, all comparators that are biased below the voltage turn on and all those biased above it remain off. Since all comparators change state simultaneously, the quantization process is a one-step operation.

A second step is required, however, since the logic output of the comparators is not in binary form. Therefore,

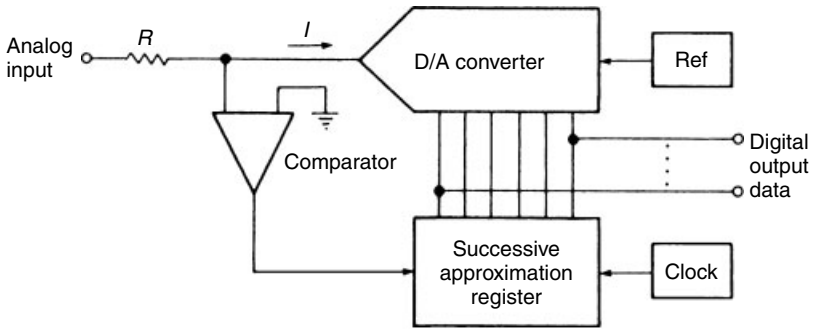

Figure 2. Successive-approximation A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

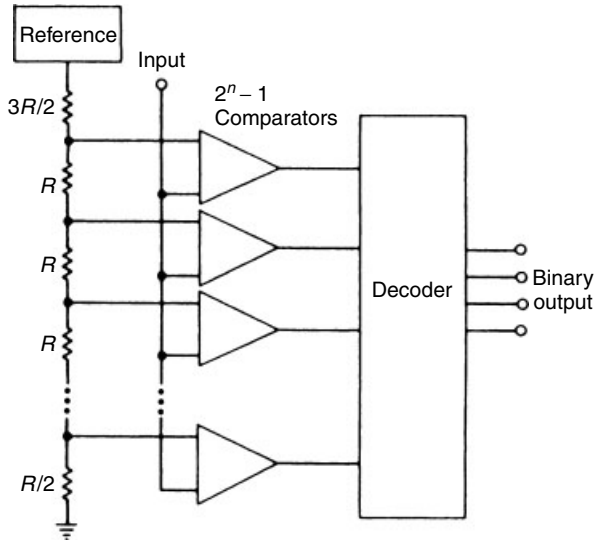

Figure 4. 4-bit parallel A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

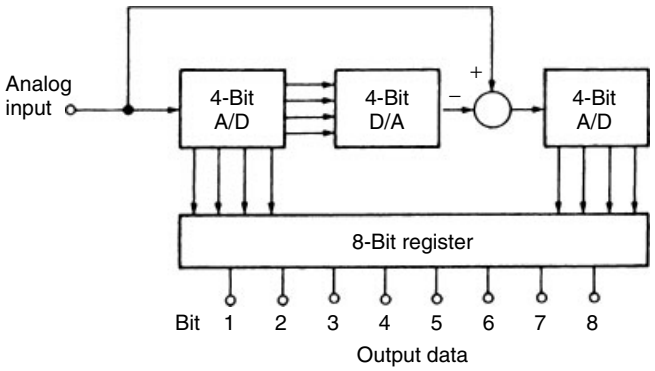

Figure 5. Two-stage parallel 8-bit A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

an ultrafast decoder circuit is employed to make the logic conversion to binary. The parallel technique reaches the ultimate at high speed because only two sequential operations are required to make the conversion.

The limitation of the method, however, is in the large number of comparators required for even moderate resolutions. A 4-bit converter, for example, requires only 15 comparators, but an 8-bit converter needs 255. For this reason, it is common practice to implement an 8-bit A/D with two 4-bit stages as shown in Figure 5.

The result of the first 4-bit conversion is converted back to analog by means of an ultrafast 4-bit D/A and then subtracted from the analog input. The resulting residue is then converted by the second 4-bit A/D and the two sets of data are accumulated in the 8-bit output register. Converters of this type achieve 8-bit conversions at rates of 20 MHz and higher, while single-stage 4-bit conversions can reach 50 to 100 MHz rates.

1 Indirect A/D Conversion 962
2 Dual-slope A/D Conversion 962
3 Charge-balancing A/D Conversion 962
Further Reading 964

1 INDIRECT A/D CONVERSION

A class of analog-to-digital (A/D) converters, known as *integrating type*, operates by an indirect conversion method. The unknown input voltage is converted into a time period, which is then measured by a clock and counter. A number of variations exist on the basic principle such as single-slope, dual-slope, and triple-slope methods. In addition, there is another technique – completely different – that is known as the *charge-balancing*, *quantized-feedback method* or sigma-delta modulator.

The most popular of these methods are dual-slope and charge balancing; although both are slow, they have excellent linearity characteristics with the capability of rejecting input noise. Because of these characteristics, integrating type A/D converters are almost exclusively used in digital panel meters, digital multimeters, and other comparatively slow measurement applications.

2 DUAL-SLOPE A/D CONVERSION

The dual-slope technique, shown in Figure 1, is perhaps the best known. Conversion begins when the unknown input voltage is switched to the integrator input; at the same time, the counter begins to count clock pulses and counts up to overflow. At this point, the control circuit switches the integrator to the negative reference voltage, which is integrated until the output is back to zero. Clock pulses are counted during this time until the comparator detects the zero crossing and turns them off.

The counter output is then the converted digital word. Figure 2 shows the integrator output waveform where T_1 is a fixed time and T_2 is the time proportional to the input voltage. The times are related as follows:

$$T_2 = T_1 \frac{V_{\text{in}}}{V_{\text{ref}}} \tag{1}$$

The digital output word, therefore, represents the ratio of the input voltage to the reference voltage.

Dual-slope conversion has several important features. First, conversion accuracy is independent of the stability of the clock and integrating capacitor so long as they are constant during the conversion period. Accuracy depends only on the reference accuracy and the integrator circuit linearity. Second, the periodic noise rejection of the converter can be infinite if T_1 is set to equal the period of the noise. To reject 60 Hz power noise, therefore, requires that T_1 be 16.667 ms or its multiples.

3 CHARGE-BALANCING A/D CONVERSION

The charge-balancing, or quantized-feedback, method of conversion is based on the principle of generating a pulse train with a frequency proportional to the input voltage and then counting the pulses for a fixed period of time. This circuit is shown in Figure 3. Except for the counter and timer,

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

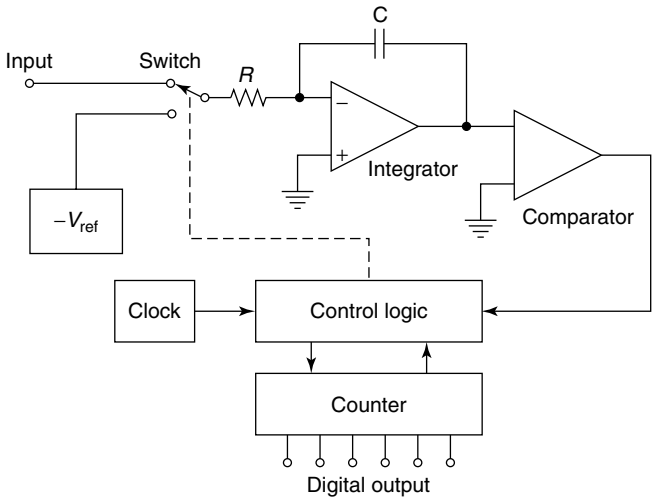

Figure 1. Dual-slope A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

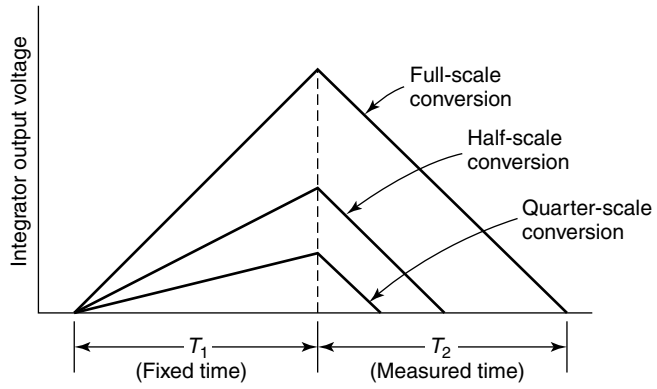

Figure 2. Integrator output waveform for dual-slope A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

the circuit is a voltage-to-frequency (V/F) converter that generates an output pulse rate proportional to input voltage.

The circuit operates as follows. A positive input voltage causes a current to flow into the operational integrator through R_1. This current is integrated, producing a negative going ramp at the output. Each time the ramp crosses zero, the comparator output triggers a precision pulse generator, which puts out a constant width pulse.

The pulse output controls switch S_1, which connects R_2 to the negative reference for the duration of the pulse. During this time, a pulse of current flows out of the integrator-summing junction, producing a fast, positive ramp at the integrator output. This process is repeated, generating a train of current pulses, which exactly balances the input current – hence the name charge balancing. This balance

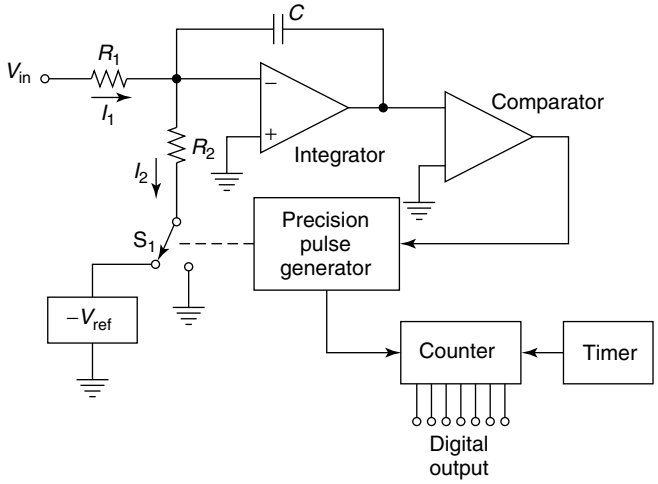

Figure 3. Charge-balancing A/D converter. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

has the following relationship:

$$f = \frac{1}{\tau}\frac{V_{\text{in}}}{V_{\text{ref}}}\frac{R_2}{R_1} \tag{2}$$

where τ is the pulse width and f the frequency.

A higher input voltage, therefore, causes the integrator to ramp up and down faster, producing higher frequency output pulses. The timer circuit sets a fixed time period for counting and the number of pulses within this period represents the digital output.

If the output of the comparator is synchronized with a clock signal and directly used to control the switch S_1 as the pulse generator and more than one clock period is needed to balance the current of maximum input voltage over two clock periods, the circuit becomes a sigma-delta modulator. The synchronized comparator output signal generates a sequence of 1 and 0, and the output pulse density balances the input voltage. The counter for the digital output counts the periods n where the switch is connected to the reference voltage and its relation to the used number N of clock periods in the time window represents the digital output signal.

$$n = N\frac{V_{\text{in}}}{V_{\text{ref}}}\frac{R_2}{R_1} \tag{3}$$

Like the dual-slope converter, the circuit also integrates input noise, and if the timer is synchronized with the noise frequency, infinite rejection results. Figure 4 shows the noise rejection characteristic of all integrating type A/D converters with rejection plotted against the ratio of integration period to noise period.

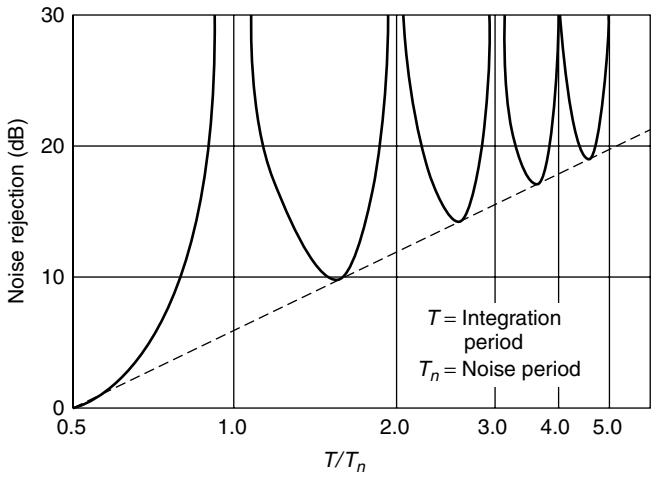

Figure 4. Noise rejection for integrating type A/D converters. (Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

1 INTRODUCTION TO D/A CONVERTERS

Digital-to-analog (D/A) converters are the devices by which computers communicate with the outside analog world. They are employed in a variety of applications from CRT display systems and voice synthesizers to automatic test systems, digitally controlled attenuators, and process control actuators. In addition, they are key components inside most analog-to-digital (A/D) converters. D/A converters are also referred to as *DACs* and are termed *decoders* by communications engineers.

The transfer characteristic of an ideal 3-bit D/A converter is shown in Figure 1. Each input code word produces a single, discrete analog output value, generally, but not always, a voltage. Over the output range of the converter 2^n different values are produced including zero; and the output has a one-to-one correspondence with input, which is not true for A/D converters.

There are many different circuit techniques used to implement D/A converters, but a few popular ones are widely used today. Virtually all D/A converters in use are of the *parallel type* where all bits change simultaneously upon application of an input code word; *serial type* D/A converters, on the other hand, produce an analog output only after receiving all digital input data in sequential form.

2 WEIGHTED CURRENT SOURCE D/A CONVERTER

The most popular D/A converter design in use today is the weighted current source circuit illustrated in Figure 2. An array of switched transistor current sources is used with binary weighted currents. The binary weighting is achieved by using emitter resistors with binary related values of $R, 2R, 4R, 8R, \ldots 2^{n-1}R$. The resulting collector currents are then added together at the current summing line.

The current sources are switched on or off from standard TTL semiconductor device inputs by means of the control diodes connected to each emitter. When the TTL input is high, the current source is on; when the input is low, it is off, with the current flowing through the control diode. Fast switching speed is achieved because there is direct control of the transistor current, and the current sources never go into saturation.

To interface with standard TTL levels, the current sources are biased to a base voltage of $+1.2$ V. The emitter currents are regulated to constant values by means of the control amplifier and a precision voltage reference circuit together with a binary transistor.

The summed output currents from all current sources that are on go to an operational amplifier summing junction; the amplifier converts this output current into an output voltage. In some D/A converters, the output current is used to directly drive a resistor load for maximum speed, but the positive output voltage in this case is limited to about $+1$ V.

The weighted current source design has the advantage of simplicity and high speed. Both PNP and NPN transistor current sources can be used with this technique although the TTL interfacing is more difficult with NPN sources. This

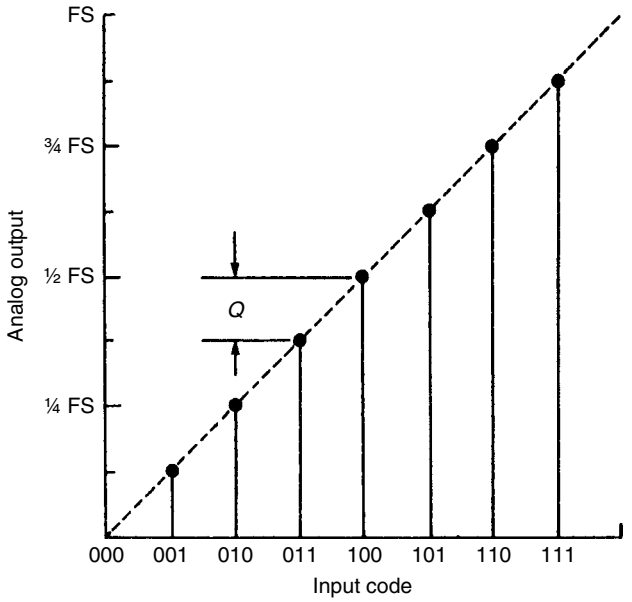

Figure 1. Transfer characteristic of ideal 3-bit D/A converter. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

technique is used in most monolithic, hybrid, and modular D/A converters.

A difficulty in implementing the higher resolution D/A converter designs to this concept is that a wide range of emitter resistors is required and very high value resistors cause problems with both temperature stability and switching speed. To overcome these problems, weighted current sources are used in identical groups, with the output of each group divided down by a resistor divider as shown in Figure 3.

The resistor network, R_1 through R_4, divides the output of group 3 down by a factor of 256 and the output of group 2 down by a factor of 16 with respect to the output of group 1. Each group is identical, with four current sources of the type shown in Figure 2, having binary current weights of 1, 2, 4, 8. Figure 3 also illustrates the method of achieving a bipolar output by deriving an offset current from the reference circuit, which is then subtracted from the output current line through resistor R_O. This current is set to exactly one half of the full scale output current.

3 *R*–2*R* D/A CONVERTER

A second popular technique for D/A conversion is the $R-2R$ ladder method. As shown in Figure 4, the network

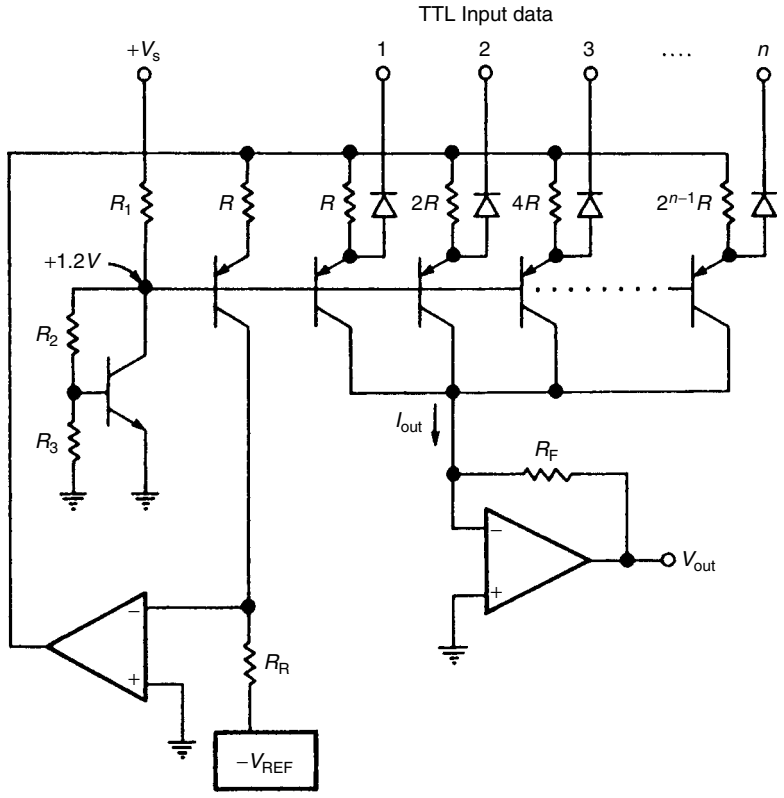

Figure 2. Weighted current source D/A converter. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

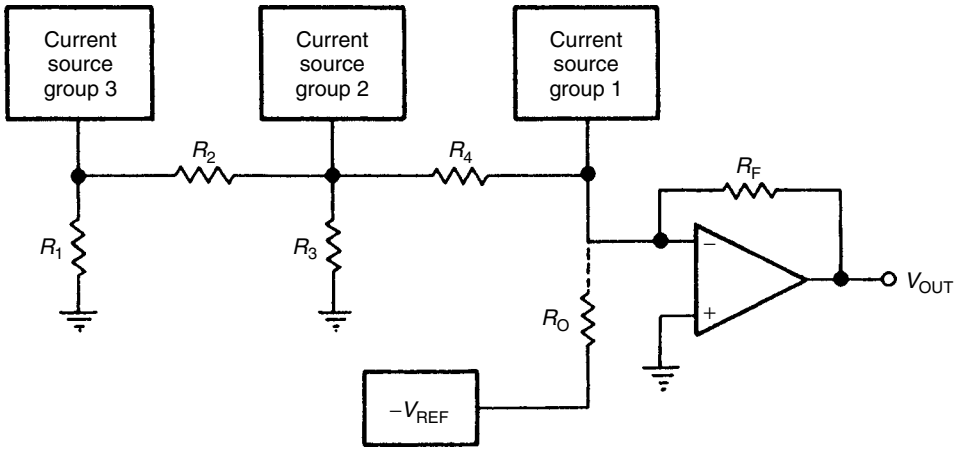

Figure 3. Current dividing the outputs of weighted current source groups. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

consists of series resistors of value R and shunt resistors of values $2R$. The bottom of each shunt resistor has a single-pole double-throw electronic switch, which connects the resistor to either ground or to the output current summing line. As in the previous circuit, the output current summing line goes to an operational amplifier that converts current to voltage.

The operation of the $R-2R$ ladder network is based on the binary division of current as it flows down the ladder. Examination of the ladder configuration reveals that at point A, looking to the right, one measures a resistance of $2R$; therefore, the reference input to the ladder has a resistance of R. At the reference input, the current splits into two equal parts since it sees equal resistances in either direction. Likewise, the current flowing down the ladder to the right continues to divide into two equal parts at each resistor junction.

The result is binary weighted currents flowing down each shunt resistor in the ladder. The digitally controlled switches direct the currents to either the summing line or to ground. Assuming all bits are on, as shown in the diagram, the output current is

$$I_{OUT} = \frac{V_{REF}}{R}\left(\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots + \frac{1}{2^n}\right) \qquad (1)$$

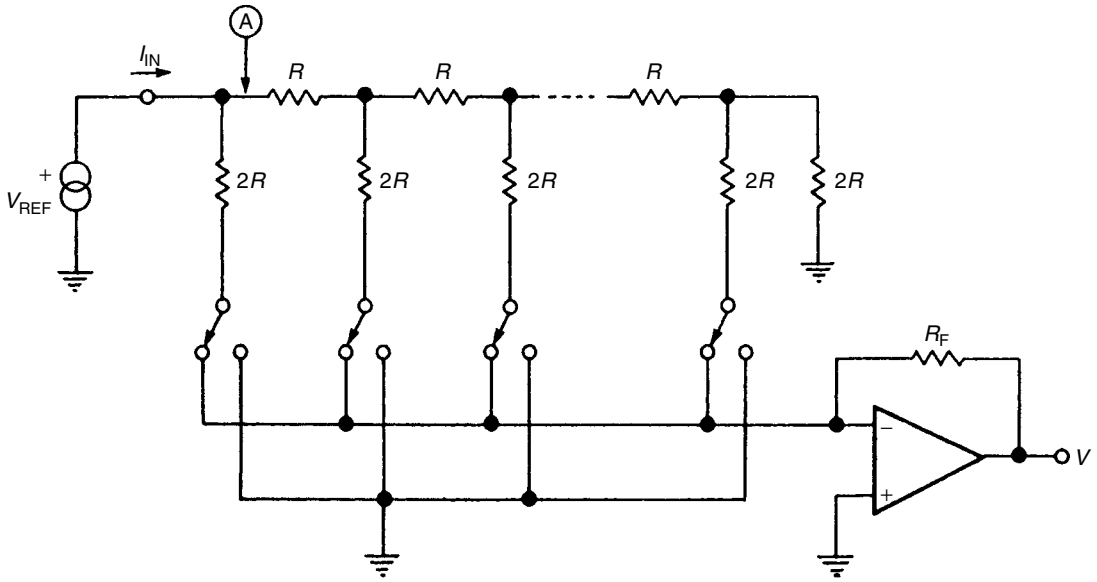

Figure 4. $R-2R$ ladder D/A converter. (*Source*: Reproduced from *Handbook of Measurement Science, Volume One*, Sydenham, 1983 © John Wiley & Sons Ltd.)

which is a binary series. The sum of all currents is then

$$I_{\text{OUT}} = \frac{V_{\text{REF}}}{R}(1 - 2^{-n}) \tag{2}$$

where the 2^{-n} term physically represents the portion of the input current flowing through the $2R$ terminating resistor to ground at the far right.

The advantage of the R–$2R$ ladder technique is that only two values of resistors are required, with the resultant ease of matching or trimming and excellent temperature tracking. In addition, for high speed applications, relatively low resistor values can be used. Excellent results can be obtained for high resolution D/A converters by using laser-trimmed thin film resistor networks.

4 MULTIPLYING AND DEGLITCHING D/A CONVERTERS

The R–$2R$ ladder method is specifically used for multiplying D/A converters. With these converters, the reference voltage can be varied over the full range of $\pm V_{\text{max}}$ with the output being the product of the reference voltage and the digital input word. Multiplication can be performed in 1, 2, or 4 algebraic quadrants.

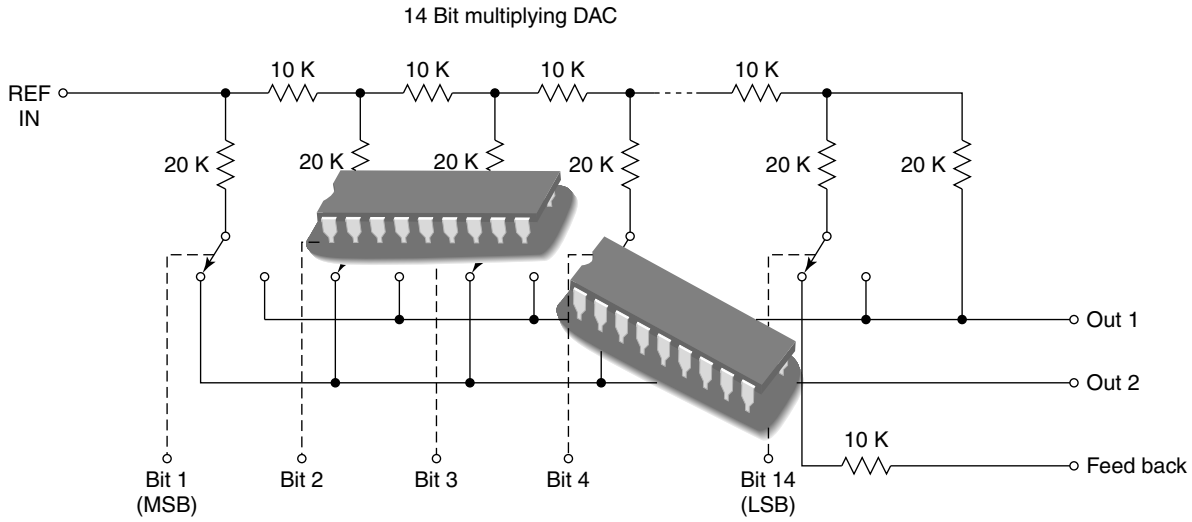

Figure 5. CMOS 14-bit multiplying D/A converters. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

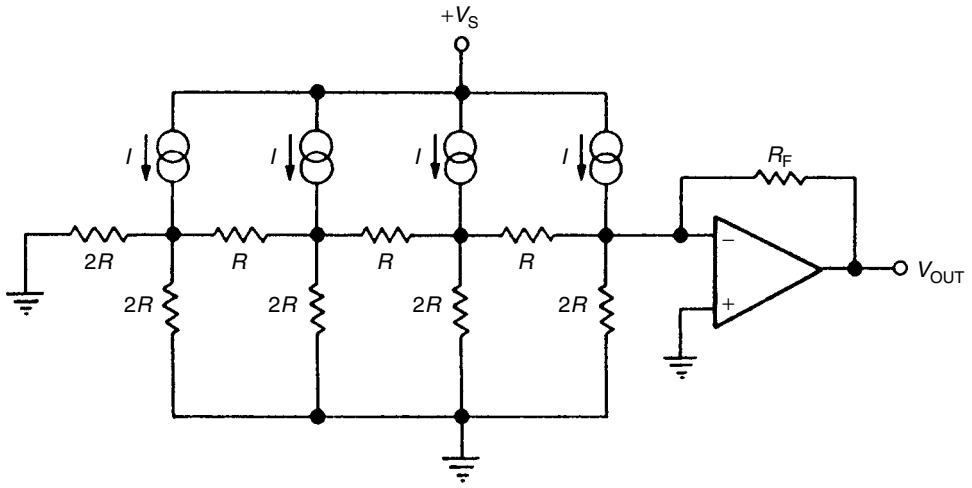

Figure 6. D/A converter employing R–$2R$ ladder with equal value switched current sources. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

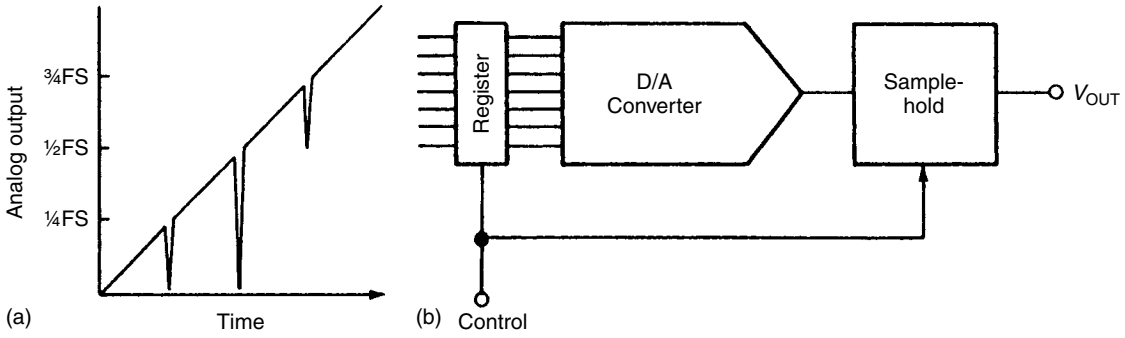

Figure 7. (a) Output glitches and (b) deglitched D/A converter. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

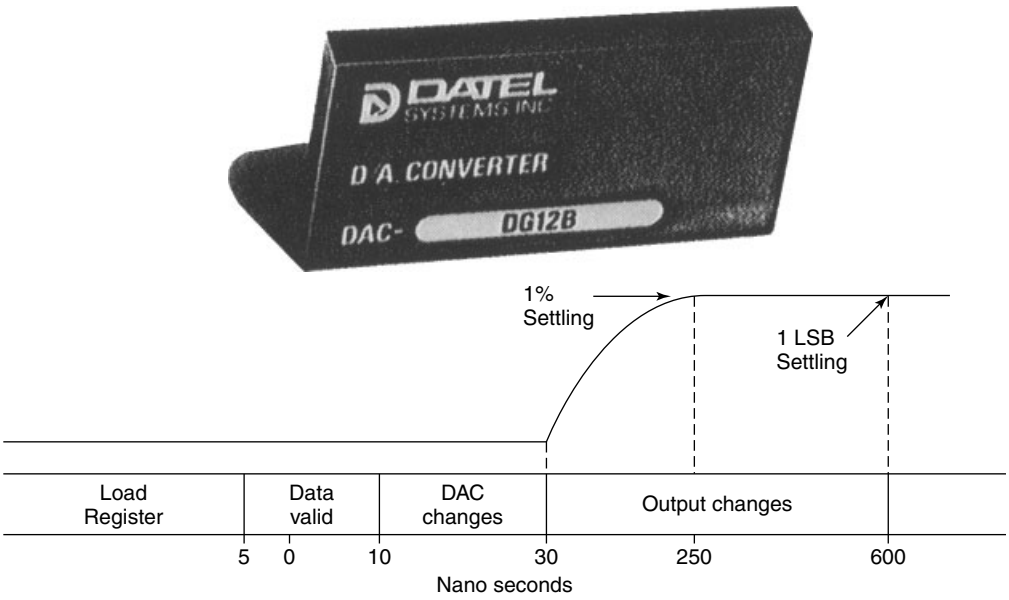

Figure 8. Modular deglitched D/A converter. (*Source*: Reproduced from *Handbook of Measurement Science*, Volume One, Sydenham, 1983 © John Wiley & Sons Ltd.)

If the reference voltage is unipolar, the circuit is a one-quadrant multiplying DAC; if it is bipolar, the circuit is a two-quadrant multiplying DAC. For a four-quadrant operation the two current summing lines shown in Figure 4 must be subtracted from each other by operational amplifiers.

In multiplying D/A converters, the electronic switches are usually implemented with CMOS devices. Multiplying DACs are commonly used in automatic gain controls, CRT character generation, complex function generators, digital attenuators, and divider circuits. Figure 5 shows two 14-bit multiplying CMOS D/A converters.

Another important D/A converter design takes advantage of the best features of both the weighted current source technique and the $R-2R$ ladder technique. This circuit, shown in Figure 6, uses equal value switched current sources to drive the junctions of the $R-2R$ ladder network. The advantage of the equal value current sources is obvious since all emitter resistors are identical and switching speeds are also identical. This technique is used in many ultrahigh speed D/A converters.

One other specialized type D/A converter used primarily in CRT display systems is the deglitched D/A converter. All D/A converters produce output spikes, or glitches, which are most serious at the major output transitions of $\frac{1}{4}$FS, $\frac{1}{2}$FS, and $\frac{3}{4}$FS as illustrated in Figure 7(a).

Glitches are caused by small time differences between some current sources turning off and others turning on. Take, for example, the major code transition at half scale from $0111\cdots1$ to $1000\cdots0$. Here, the MSB current source turns on while all other current sources turn off. The small difference in switching times results in a narrow half-scale glitch. Such a glitch produces distorted characters on CRT displays.

Glitches can be virtually eliminated by the circuit shown in Figure 7(b). The digital input to a D/A converter is controlled by an input register while the converter output goes to a specially designed sample-hold circuit. When the digital input is updated by the register, the sample-hold is switched into the hold mode. After the D/A converter has changed to its new output value and all glitches have settled out, the sample-hold is then switched back into the tracking mode. When this happens, the output changes smoothly from its previous value to the new value with no glitches present. Figure 8 shows a modular deglitched D/A converter, which contains the circuitry just described.

1 PURPOSE AND ROLE OF THE Z-TRANSFORM IN MEASUREMENT SYSTEMS

The z-transform is an invaluable tool for representing, analyzing, and designing discrete time signals and systems. Since most measurement systems now contain significant digital signal processing (DSP), the z-transform is an important element in measurement system design. Information about signals can be obtained by examining their z-transforms. In particular, the stability or instability of a linear time invariant discrete system is characterized by the location of the poles in the z-plane. It also indicates how the system responds to particular oscillatory components of the input.

Moreover, the use of z-transform techniques permits simple algebraic manipulations, that is, it facilitates the solution to difference equations because convolution operators are transformed into simple algebraic ones. In many cases, the sum of finite or infinite series for the z-transform can be expressed in a closed form expression, which offers a compact alternative representation of signals.

Prototype continuous time filters can be converted into high-quality digital filters by simple mapping from the s-domain to the z-domain. Consequently, the z-transform has become an important tool for the analysis and design of digital filters (**Article 148, General Performance of the Digital Filter, Volume 3**; **Article 149, Low-, High-, and Band-pass Digital Filters, Volume 3**; **Article 150, Finite Infinite Impulse Response (IIR) Digital Filters, Volume 3**; **Article 151, Finite Impulse Response (FIR) Digital Filters, Volume 3**).

2 INTRODUCTION TO Z-TRANSFORM THEORY

The z-transform of a sequence $x[n]$ is defined as

$$Z\{x[n]\} \equiv X(z) = \sum_{n=-\infty}^{\infty} x[n]z^{-n} \tag{1}$$

where z is a complex variable.

If z is defined as $z = re^{j\omega}$, where $r = |z|$ is the module of z and ω its argument, then (1) becomes

$$X(re^{j\omega}) = \sum_{n=-\infty}^{\infty} x[n]r^{-n}e^{-j\omega n} \tag{2}$$

Equation (2) can be interpreted as the discrete time Fourier transform (DTFT) of the modified sequence, $x[n]r^{-n}$.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

For $r = 1$, (2) reduces to the Fourier transform of $x[n]$, provided the latter exists. The contour $r = |z| = 1$ is a circle in the z-plane of unity radius and is called the *unit circle*.

The definition, (1), can be applied to the impulse response sequence, $h[n]$, of a digital filter. The z-transform of $h[n]$ is called the *transfer function* of the filter and is defined as

$$H(z) = \sum_{n=-\infty}^{\infty} h[n]z^{-n} \tag{3}$$

3 REGION OF CONVERGENCE

Since the z-transform is an infinite power series, it exists only for those values of z for which this series converges. For a given sequence, the set of values for which its z-transform converges is called the *region of convergence* (ROC).

The z-transform exists when the finite sum of (1) converges. A necessary condition for convergence is absolute summability of $x[n]z^{-n}$. Since $\left|x[n]z^{-n}\right| = \left|x[n]r^{-n}\right|$, then

$$\sum_{n=-\infty}^{\infty} \left|x[n]r^{-n}\right| < \infty \tag{4}$$

The region of convergence of a z-transform is important in that without knowledge of the ROC, there is no unique relationship between a sequence and its z-transform. Hence, a z-transform must always be specified with its region of convergence. Moreover, if the ROC of a z-transform of a sequence includes the unit circle, the Fourier transform of the sequence is obtained simply by evaluating the z-transform on the unit circle (Figure 1).

One-sided exponential signals are encountered frequently in engineering problems because one is interested in the behavior of a signal either before or after a given time instant. With such signals, the magnitude of one or more poles determines the ROC boundaries. Some of these properties of the ROC are illustrated in the examples that follow.

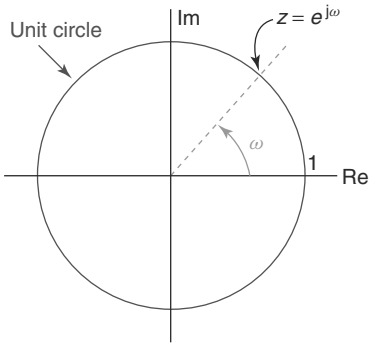

Figure 1. The unit circle.

Example 1. Right-sided sequence

Determine the z-transform of the signal,

$$x[n] = a^n u[n] = \begin{cases} a^n, & n \geq 0 \\ 0, & n < 0 \end{cases} = \sum_{n=0}^{\infty} a^n z^{-n}$$

Solution: Because $x[n]$ is nonzero only for $n \geq 0$, the sequence is known as a *right-sided* sequence.

From the definition, (1)

$$X(z) = \sum_{n=-\infty}^{\infty} x[n]z^{-n} = \sum_{n=0}^{\infty} a^n z^{-n} = \sum_{n=0}^{\infty} (az^{-1})^n$$

For convergence, $\sum_{n=0}^{\infty} |(az^{-1})^n| < \infty$

Thus the region of convergence is the range of values of z for which $|az^{-1}| < 1$ or equivalently, $|z| > |a|$, see Figure 2. Inside the ROC, the infinite series converges to

$$X(z) = \sum_{n=0}^{\infty} (az^{-1})^n = \frac{1}{1 - az^{-1}} = \frac{z}{z - a} \quad \text{for } |z| > |a|$$

Example 2. Left-sided sequence

Determine the z-transform of the signal,

$$x[n] = -a^n u[-n-1] = \begin{cases} -a^n, & n \leq -1 \\ 0, & n \geq 0 \end{cases}$$

$$= \sum_{n=-\infty}^{-1} (-a)^n z^{-n}$$

Solution: Because $x[n]$ is nonzero only for $n \leq -1$, the sequence is known as a *left-sided* sequence.

From the definition, (1)

$$X(z) = \sum_{n=-\infty}^{\infty} x[n]z^{-n} = -\sum_{n=-\infty}^{-1} a^n z^{-n}$$

$$= \sum_{n=1}^{\infty} (a^{-1}z)^n = 1 - \sum_{n=0}^{\infty} (a^{-1}z)^n$$

ROC is given by, $|a^{-1}z| < 1$ or equivalently, $|z| < |a|$ (see Figure 3). Inside the ROC, the infinite series converges to

$$X(z) = 1 - \frac{1}{1 - a^{-1}z} = \frac{z}{z - a} \quad \text{for} \quad |z| < |a|$$

Example 3. Two-sided sequence

Determine the z-transform of the signal,

$$x[n] = \left(-\frac{1}{3}\right)^n u[n] - \left(\frac{1}{2}\right)^n u[-n-1]$$

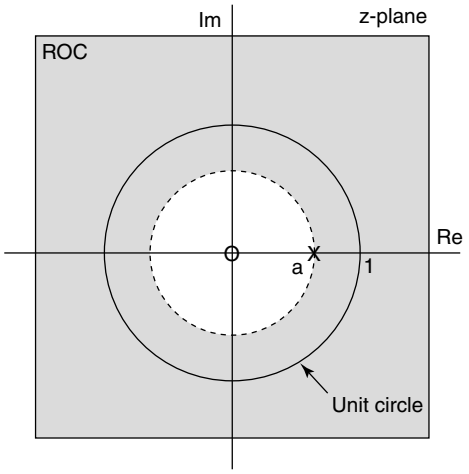

Figure 2. Pole-zero plot and ROC for a right-sided sequence.

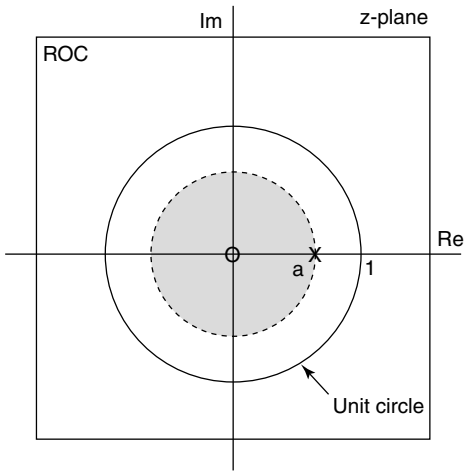

Figure 3. Pole-zero plot and ROC for a left-sided sequence.

Solution: From Examples 1, 2 and Table 2 the z-transform is

$$\left(-\frac{1}{3}\right)^n u[n] \overset{z}{\longleftrightarrow} \frac{1}{1+\frac{1}{3}z^{-1}}, \text{ ROC is } |z| > \frac{1}{3}$$

$$\left(\frac{1}{2}\right)^n u[-n-1] \overset{z}{\longleftrightarrow} \frac{1}{1-\frac{1}{2}z^{-1}}, \text{ ROC is } |z| < \frac{1}{2}$$

$$X(z) = \frac{1}{1+\frac{1}{3}z^{-1}} + \frac{1}{1-\frac{1}{2}z^{-1}}, \text{ ROC is } \frac{1}{3} < |z| < \frac{1}{2}$$

(see Figure 4).

4 PROPERTIES OF THE REGION OF CONVERGENCE

The basic properties of the ROC depend on the nature of the signal (for more details see Oppenheim and Schafer (1999) and Proakis and Manolakis (1996)).

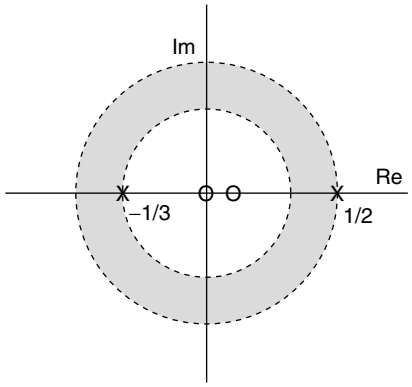

Figure 4. Pole-zero plot and ROC for a two-sided sequence.

Property 1: The ROC is a ring or a disk in the z-plane centered at the origin (Figures 2, 3, 4, and 6).

Property 2: The ROC cannot contain any poles, (Figures 2, 3, and 4).

Property 3: The Fourier transform of $x[n]$ converges absolutely if and only if the ROC of the z-transform of $x[n]$ includes the unit circle.

Property 4: If $x[n]$ is a finite duration sequence, that is, a sequence that is zero except in finite interval $-\infty < M_1 \leq n \leq M_2 < \infty$, then the ROC is the entire plane, except possibly $z = 0$ or $z = \infty$.

Property 5: If $x[n]$ is a right-sided sequence, that is, a sequence for $n < M_1 < \infty$, the region of convergence extends outward from the outermost finite pole in $X(z)$ to, and possibly include, $z = \infty$ (Figure 2).

Property 6: If $x[n]$ is a left-sided sequence, that is, a sequence for $-\infty < M_2 < n$, the region of convergence extends inward from the innermost nonzero pole in $X(z)$ to, and possibly include, $z = 0$ (Figure 3).

Property 7: A two-sided sequence is an infinite-duration sequence that is neither right sided nor left sided. If $x[n]$ is a two-sided sequence, the ROC will consist of a ring in the z-plane, bounded on the interior and exterior by a pole and, consistent with property 2, not containing any poles (Figure 4).

Property 8: The ROC must be a connected region (Figure 2, 3, 4, 5, and 6).

5 PROPERTIES OF Z-TRANSFORM

The z-transform possesses a number of properties that make it an extremely valuable tool in the study of discrete time signals and systems. Some of the useful properties that

Table 1. Properties of the z-transform.

Property	Sequence	z-transform	ROC
	$x[n]$	$X(z)$	ROC: $R_2 < \|z\| < R_1$
	$x_1[n]$	$X_1(z)$	R_{1c}
	$x_2[n]$	$X_2(z)$	R_{2c}
Linearity	$ax_1[n] + bx_2[n]$	$aX_1(z) + bX_2(z)$	Includes $R_{1c} \cap R_{2c}$
Time shift	$x_[n - n_o]$	$z^{-n_o}X(z)$	That of $X(z)$, except possibly $z = 0$ if $n_0 > 0$ and $z = \infty$ if $n_0 < 0$
Frequency scaling	$a^n x[n]$	$X(a^{-1}z)$	$\|a\|R_2 < \|z\| < \|a\|R_1$
Time reversal	$x[-n]$	$X(z^{-1})$	$\frac{1}{R_2} < \|z\| < \frac{1}{R_1}$
Multiplication by n	$nx[n]$	$-z\dfrac{d}{dz}X(z)$	ROC
Convolution	$x_1[n]^*x_2[n]$	$X_1(z)X_2(z)$	At least the intersection of R_{1c} and R_{2c}
Conjugation	$x^*[n]$	$X^*(z^*)$	ROC
Real part	$Re\{x[n]\}$	$\frac{1}{2}\{X(z) + X^*(z^*)\}$	Includes ROC
Imaginary part	$Im\{x[n]\}$	$\frac{1}{j2}\{X(z) - X^*(z^*)\}$	Includes ROC
Multiplication	$x_1[n]x_2[n]$	$\frac{1}{j2\pi}\oint X_1(v)X_2(\frac{z}{v})v^{-1}dv$	At least, $R_{1l}R_{2l} < \|z\| < R_{1u}R_{2u}$

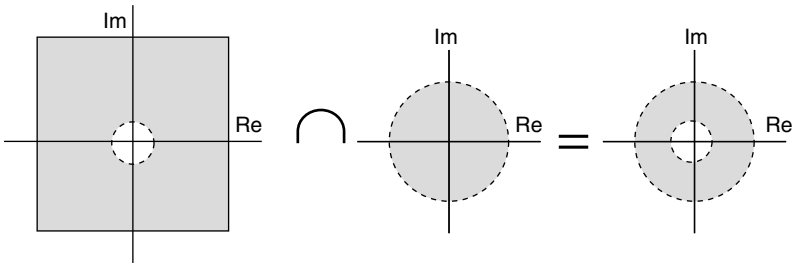

Figure 5. Intersection of the ROCs of the right-sided and left-sided sequences.

have found practical use in digital signal processing are summarized in Table 1.

6 SOME COMMON Z-TRANSFORM PAIRS

The recovery of a time domain signal from its z-transform, the inverse z-transform, can often be easily evaluated by expressing $X(z)$ as a linear combination of simpler basic z-transform pairs and the z-transform properties to invert a large class of z-transform. The z-transform pairs of common sequences are given in Table 2.

7 THE INVERSE Z-TRANSFORM

There are three methods that are often used for finding a sequence $x[n]$, given its z-transform $X(z)$.

7.1 Direct method (using the inversion integral)

$$x[n] = \frac{1}{j2\pi}\oint_c X(z)z^{n-1}dz \tag{5}$$

where $\oint_c$ represents integration along the closed contour, c, in the counter-clockwise direction in the z-plane. The contour must be chosen to lie in the region of convergence of $X(z)$.

7.2 Power series expansion method

The power series can be obtained by arranging the numerator and the denominator of $X(z)$ in descending powers of z and then dividing the numerator by the dominator using long division.

Given a z-transform $X(z)$ with its ROC, $X(z)$ can be expanded into a power series of the form $X(z) = \sum_{n=-\infty}^{\infty} c_n z^{-n}$, which converges in the ROC. Then by the uniqueness of the z-transform, $x[n] = c_n$ for all n.

Table 2. Some common z-transform pairs.

Signal, $x[n]$	z-transform, $X(z)$	Region of Convergence
$x[n] = \frac{1}{j2\pi} \oint X(z) z^{n-1} dz$	$X(z) = \sum_{-\infty}^{\infty} x[n] z^{-n}$	ROC
$\delta[n]$	1	All z
$\delta[n-m]$	z^{-m}	All z
$u[n]$	$\frac{1}{1-z^{-1}}$	$\|z\| > 1$
$a^n u[n]$	$\frac{1}{1-az^{-1}}$	$\|z\| > a$
$na^n u[n]$	$\frac{az^{-1}}{(1-az^{-1})^2}$	$\|z\| > a$
$-a^n u[-n-1]$	$\frac{1}{1-az^{-1}}$	$\|z\| < a$
$-na^n u[-n-1]$	$\frac{az^{-1}}{(1-az^{-1})^2}$	$\|z\| < a$
$\cos(\omega_o n) u[n]$	$\frac{1 - z^{-1}\cos(\omega_o)}{1 - 2z^{-1}\cos(\omega_o) + z^{-2}}$	$\|z\| > 1$
$\sin(\omega_o n) u[n]$	$\frac{z^{-1}\cos(\omega_o)}{1 - 2z^{-1}\cos(\omega_o) + z^{-2}}$	$\|z\| > 1$
$a^n \cos(\omega_o n) u[n]$	$\frac{1 - az^{-1}\cos(\omega_o)}{1 - 2az^{-1}\cos(\omega_o) + a^2 z^{-2}}$	$\|z\| > a$
$a^n \sin(\omega_o n) u[n]$	$\frac{az^{-1}\cos(\omega_o)}{1 - 2az^{-1}\cos(\omega_o) + a^2 z^{-2}}$	$\|z\| > a$

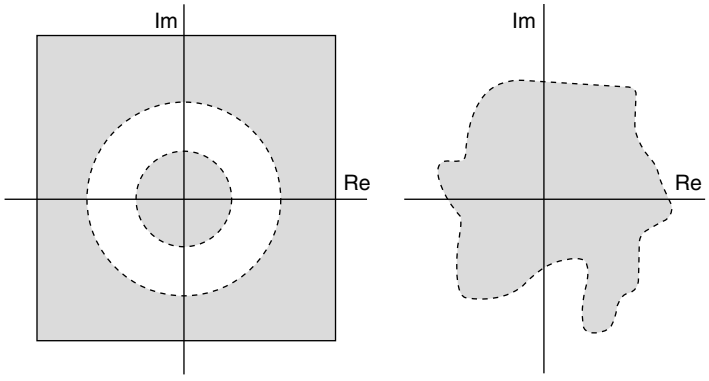

Figure 6. Unacceptable ROC.

7.3 Partial fraction expansion method

In the partial expansion method, the z-transform is first expanded into a sum of simple partial fractions. The inverse z-transform of each partial fraction is then obtained from tables, such as Table 1, and then summed to give the overall inverse z-transform.

In many practical cases of linear time invariant (LTI) systems, the z-transforms are rational functions of z^{-1} and given by

$$X(z) = \frac{b_0 + b_1 z^{-1} + b_2 z^{-2} + \cdots + b_M z^{-M}}{a_0 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_N z^{-N}} = \frac{\sum_{k=0}^{M} b_k z^{-k}}{\sum_{k=0}^{N} a_k z^{-k}} \tag{6}$$

If the poles of $X(z)$ are of the first order and, for simplicity, $N = M$, then $X(z)$ can be rewritten as

$$X(z) = B_0 + \frac{A_1}{1 - p_1 z^{-1}} + \frac{A_2}{1 - p_2 z^{-1}} + \cdots + \frac{A_M}{1 - p_M z^{-1}}$$

$$X(z) = B_0 + \frac{A_1 z}{z - p_1} + \frac{A_2 z}{z - p_2} + \cdots + \frac{A_M z}{z - p_M} = B_0 + \sum_{k=1}^{M} \frac{A_k z}{z - p_k} \quad (7)$$

where p_k are the poles of $X(z)$, assumed distinct, A_k are the partial fraction coefficients, and $B_0 = b_M/a_M$.

The coefficients A_k may be obtained by multiplying both sides of (7) by $z - p_k/z$ and setting $z = p_k$, that is,

$$A_k = \left. \frac{X(z)}{z}(z - p_k) \right|_{z=p_k} \quad (8)$$

8 APPLICATION OF THE Z-TRANSFORM IN SIGNAL PROCESSING

One of the most important applications of the z-transform in DSP is in the design and analysis of the errors in digital filters, (Oppenheim and Schafer, 1999) and (Proakis and Manolakis, 1996). It is used extensively to determine the coefficients of digital filters, especially Infinite Impulse Response (IIR) filters (**Article 150, Finite Infinite Impulse Response (IIR) Digital Filters, Volume 3**). Another important application of the z-transform in discrete filter design is in the representation of digital filter structures. These are often represented in the form of block diagrams, which represent the difference equations or equivalently the transfer functions.

8.1 Pole and zero description in the discrete time systems

In most practical discrete time systems, the transfer function, $H(z)$, can be expressed in terms of its poles and zeros, as shown by (9).

$$X(z) = \frac{b_0 + b_1 z^{-1} + b_2 z^{-2} + \cdots + b_M z^{-M}}{a_0 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_M z^{-M}} = \frac{\sum_{k=0}^{M} b_k z^{-k}}{\sum_{k=0}^{M} a_k z^{-k}} \quad (9)$$

If $H(z)$ has poles at $z = p_1, p_2, \ldots, p_M$ and zero at $z = z_1, z_2, \ldots, z_M$, then $H(z)$ can be factored and represented as

$$X(z) = K \frac{(z - z_1)(z - z_2)\ldots(z - z_M)}{(z - p_1)(z - p_2)\ldots(z - p_M)} \quad (10)$$

where K is the gain factor.

A plot of the poles and zeros of the transfer function is known as the *pole-zero diagram* and provides a useful way of representing and analyzing the filter. For example, for the filter to be stable, all its poles must lie within the unit circle. There is no restriction on the zero location.

8.2 Frequency response estimation

In the design of digital filters, it is often necessary to examine the spectrum of the filter to establish that the desired specifications are satisfied. The frequency response of a system can be readily obtained from the z-transform and given by

$$H(e^{j\omega t}) = \sum_{n=-\infty}^{\infty} h[n] z^{-n}|_{z=e^{j\omega t}} = \sum_{n=-\infty}^{\infty} h[n] e^{-jn\omega t} \quad (11)$$

where $H(e^{j\omega t})$ is the frequency response of the system. In general, $H(e^{j\omega t})$ is complex where the modulus represents its magnitude response and the phase response of the system.

9 CAUSALITY AND STABILITY

A causal linear time invariant system is one whose unit impulse response, $h[n]$, satisfies the condition

$$h[n] = 0, \quad n < 0 \quad (12)$$

Therefore, the impulse response of a causal LTI system is determined from the transfer function by using the right-sided inverse transforms. Consequently, an LTI system is causal if and only if the ROC of the system function is outside the maximum pole circle.

Anticausal signals, on the other hand, have ROC that is inside the minimum pole circle. If an LTI system is stable, then the impulse response is absolutely summable and the DTFT of the impulse response exists. Hence, the ROC must include the unit circle. Therefore, an LTI system is Bounded-Input Bounded-Output (BIBO) stable if and only if the ROC of the system function includes the unit circle.

Example 4. A discrete time system is characterized by the following transfer function

$$H(z) = \frac{3 - 4z^{-1}}{1 - 3.5z^{-1} + 1.5z^{-2}}$$

1. Specify the ROC of $H(z)$ and determine $h[n]$ for the following conditions
   (a) the system is stable
   (b) the system is causal
   (c) the system is anticausal.
2. Plot the pole-zero diagram of the system.
3. Plot the frequency response of the system. Assume a sampling frequency of 500 Hz and a resolution of less than 1 Hz.

Solution:

1. *ROC and $h[n]$*

$$H(z) = \frac{3 - 4z^{-1}}{1 - 3.5z^{-1} + 1.5z^{-2}} = \frac{z(3z - 4)}{z^2 - 3.5z + 1.5}$$

The poles of $H(z)$ are $p_1 = 0.5$ and $p_1 = 3$. Therefore, the expansion of the form, (6), is

$$\frac{H(z)}{z} = \frac{3z - 4}{(z - 0.5)(z - 3)} = \frac{A_1}{z - 0.5} + \frac{A_2}{z - 3}$$

$$A_1 = \frac{3z - 4}{(z - 0.5)(z - 3)} \cdot (z - 0.5)\Big|_{z=0.5}$$

$$= \frac{3 \times 0.5 - 4}{0.5 - 3} = 1$$

$$A_2 = \frac{3z - 4}{(z - 0.5)(z - 3)} \cdot (z - 3)\Big|_{z=3}$$

$$= \frac{3 \times 3 - 4}{3 - 0.5} = 2$$

$$\therefore \frac{H(z)}{z} = \frac{1}{z - 0.5} + \frac{2}{z - 3}$$

$$H(z) = \frac{1}{1 - 0.5z^{-1}} + \frac{2}{1 - 3z^{-1}}$$

(a) *Stable system*
For the system to be stable, the ROC must include the unit circle, hence $0.5 < |z| < 3$. Consequently, $h[n]$ can be obtained using Table 2 and is given by

$$h[n] = 0.5^n u[n] - 2(3)^n u[-n - 1].$$

The system is noncausal.

(b) *Causal system*
For the system to be causal, the ROC of the system function is outside the maximum pole circle, that is, $|z| > 3$. In this case, $h[n]$ is,

$$h[n] = 0.5^n u[n] + 2(3)^n u[n].$$

The system is unstable.

(c) *Anticausal system*
For the system to be anticausal, the ROC of the system function is inside the minimum pole circle, that is, $|z| < 0.5$. In this case, the impulse response

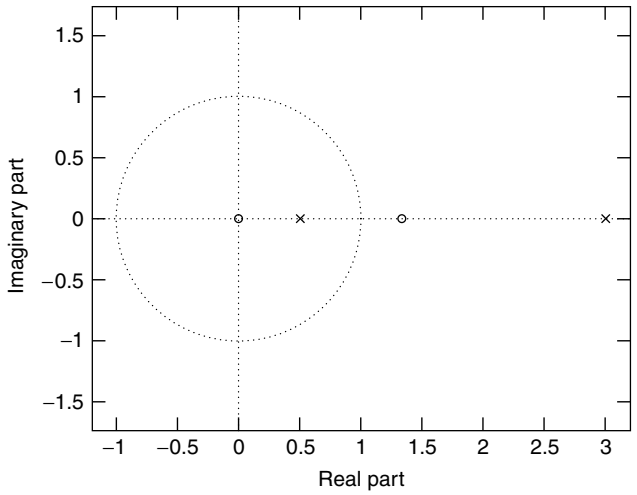

Figure 7. Pole-zero diagram.

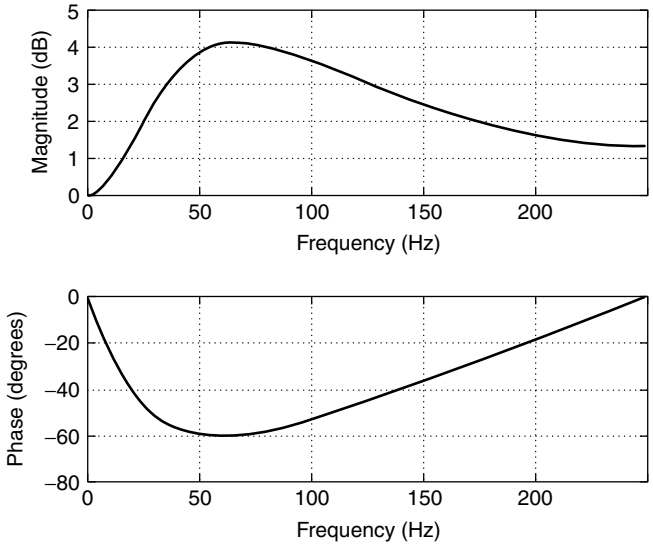

Figure 8. Frequency response.

is given by

$$h[n] = -0.5^n u[-n-1] - 2(3)^n u[-n-1].$$

The system is unstable.

2. *Plot of pole-zero diagram*

Figure 7 shows the locations of the poles and zeros of the discrete time system in the pole-zero diagram. MATLAB software is used for the plot shown in Figure 7 (for more details see Ifeachor and Jervis (2002)).

3. *Plot of frequency response*

Figure 8 shows the frequency response of the discrete time system. MATLAB software is used for the plot shown in Figure 8 (for more details see Ifeachor and Jervis (2002)).

1 FOURIER SPECTRUM OF PERIODIC SIGNALS

Each periodic signal with $x(t) = x(t + T_0)$ can be described as a sum of harmonic functions shown in (1) (*see also* **Article 27, Signals in the Frequency Domain, Volume 1**). The time shift T_0 represents the fundamental frequency $\omega_0 = 2\pi f_0 = 2\pi / T_0$. The frequencies of the harmonic functions are the fundamental frequency and its multiples like $k\omega_0$ with $k \in \mathbb{N}$. The even components of the periodic signal are specified with the cosine functions and the odd components with the sine functions. The amplitudes are the values of the variables a_k and b_k for the kth frequency while the component $a_0/2$ represents the DC-value.

$$x(t) = \frac{a_0}{2} + \sum_{k=1}^{\infty} [a_k \cos(k\omega_0 t) + b_k \sin(k\omega_0 t)] \quad (1)$$

A typical example with the components of a square wave function is shown in Figure 1. It shows three harmonic functions and the sum of these functions and the desired square wave function, which can be achieved when all harmonic components would be used.

If the periodic signal is known, the coefficients a_k and b_k can be calculated with an integral over one period of the fundamental frequency according to (2) and (3). Quite often t_0 is set to zero or $-T_0/2$.

$$a_k = \frac{2}{T_0} \int_{t_0}^{t_0+T_0} x(t) \cos(k\omega_0 t)\, \mathrm{d}t \quad k \in \mathbb{N}_0 \quad (2)$$

$$b_k = \frac{2}{T_0} \int_{t_0}^{t_0+T_0} x(t) \sin(k\omega_0 t)\, \mathrm{d}t \quad k \in \mathbb{N} \quad (3)$$

The harmonic functions in (1) can be substituted according to the Euler's theorem shown in (4) and (5).

$$\cos(\varphi) = \frac{1}{2}(\mathrm{e}^{\mathrm{j}\varphi} + \mathrm{e}^{-\mathrm{j}\varphi}) \quad (4)$$

$$\sin(\varphi) = \frac{1}{\mathrm{j}2}(\mathrm{e}^{\mathrm{j}\varphi} - \mathrm{e}^{-\mathrm{j}\varphi}) \quad (5)$$

Using this description, the time function $x(t)$ can be described with (6).

$$x(t) = \frac{a_0}{2} + \sum_{k=1}^{\infty} \left[\frac{1}{2}(a_k - \mathrm{j}b_k)\mathrm{e}^{\mathrm{j}k\omega_0 t} + \frac{1}{2}(a_k + \mathrm{j}b_k)\mathrm{e}^{-\mathrm{j}k\omega_0 t} \right] \quad (6)$$

The term $0.5(a_k - \mathrm{j}b_k)$ can be substituted by a complex value $\underline{c}_k$ while k has a positive value. The DC-value $a_0/2$ can be substituted by c_0 and the term $0.5(a_k + \mathrm{j}b_k)$ with a positive value of k can be substituted by a complex value $\underline{c}_{-k}$. The last part can be rewritten as $0.5(a_k - \mathrm{j}b_k)$ while k has a negative value and so it becomes $\underline{c}_k$ for $k < 0$. These substitutions are shown in (7) to (10).

$$\underline{c}_k = \frac{1}{2}(a_k - \mathrm{j}b_k) \quad k \in \mathbb{N} \quad \{1, 2, 3, \ldots, +\infty\} \quad (7)$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

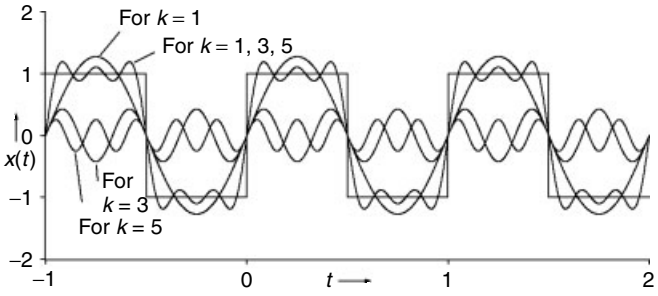

Figure 1. Square wave and 3 harmonics and sum of harmonics.

$$c_0 = \frac{1}{2}a_0 \tag{8}$$

$$\underline{c}_{-k} = \frac{1}{2}(a_k + \mathrm{j}b_k) \quad k \in \mathbb{N} \quad \{1, 2, 3, \ldots, +\infty\} \tag{9}$$

$$\underline{c}_k = \frac{1}{2}(a_k - \mathrm{j}b_k) \quad -k \in \mathbb{N} \quad \{-1, -2, -3, \ldots, -\infty\} \tag{10}$$

With this substitution, (1) becomes very compact and can be rewritten as (11).

$$x(t) = \sum_{k=-\infty}^{\infty} \underline{c}_k \mathrm{e}^{\mathrm{j}k\omega_0 t} \qquad k \in \mathbb{Z} \tag{11}$$

The variables $\underline{c}_k$ can be calculated using (7) or (10) with (2) and (3) for the variables a_k and b_k and the Euler's theorem to replace the cosine and sine functions. This leads to (12). If $x(t)$ is a real time function, the coefficients $\underline{c}_k = \underline{c}^*_{-k}$ (conjugate complex), based on the even cosine function of the real parts and the odd sine function of the imaginary parts.

$$\underline{c}_k = \frac{1}{T_0}\int_{t_0}^{t_0+T_0} x(t)\mathrm{e}^{-\mathrm{j}k\omega_0 t}\,\mathrm{d}t \qquad k \in \mathbb{Z} \tag{12}$$

The values of the Fourier coefficients a_k of an even pulse train with the amplitude 1 follows the si-function with the maximum amplitude of $2T_1/T_0$ for $k \in \mathbb{N}$ according to (13). The real values of the complex coefficients $\underline{c}_k$ follows the si-function with the maximum value of T_1/T_0 for $k \in \mathbb{Z}$ according to (14). Figure 2 shows a part of an even pulse train with $T_1 = T_0/4$, the coefficients of a_k (b_k are all zero) and the real part of $\underline{c}_k$ (imaginary parts of $\underline{c}_k$ are all zero).

$$a_k = \frac{2T_1}{T_0}\frac{\sin\left(\dfrac{k\pi T_1}{T_0}\right)}{\dfrac{k\pi T_1}{T_0}} = \frac{2T_1}{T_0}\,\mathrm{si}\left(\frac{k\pi T_1}{T_0}\right); \quad b_k = 0 \tag{13}$$

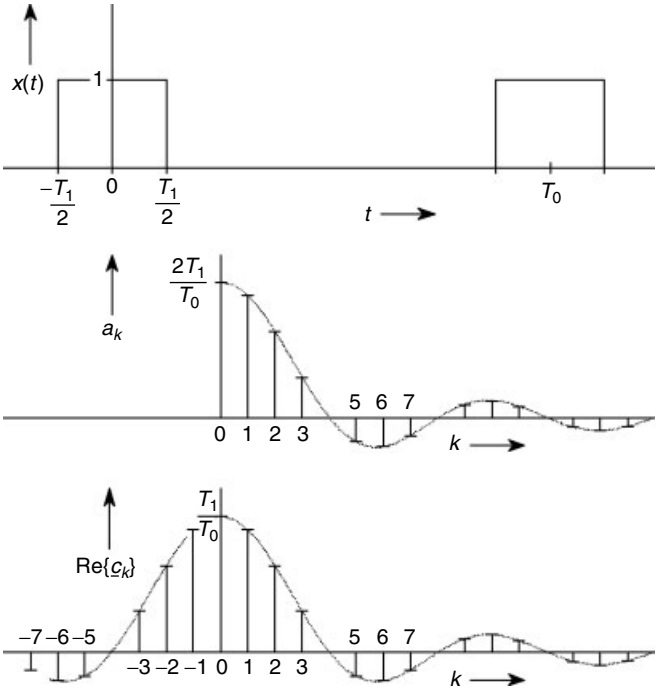

Figure 2. Even pulse train, Fourier coefficients a_k and complex Fourier coefficients $\underline{c}_k$.

$$\underline{c}_k = \frac{T_1}{T_0}\frac{\sin\left(\dfrac{k\pi T_1}{T_0}\right)}{\dfrac{k\pi T_1}{T_0}} + \mathrm{j}0 = \frac{T_1}{T_0}\,\mathrm{si}\left(\frac{k\pi T_1}{T_0}\right) + \mathrm{j}0 \tag{14}$$

2 ALIASING DISTORTION

For digital signal processing, it is necessary to convert an analog function into a digital representation. Therefore, the analog function is sampled with a constant sampling rate and each value is converted into a digital representation (*see also* **Article 138, Sampling Theory Relevant to DAS, Volume 3**). The function of sampling can be regarded as a multiplication of the original analog function with an impulse train of Dirac impulses as described in (15). Each sampled value x_n is the value of the original function $x(t)$ at the location nT_s of the time shifted Dirac impulses $\delta(t - nT_\mathrm{s})$.

$$x_n = x(nT_\mathrm{s}) = x(t) \times s(t) = x(t)\sum_{n=-\infty}^{\infty}\delta(t - nT_\mathrm{s}) \tag{15}$$

Such a multiplication in the time domain is equivalent to a convolution in the frequency domain. The spectrum of the original signal can be described with the frequencies up to a maximum frequency or cutoff frequency f_c. On the

basis of the description of a real-time function with complex Fourier coefficients, described in the previous section for a periodic signal, the frequency components cover an area between $-f_c$ to $+f_c$. The frequency of a Dirac impulse train has only frequency components at $f_s = 1/T_s$ and its multiples like $nf_s = n/T_s$. On the basis of the convolution, we can find the complex frequency values of the original analog signal around all frequencies of the Dirac impulse train. We get a periodic spectrum as shown in Figure 3.

The complete information of the analog signal can be found around each frequency component nf_s of the Dirac impulse train. Using an ideal filter, we can select a frequency area of, for example, $-f_c$ to $+f_c$. In this case, we get the original analog function back as shown with the dotted line in Figure 3. This works as long as the frequency areas of the reproduced original spectrum do not overlap. When the sampling frequency is not high enough ($f_s < 2f_c$), the spectrums will overlap. This effect is called *frequency folding* (*see also* **Article 138, Sampling Theory Relevant to DAS, Volume 3** and **Article 31, Discrete Signal Theory, Volume 1**). In this case, the ideal filter would select not only the original frequency components but also the overlapping part of the reproduced frequency components as shown in Figure 4.

The selection of an ideal filter for the frequency components between $-f_c$ and $+f_c$ causes a deviation within the reproduced analog signal. The frequencies f of the original spectrum appear at the frequency $f_s - f$. If these frequencies are in the overlapping part, they will be interpreted as frequency components with values of $f_s - f$. So you get frequency components with different frequencies out of the original signal. This effect is called *aliasing effect* of the sampling process or aliasing distortion. To avoid this, the frequency of the sampling rate has to fulfil (16). To meet this condition, you have to use a sampling rate that is high enough or you have to reduce the frequency area of the analog signal using analog low pass filters as antialias filters.

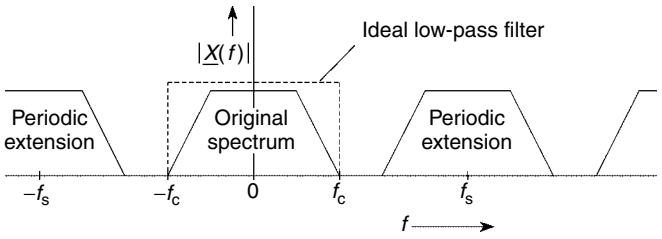

Figure 3. Spectrum of a sampled signal with $f_s > 2f_c$.

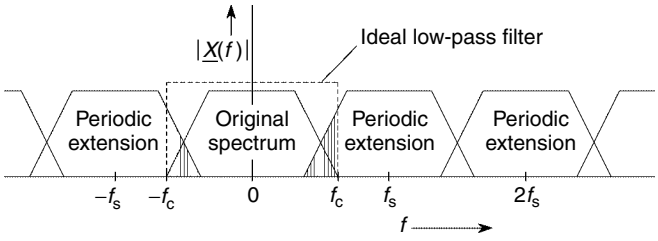

Figure 4. Spectrum of a sampled signal with $f_s < 2f_c$ with frequency folding.

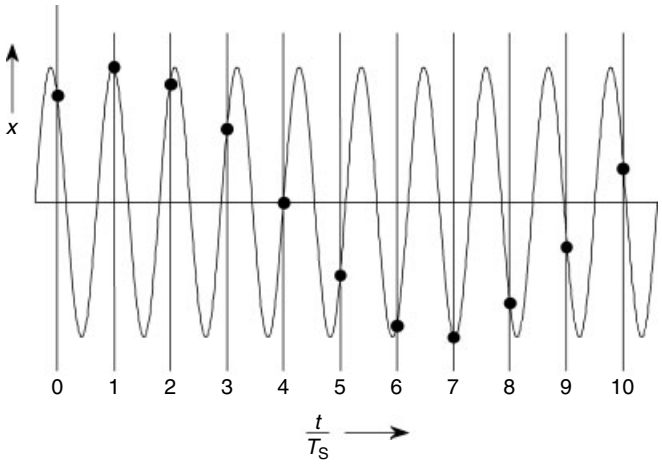

Figure 5. Sampled sine function with alias distortion.

$$f_s \geq 2f_c \tag{16}$$

A simple example of the aliasing effect is shown in Figure 5, where a sine function is sampled with an unsuitable sampling rate. It can be seen that the indicated sample points suggest a frequency component that is not part of the original function.

3 DISCRETE FOURIER TRANSFORM

If we use a digital system to convert the sampled time function into the frequency domain, (12) of the previous section becomes (17). The complex spectral component $\underline{X}_k$ is the sum of all sampled time values x_n multiplied with an arrow within the complex plane adjusted with its number of periods k to the corresponding time position n within the used time window of N samples.

$$\underline{X}_k = \sum_{n=0}^{N-1} x_n e^{-j2\pi nk/N} \quad N \in \mathbb{N} \tag{17}$$

Figure 6 illustrates the function of this equation. On the left-hand side, you see a sine function, which can be described with N samples from 0 to $N-1$. The dimension of the real part is the horizontal line and the time is the vertical line. You can imagine the imaginary part, which would be orthogonal to these two dimensions. The function

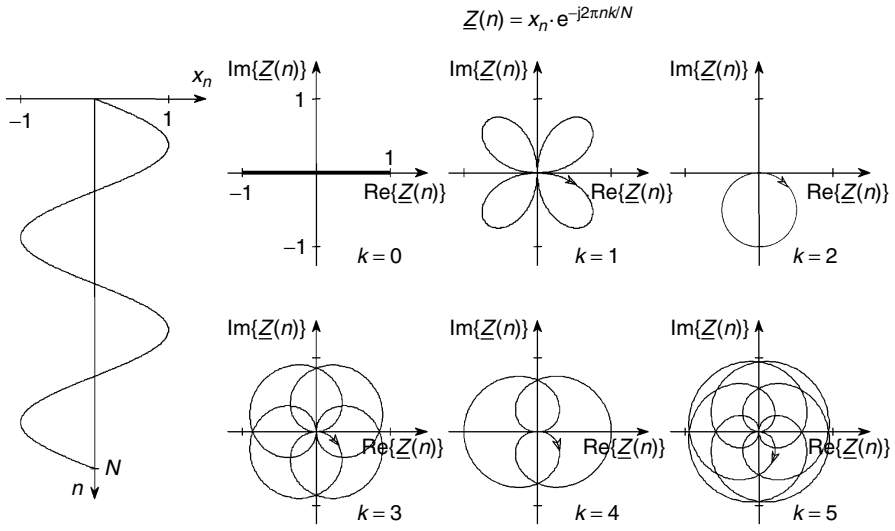

Figure 6. Graphical interpretation of the DFT.

$e^{-j2\pi nk/N}$ twists the time function with k revolutions at the end where the Nth sample would be. The other six diagrams show the projection of this twisted sine function into the complex plane where the real part is the horizontal line and the imaginary part is the vertical line. If $k = 0$, the function is not twisted and the projection describes a horizontal line as shown in the top left diagram. The sum $\underline{X}_0$ of all components is zero, which means that the sine function has no DC component. If $k = 1$, the resulting projection is shown in the top middle diagram. It describes a symmetric function and the sum $\underline{X}_1$ of all components is zero, which means that the analyzed sine function has no component with 1 period in the time window. If $k = 2$, the resulting projection is shown in the top right diagram. It describes a circle around $-j0.5$ with two revolutions and the sum $\underline{X}_2$ of all components is $-jN/2$, which means that the analyzed sine function has a component with 2 periods in the time window. Nevertheless, all other values of k up to $N - 1$ will produce a sum with the value of zero except $k = N - 2$ where the sum has the value $+jN/2$. Using (17), the sine function with two periods in the time window is transformed into a description with $\underline{X}_2 = -jN/2$ and $\underline{X}_{N-2} = +jN/2$.

There exist slightly different equations for this transformation. Some have used average values, which is the sum divided by the number of elements and so the values of the spectrum become independent of the number of samples. In this case, all following equations and scaling might be different based on this factor. The equations in this article have used the more often described equations of the discrete Fourier transform where the factor $1/N$ is used in the inverse Fourier transform. This is the sum of all complex frequency components $\underline{X}_k$ adjusted with the number of periods k and the used time position n within the used time window of N samples according to (18).

$$x_n = \frac{1}{N} \sum_{k=0}^{N-1} \underline{X}_k \, e^{j2\pi nk/N} \quad N \in \mathbb{N} \tag{18}$$

Figure 7 shows the inverse Fourier transform with the values determined in Figure 6. In the complex plane, the two components with the amplitude $N/2$ are shown. For the time position $n = 0$, the sum of both components is zero and this is the value of x_0. The value of $x_{N/16}$ where $n = N/16$ ($n \in \mathbb{N}$), the component of X_2 will rotate counterclockwise with 45° or $\pi/4$ and the component of X_{N-2} will rotate clockwise with 45° or $\pi/4$. The sum of both components yields $x_{N/16} = \sin(\pi/4) \approx 0.707$. On the basis of the symmetric frequency components of a real time function, all values x_n have an imaginary part of zero.

4 FAST FOURIER TRANSFORM

A central operation of the Fourier transform and the inverse Fourier transform is a complex multiplication with sine and cosine terms. For the calculation of all values, there are around N^2 complex multiplications and additions necessary. For a large number N of sample points, the calculation time of the frequency components becomes quite long and so several attempts have been made to reduce the amount of necessary computational time for solving this equation.

The used factor of $e^{2\pi nk/N}$ is a revolving arrow around the unit circle in the complex plane. The basic step size is $e^{2\pi/N}$. If N has the value of 2 to the power of ν

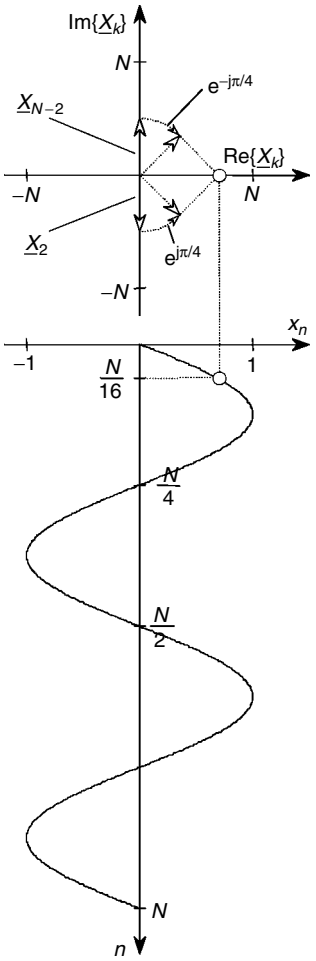

Figure 7. Graphical interpretation of the inverse DFT.

where $\nu \in \mathbb{N}$, you get the same positions of this arrow at different combinations of nk/N. Figure 8 shows this effect for $N = 16$ samples for 4 different values of k.

A very efficient algorithm using this effect was published by Cooley and Tukey in 1965. Their algorithm needs about $N \log_2(N)$ multiplications and additions. This is the reason why this algorithm is $N/\log_2(N)$ faster. Table 1 shows this factor for different numbers of samples. For $N = 16\,384$ samples, the relation of the time difference is nearly the same as 1 h for the discrete Fourier transform (DFT) down to 3 s for the fast Fourier transform (FFT). On the basis of this, it is highly recommended to use $N = 2^\nu$ with $\nu \in \mathbb{N}$ samples for data acquisition.

5 WINDOWING

One problem of data acquisition is to find the right size of the time window with N samples to truncate the sampled function. It is not a problem if it covers one period or its multiples of a periodic signal, but that is usually not the case. The used segment of the sampled

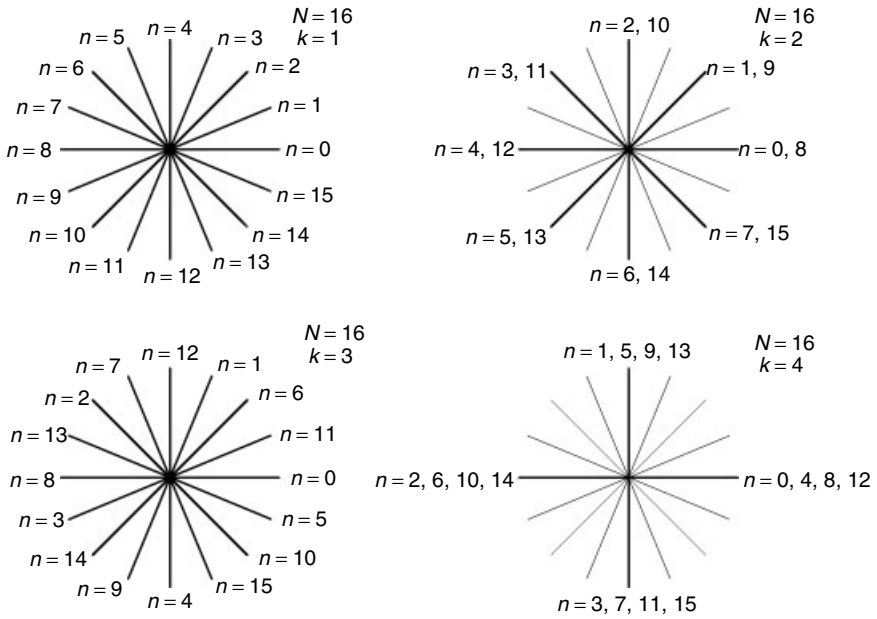

Figure 8. Arrow positions around the unit circle used for the FFT algorithm.

time signal can be regarded as a multiplication of the original analog signal with a single pulse selecting the time window. The spectrum of the samples is the convolution of the spectrum of the time function with the spectrum of the single pulse (time window or truncation window). In this case, the spectrum is continuous and the DFT (or FFT) algorithm determines values of the continuous spectrum at the frequencies $f_0 = 1/T_0$ and its multiples up to $(N-1)f_0$. The behavior of the continuous function between these points is unknown. I would prefer a different view. If we use the discrete spectrum of the DFT (mean values are zero), we get a description of a periodic signal in the time domain, where the N samples cover one period. In fact, the continuous signal of the analog function between these samples is unknown, but better to imagine. If this periodic signal describes the signal you want to analyze, the complex spectral values can be used. The problem with the periodic extension is to get a continuous periodic signal at the edges of the used period. Figure 9(a) shows two sampled sine waves of 20 periods and Figure 9(b) shows 20.5 periods in the time window. If we extend this period, we get the original signal in the case in Figure 9(a) and based on this we get a very good spectral description indicating 20 periods in the time window. If we extend the period in Figure 9(b), we get a nonharmonic connection between these periods. This produces a distribution or leakage distortion of the spectral line as shown in the amplitude spectrum in Figure 9(b). The reason is the nonharmonic connection of the periodic extension.

There have been several attempts at creating a weighting function or truncation window function of the used time window. Each can be regarded as a multiplication of this window with the time signal. The result is the convolution

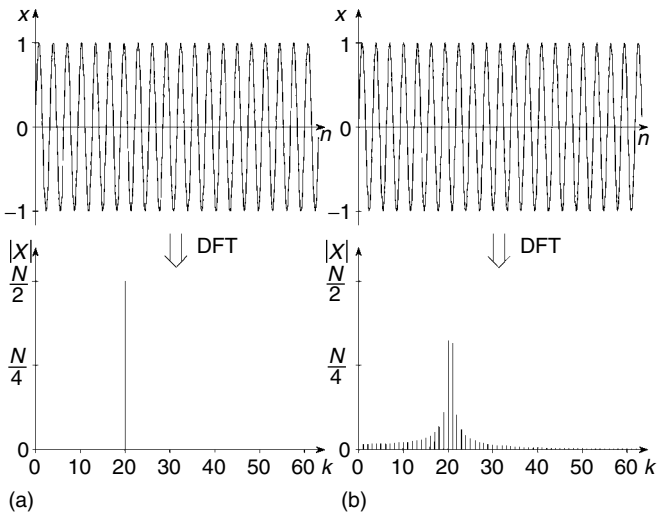

Figure 9. Amplitude spectrums of sampled sine functions.

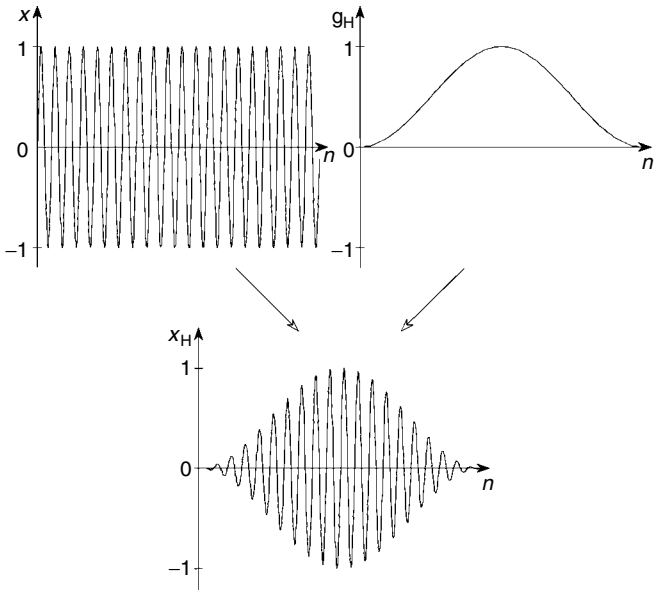

Figure 10. Function of the Hanning weighting window.

of both spectrums (*see also* **Article 31, Discrete Signal Theory, Volume 1**). An often used weighting function is the Hanning window, where each sampled value is weighted with a value according to (19).

$$g_{\mathrm{H}n} = \frac{1}{2}\left(1 - \cos\left(\frac{n \times 2\pi}{N}\right)\right) \qquad n \in \{0, 1, 2, 3, \ldots, N-1\} \quad (19)$$

Figure 10 shows the behavior in the time domain.

In this case, the periodic extended signal of the sampled time window has got an amplitude modulation with the frequency f_0. This creates side bands if we have only multiple periods in our time segment of N samples as shown in Figure 11(a). If we have fractions of such a signal as shown on the right-hand side in Figure 10, we get only a small leakage distortion of the original spectrum at 20.5 f_0 of the spectrum. It is much easier to analyze such a spectral description.

6 AVERAGING IN TIME AND FREQUENCY DOMAIN

Quite often the signal we want to analyze is covered in noise. This means that we have a signal, for example, a square wave function, we want to analyze and disturbing noise. One data acquisition process with N samples provides a spectrum, which does not give us the necessary accuracy. If the process is continuous, and if we can measure several time windows with the same conditions, we

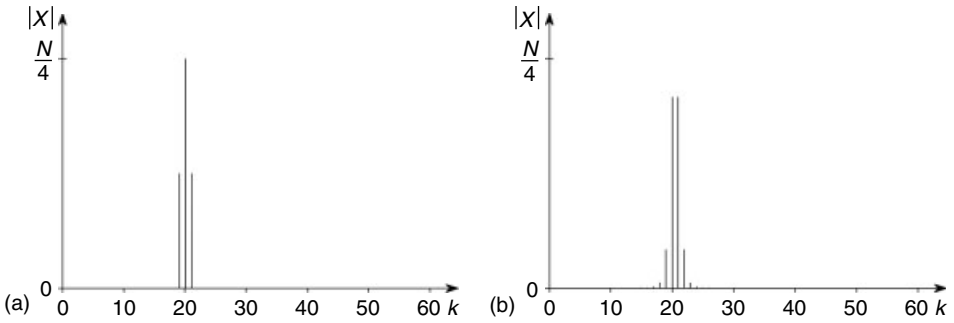

Figure 11. Amplitude spectrums of sampled sine functions with Hanning weighting window.

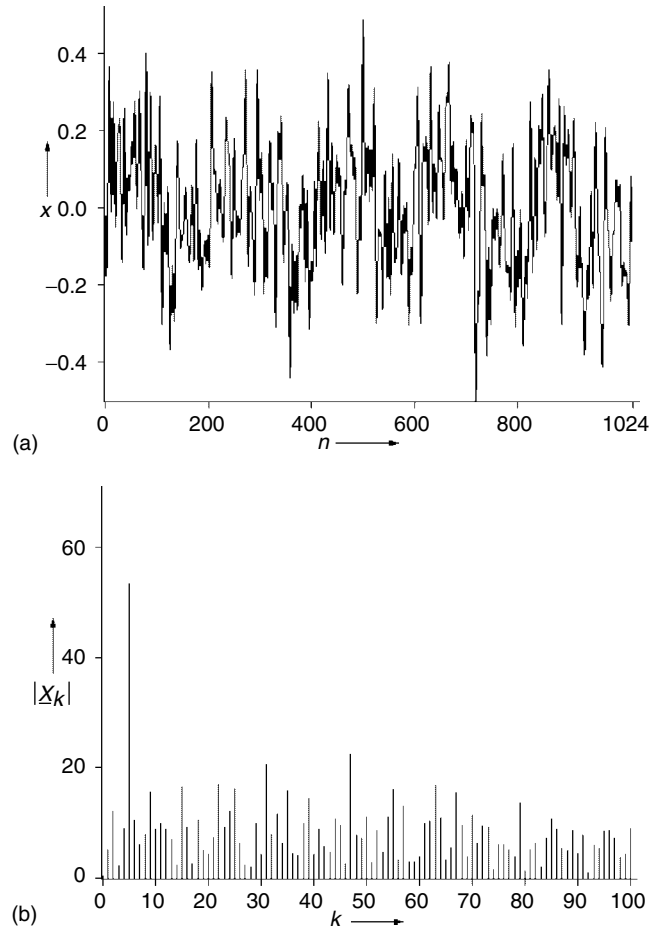

Figure 12. Square wave signal and noise in the time and frequency domain.

can use an average algorithm. Let us assume that the signal has a stable amplitude and frequency, and that the noise has a spectrum where the values in each time segment varies around a mean value. The behavior of such spectral components can be described with a mean value and a standard deviation. Figure 12 shows a measured square wave signal of 5 periods with noise sampled with 1024 samples and the spectrum up to $k = 100$.

If you cannot use a synchronization with the square wave signal, the phase of all components of our square wave function varies and we can only average the amplitude spectrum of all measured time windows as described in (20). If we use only the amplitude spectrum $|\underline{X}_k|$, we cannot apply the inverse DFT to regenerate the time signal based on the missing phase of the frequency components. Using this average function, we get the spectrum of the signal added with the average value of the noise. The standard deviation of the noise components around its mean value will be reduced. Such a spectrum is shown in Figure 13 with an average over 100 time windows ($M = 100$). The frequency components of the square wave signal can be seen easily.

$$\overline{|\underline{X}_k|} = \frac{1}{M}\sum_{m=1}^{M}|\underline{X}_{km}| \qquad k \in \{0, 1, 2, 3, \ldots, N-1\} \quad (20)$$

If we can get a synchronized time window for data acquisition, for example, with a separate trigger signal, the phase of the spectral components of our signal will not change in the spectrum and we can apply the average

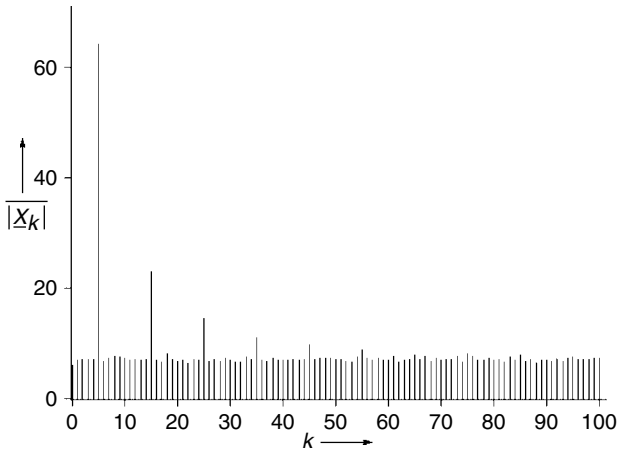

Figure 13. Averaged amplitude spectrum of a square wave signal and noise.

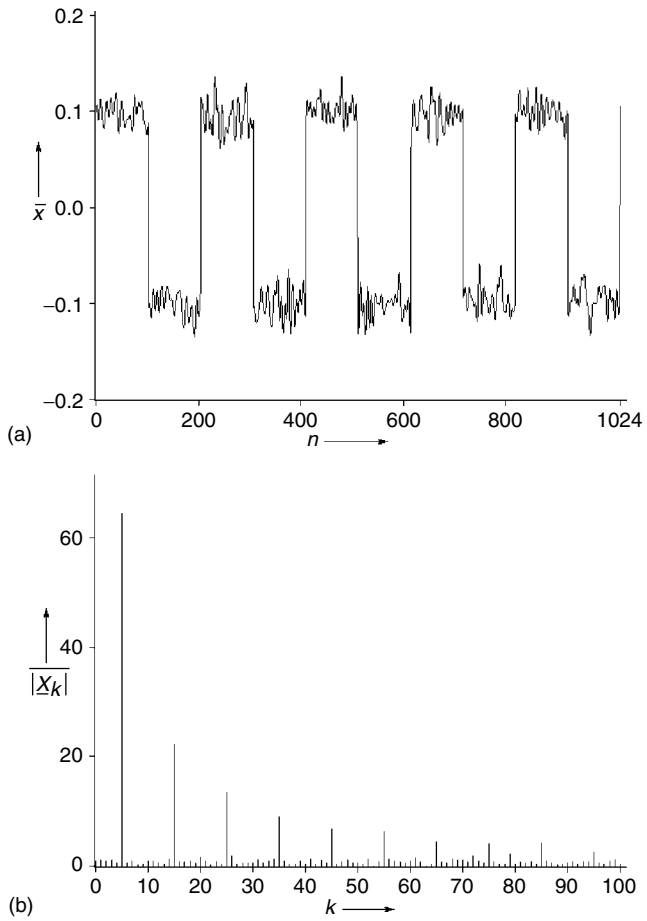

Figure 14. Averaged square wave signal and noise in the time and frequency domain.

algorithm to the time signal. The phase of the noise signal is not synchronized and on the basis of this effect the value of those spectral components will be reduced. The average algorithm can be applied to the time signal (21) or to the complex spectral values (22). Figure 14 shows a time signal and its spectrum of 100 time windows ($M = 100$) as presented in Figure 12. The remaining noise becomes much smaller and the frequency components of the square wave signal can be analyzed to higher frequency components compared with the spectrum shown in Figure 13.

$$\overline{x_n} = \frac{1}{M}\sum_{m=1}^{M} x_{nm} \qquad n \in \{0, 1, 2, 3, \ldots, N-1\} \qquad (21)$$

$$\overline{\underline{X}_k} = \frac{1}{M}\sum_{m=1}^{M} \underline{X}_{km} \qquad k \in \{0, 1, 2, 3, \ldots, N-1\} \qquad (22)$$

1 ELEMENTS OF DIGITAL SIGNAL PROCESSING (DSP)

Most Digital Signal Processing (DSP) devices incorporate similar functions and features, the reason for this is clear when we consider the fundamental algorithms for which they are designed to process. The majority of DSP algorithms currently in widespread use fall into the following categories: Filtering of signals (convolution), Transformation of signals (e.g. time to frequency domain) or Correlation (comparison of signals), (Ifeachor and Jervis, 2001).

Considering the first of these terms; 'Digital filtering', generally refers to a numerical operation governed by the following relationship

$$y(i) = \sum_{k=0}^{K} b(k)x(i-k) - \sum_{m=1}^{M} a(m)y(i-m) \qquad (1)$$

Without really going into the mathematics of this relationship, it can be seen that the process of digital filtering a signal requires a number of addition $\mathbf{\Sigma}$, subtraction, and multiplication $a(m)y(i-m)$ operations. In the relationship, the values $b(k)$ and $a(m)$ represent two tables of filter coefficients stored in memory. These will be multiplied by tables of past input $x(i-k)$ and output $y(i-m)$ samples respectively. Each time a new input sample arrives it will be placed on the top of the input sample table and the oldest sample removed. Similarly, new output samples will be placed onto the top of the output sample table and the oldest removed; hence, both data tables always have a fixed length for any given filter design. Figure 1 depicts the basic arrangement for a single table of coefficients and past output samples.

The process outlined above indicates the features that will be required on any general purpose DSP device. It should be able to efficiently access and manage its memory areas and simultaneously handle the flow of data into and out of its data ports. For real-time operation, the DSP device will also require a fast arithmetic unit, special memory addressing modes, and good support for interfacing to external I/O.

Another example of a common DSP algorithm is the Fast Fourier Transform (FFT), which is essentially an efficient method for calculating the Discrete Fourier Transform (DFT). The FFT was first described in 1963 by Cooley and Tukey, and has become widely used for obtaining the frequency domain representation of time domain signals. The mathematical relationship used to describe the DFT is given in (2).

$$X(K) = \sum_{n=0}^{N-1} x(n)W_N^{nK}, \quad \text{where } W_N^{nK} = \mathrm{e}^{-\frac{j2\pi nm}{N}} \qquad (2)$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

ISBN: 0-470-02143-8.

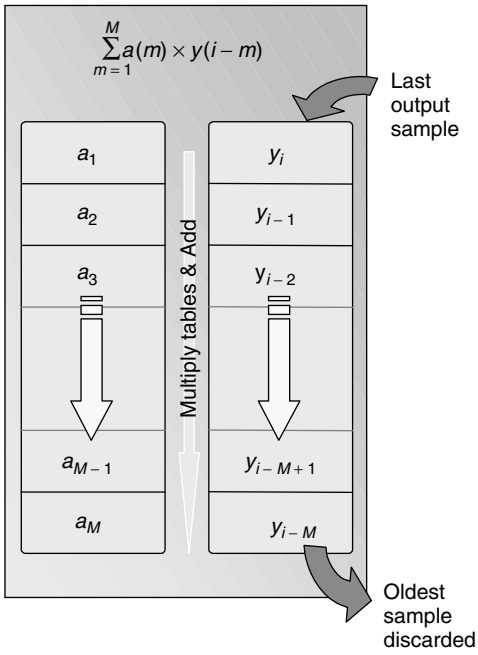

Figure 1. Filter coefficients and samples.

It can be seen that the relationship for the DFT again calls for storage of a list of coefficients W_N^{nK} (often referred to as *Twiddle factors*) in memory along with a list of sample data. The frequency resolution of the DFT is determined by the number of sample points used in the calculation and hence this directly determines the number of sample points/twiddle factor values that need to be stored in memory. The requirement for efficient data access and memory management is therefore a requirement for this DSP application as are a fast arithmetic unit and specialist memory addressing modes.

Correlation, Convolution, and Power Spectral Density are all examples of functions related to the Discrete Fourier Transform. These common signal processing functions can all be executed in the digital domain using schemes similar to that shown in the equation for the DFT, (2).

In a typical system using a DSP device, the sampled data will arrive with a regular period at the input to the DSP. On the arrival of each data sample, the DSP will carry out the calculations described by the algorithm and the resulting data will be presented to the DSP output, again at a regular period. Clearly, the DSP must be quick enough to complete algorithm processing before the next new data sample arrives. This characteristic is essential for any device that will be used successfully to implement DSP algorithms in real time.

It is apparent, from the expressions for the DFT and digital filtering, that the DSP device must carry out numerous arithmetic operations. In addition, extra steps must usually be taken by the DSP programmer to ensure that calculation errors will not occur under normal operation. Most DSP devices incorporate a number of arithmetic features that ease this process such as saturation arithmetic and overflow detection.

2 BASIC DSP FUNCTIONS

Following the previous discussion about the nature of typical DSP algorithms, it will be apparent that a number of characteristics are desirable for any DSP device, which is used to implement real-time DSP algorithms. Some of these fundamental DSP device functions are summarized in the following section.

2.1 The 'multiply accumulate' operation (MAC)

Each of the fundamental signal processing algorithms discussed in the previous section have operated upon data samples by calculating a running sum (accumulation) of a series of products. A DSP device must therefore be able to accumulate a series of multiplication results, this is known as the *Multiply Accumulate*, or MAC operation. The MAC is one of the most fundamental and distinct features that should be found on any dedicated DSP device.

2.2 Efficient data access–specialized memory addressing

The DSP must be able to access its memory areas as efficiently as possible so that the processor does not waste time waiting for data to be fetched. In the case of the MAC operation, which typically runs repeatedly very quickly for short bursts of time, it is important that an efficient MAC operation is not held up while waiting for data to be fetched from memory. Typically, DSP devices will provide a number of different methods for fetching data and determining its address within memory. The FFT, for example, makes use of so-called bit-reversed addressing. The output of an FFT algorithm is usually 'bit reversed', that is, the data points get out of sequence in a predictable way as a result of the FFT operation. This is rectified by accessing the data points using a bit-reversed addressing scheme that most DSP devices provide.

Another DSP specific addressing mode is the circular buffer, depicted in Figure 2, in which an area of memory can be made to appear as a continuous loop. Typically, data pointers are used to indicate the current data input location. Each time a data transfer takes place, the pointer is shifted one place further round the buffer.

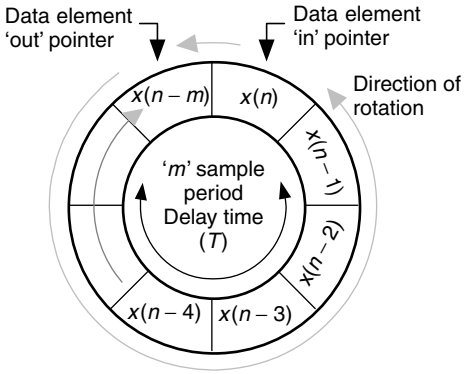

Figure 2. DSP circular buffer.

2.3 Deterministic performance

When a DSP algorithm is to be performed in real time using a DSP device, it is important that the programmer is able to predict the amount of processor time the function will take to complete, that is, DSP processing must be deterministic. If the processor operation is not deterministic, then problems can arise when large amounts of data are being processed in real time. Real-time performance is a term used to describe many DSP systems; it can be defined as

> Completing the required processing task quickly enough so that system performance can continue without being hindered by the processing overhead.

2.4 Extensive interfacing capabilities

Real-time DSP systems must be able to process signals that come from real-world sources such as data from an analog to a digital converter. The DSP device must therefore incorporate extensive interfacing capabilities so that transducers, data acquisition devices, memory or a system host can be connected efficiently. Most DSP devices provide on-chip interface components that require minimal external circuitry and only limited intervention by the main core of the DSP processor. The benefit of this is that processor time is not wasted interacting with slow peripherals

2.5 Superscalar operation

Superscalar mode of operation is a term often used in relation to DSP devices. Superscalar operation means that the device can execute multiple instructions in parallel. This explains why a DSP can be rated at 1600 MIPS even though the processor clock is only 200 MHz. In this case, the DSP executes eight parallel operations per instruction cycle. Superscalar operation is utilized heavily in most DSP devices, an example is the common MAC operation in which two instructions are executed in parallel, that is, the Multiply and Accumulate. Usually, the MAC is run in parallel with other operations such as data fetches and address pointer updates all of which operate simultaneously in the same instruction cycle. The result is that hundreds of millions of operations can (in principle) be performed per second.

2.6 Hardware repeat loop

Programmable DSP devices have instruction sets that contain unique features for DSP algorithm work. One particular feature, which is not generally available on a microprocessor, is hardware support for instruction looping. This recognizes that DSP algorithms consist of compact code segments that need to run very efficiently at full speed.

For example, in a filtering application, the MAC instruction will be run repeatedly in short bursts each time operating on different data sets. Without hardware looping, this process would be very inefficient as a loop counter variable would need to be maintained. Using a DSP device equipped with a zero overhead loop facility, the loop counter is maintained in hardware, easing the burden on the processor core. Also, the instruction is fetched from memory once and run many times thus giving a further potential speed increase.

3 IMPLEMENTATION OF DSP FUNCTIONS IN MICROELECTRONIC FORM

It is possible to perform DSP functions in real time using a standard microprocessor as opposed to a dedicated DSP device. In fact, many of the techniques pioneered on early DSP devices have now been adopted for use on general purpose microprocessors. In addition, many microprocessor and microcontroller manufacturers quote the ability of their device to perform DSP functions, after all, there is nothing sacred about a DSP function – it is merely a mathematical relationship. The issue is whether the device is capable of performing the function quickly enough for the intended application so as to give real-time performance. Typically, a standard microprocessor will not be able to efficiently perform DSP functions such as a MAC operation, simultaneous access of two data tables in memory or highly efficient bit-reversal addressing. In such a case, it would be necessary

for the programmer to devise some sort of software scheme to produce these functions, although this will never be as quick as the dedicated DSP hardware equivalent.

Take the humble multiply operation as an example; all general purpose DSP devices are provided with dedicated hardware to perform a multiply that typically provides calculation results within one processor cycle. In comparison, a typical microprocessor carries out its multiply operation by a binary long multiplication process. When it encounters a multiply instruction, an internal sequence of operations, called a *microcode*, is invoked. This microcode performs the multiplication as a sequence of shifts and adds on successive clock cycles until the result is complete. Since the microcode has many steps, the operation requires many clock cycles to perform. The resulting overhead for multiplication on a microprocessor could be approximately 80 processor clock cycles to perform a 16-bit multiplication. Both devices can perform a multiply; its just that the DSP device is generally quicker (Bateman and Paterson-Stephens, 2003). Of course, money is also a factor; if you are prepared to pay for an expensive microprocessor, then you are likely to get more hardware features such as a dedicated multiply unit.

4 PROGRAMMABLE CHIP SETS

The programmable, or general purpose DSP device, typically encompasses all, and more, of the features that have been presented in the preceding section. The programmable DSP may be reconfigured to suit an extremely wide range of different applications. Manufacturers of these devices usually provide software development tools and evaluation/development platforms that help engineers to design and develop new applications. Often manufacturers will provide extensive customer support, design services, access to third party vendors, and ready coded software libraries downloadable from the Internet. It has been the case that general purpose programmable DSP devices have been used in small volume applications where only tens of thousands, or fewer units are expected to be sold. DSP devices are produced by a number of manufacturers including, in no particular order, those identified in the following list by:

- Lucent Technologies
- Texas Instruments
- Philips
- Analog Devices
- Motorola
- ST Microelectronics
- Harris Semiconductors
- Microchip

Certain manufacturers have gained a reputation for their devices within particular industries, usually because they have incorporated some additional targeted features. For example, Analog Devices and Motorola DSP devices have gained wide acceptance in the professional audio product market, whereas devices from Texas Instruments are used extensively within telecoms applications. In the case of the pro-audio application, this has possibly been due to the development of low-cost 24- and 32-bit processors within the product range of Analog Devices and Motorola.

All programmable DSP chip sets have a range of software development options and tools available from the manufacturer. Often, DSP code is written using the C or C++ programming language, which helps to ensure portability between different DSP platforms, see Figure 3. C/C++ is often the first choice for developing signal processing functions; however, device specific assembly language is commonly used for low level operations that deal directly with I/O devices and other hardware elements. Assembly language is also commonly used for time-critical operations in which optimum performance cannot be achieved using C code, for example, processor interrupts associated with signal I/O are typically written using assembly language (Bateman and Paterson-Stephens, 2003).

Unfortunately, no standard DSP programming language has yet emerged so it is necessary for the designers to familiarize themselves in great detail with the specifics of each new device that is used. Although many DSP manufacturers produce a family of different devices covering fixed/floating point, different performance levels (MIPS) and I/O capabilities – often each device within a family will have its own individual quirks, which prevent easy movement of DSP code from one device to another.

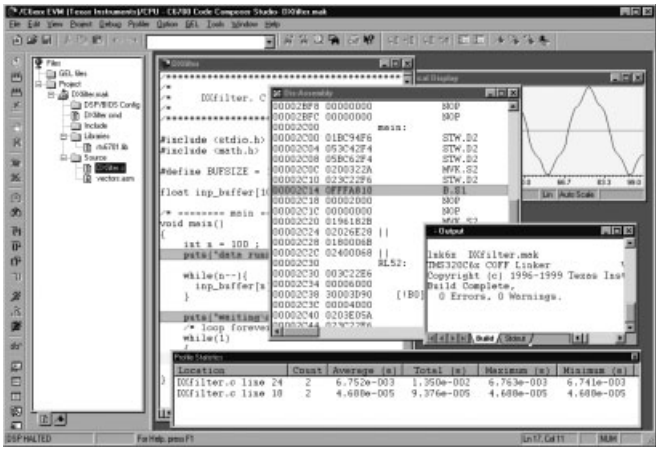

Figure 3. C/C++ program development for the TI C6x DSP processor.

5 APPLICATION SPECIFIC INTEGRATED CIRCUITS (ASICS)

This type of device is expensive to develop and production is only viable for high volume applications where sales targets are in the hundreds of thousands of units. Application Specific Integrated Circuit (ASIC) based DSP designs are expensive to develop because the level of simulation and testing required before going to fabrication is usually more rigorous – obviously, with a programmable device it is possible to make (software) changes to the design after the system has been manufactured, whereas an ASIC design, once fabricated, is fixed – mistakes are consequently very expensive. Development tools sets and test jigs for ASIC are also somewhat specialized and are consequently expensive. The ASIC option does however provide a cost effective route if the sales volumes are high since an ASIC can be developed to provide the specific functions and features required for an application and as such excess cost for unused features can be minimized (Bateman and Paterson-Stephens, 2003). The trend for general purpose DSP devices on the other hand is toward the integration of large amounts of memory, extensive, and varied I/O facilities and numerous other features. While this is useful for the general case, it is likely that many of these features will not be required in a large number of applications.

It is interesting that manufacturers of some general purpose DSP devices are now providing the option for user specified device features so that a device can be made up from a specific processing core and selected on-chip peripherals. ASIC devices also offer good reliability because they usually only perform the specific tasks for which they have been designed. Further more expensive silicon area can be minimized and because many different system functions can be brought onto the ASIC itself, the final system design can be optimized in terms of the circuit board (PCB) space required. One further issue relating to the minimization of circuit functions in silicon is that ASIC-DSP designs used for low power applications, such as mobile telephony, for example, can be optimally low power for the specific application, that is, no excess or unused circuitry means that power consumption can be kept to the minimum.

One example of an ASIC device is a surround sound decoder chip used for consumer audio applications developed and produced by consumer product manufacturers such as Yamaha or Sony. Clearly, in this type of application worldwide distribution of large numbers of units is predicted.

6 INTRODUCTION TO GATE ARRAYS

Gate Arrays and specifically Field Programmable Gate Arrays (FPGA) are finding many applications in new DSP designs. FPGAs in particular offer a number of potential advantages over the traditional programmable DSP device (Goslin, 1997). The FPGA offers the opportunity to optimize silicon use to a specific application in much the same way as an ASIC. Additional system functions that would conventionally exist outside the DSP device can potentially be brought onto the FPGA and hence minimization of circuit board space can be achieved. A Gate Array is essentially a grid of unconnected logic cells that can be linked together as required, by the use of an appropriate tool, into a functioning circuit. The process of configuring the circuitry usually fuses a mesh of links between the logic cells. FPGA devices are available in a range of sizes up to complex devices containing tens of thousands of logic elements. One of the advantages of the FPGA design route is that the configuration of circuitry can be very application specific, for example, if the designer knows that the application will only require 13-bit arithmetic, then that is all that needs to be designed. Also, greater use of parallelism can be achieved with an FPGA than a programmable DSP. For example, if a very fast convolution (filtering) processor is required that contains say 16 filter taps, the filter would require 16 multiplies and 16 adds (MACS) per new input sample. In a programmable DSP application, a fast single MAC unit will be used within a hardware loop to perform the filter function in just over 16 instruction cycles. For the FPGA approach, it would be possible to incorporate 16 independent MAC units within hardware design, which can all operate simultaneously within one system cycle. The greater potential use of parallelism in the hardware design can therefore offer greater performance than that is achievable on a general purpose programmable DSP device (Goslin, 1997).

Development and production costs are significantly lower than the ASIC route and for many engineers the development process is more familiar compared to the use of a programmable DSP device. Because the design of a DSP function within an FPGA comes down to a description of hardware, for example, multipliers, delays and so on, many engineers are already familiar with the development process and tools. Typically, a graphical CAD-based approach to design can be used or the use of an appropriate Hardware Descriptor Language (HDL). All potential DSP functions can be defined in terms of a description of hardware. Many manufacturers provide downloadable HDL libraries that define typical DSP functions such as Convolution, Correlation, and Frequency Transforms. Also, a number of programmable DSP cores from manufacturers such as Texas Instruments and Analog Devices can be purchased in HDL language form for integration into an FPGA design (Bateman and Paterson-Stephens, 2003).

7 PROCESSORS IN GENERAL

There is an important device architecture difference between a classic microprocessor compared to the DSP device, that is, the overall structure of the memory itself within the device. Most microprocessors are designed around the Von-Neuman architecture, shown in Figure 4, in which the program instructions and data items share the same memory space and hence are accessed via the same address and data buses. This strategy can be slow because the CPU needs to fetch each instruction (op-code) to be executed followed by fetching any associated data (operands) before it can start processing. Each of these tasks takes up precious time, that is, processor clock cycles.

Most DSP devices use a style of processor architecture known as the Harvard Architecture (shown in Figure 5). Using Harvard Architecture the program and data items are stored in separate memory spaces, and are accessed by independent processor buses. An example of this is DSP devices from Motorola, which make use of a Dual-Harvard Architecture with two independent data spaces, X and Y, as well as a program memory space. Using Harvard Architecture enables program and data memory to be accessed simultaneously, giving a speed advantage over a conventional microprocessor architecture (Bateman and Paterson-Stephens, 2003). DSP devices usually have sophisticated Address Generation Units (AGUs), which generate data addresses using specific addressing modes. Modulo addressing is unique to DSP devices, and is useful for automatically implementing circular buffer memory constructs and bit-reversed addressing accesses with no software overhead. The ability to auto increment and decrement values in the address registers is also useful. The term software overhead refers to an additional code, which would need to be in place to perform a function if the specific feature was not available.

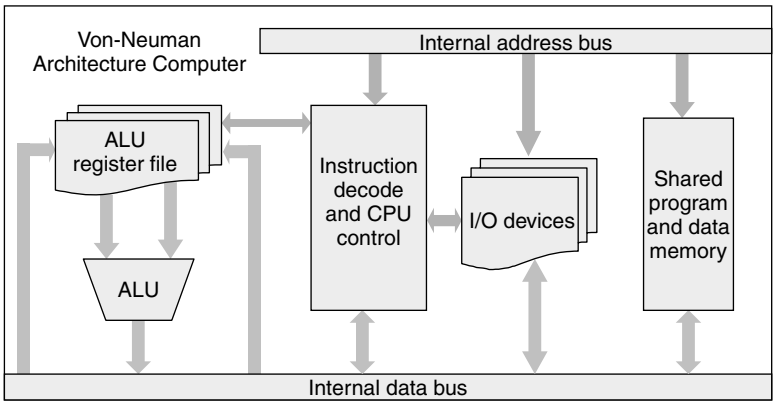

Figure 4. Von-Neuman Architecture Computer.

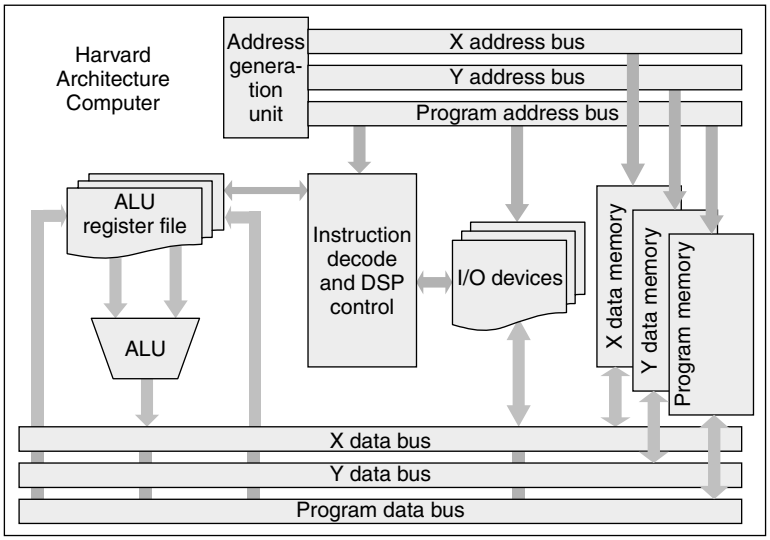

Figure 5. Harvard Architecture Computer.

Clock cycle	1	2	3	4	5	6	7	8	9
Fetch	F1			F2			F3		
Decode		D1			D2			D3	
Execute			E1			E2			E3
	Instruction cycle one			Instruction cycle two			Instruction cycle three		

Figure 6. Nonpipelined operation.

Clock cycle	1	2	3	4	5	6	7	8	9
Fetch	F1	F2	F3	F4	F5	Etc.			
Decode		D1	D2	D3	D4	D5	Etc.		
Execute			E1	E2	E3	E4	E5	Etc.	
	Instruction cycle one			Instruction cycle four					
		Instruction cycle two			Instruction cycle five				
			Instruction cycle three			Etc.			

Figure 7. Pipelined operation of DSP instructions.

DSP and Reduced Instruction Set Computer (RISC) architectures aim to deliver results from the processing core on every instruction cycle. However, in practice the processing of an instruction goes through a number of phases. The instruction must first be fetched from memory along with any associated operands, then the processing core will need to decode or interpret the instruction before finally dispatching it for execution. This scheme is shown diagrammatically in Figure 6.

The objective of pipelining is to overlap the different phases so that instructions can be fetched prior to the completion of other instructions in the pipeline. Figure 7 shows a pipelined arrangement in which the different phases of the three instructions previously shown in Figure 6 are now allowed to overlap. It can be seen that results start coming out of the core on every clock cycle. This is after a delay of two clock cycles while the first instruction ripples through the pipeline. The ability to pipeline instructions and data and the effectiveness of the pipeline comes largely from the fact that the DSP device has a very efficient memory architecture (Harvard Architecture). Many standard microprocessors attempt to pipeline instructions and data but it is doubtful that the pipeline will be as effective on a Von-Neuman compared to the Harvard Architecture (Bateman and Paterson-Stephens, 2003).

8 MEASUREMENT SYSTEM CHIP SETS

Many manufacturers produce system chip sets incorporating DSP hardware suitable for measurement applications. In fact, most general purpose DSP devices are well suited to this type of application. Standard interface methods have been adopted that allow DSP devices to be hooked up with I/O hardware for simple no fuss system development (TI-SPRA477, 1998). A standard high-speed serial interface known as I^2S has been adopted by most manufacturers, which allows a simple 3- or 4-wire interface between Analog-to-Digital (AD) and Digital-to-Analog (DA) converters and the DSP device (Bateman and Paterson-Stephens, 2003). Usually, AD and DA devices can be obtained for most applications that incorporate all the necessary timing logic and anti-aliasing filters. Furthermore, it is common practice to make use of a CODEC device that combines all the necessary analog input and output hardware, sampling logic, serial interface logic, filters, and so on. These devices offer a very simple and cost-effective way of integrating a complete measurement system into just a handful of chips. The word CODEC is used to describe a device that can be used to COde and DECode data between different formats. In the context we are considering here, the coding is from analog to digital form and the decoding is from digital back to analog. The term CODEC can also be used to describe any coder/decoder device or algorithm, for example, an algorithm that converts between a linear and compressed data format and back again could be described as a CODEC. The block diagram of a standard interface CODEC device is shown in Figure 8.

The CODEC shown in Figure 8 incorporates a parallel port that is generally used as a low speed connection through which the DSP device can send initialization information and monitor various aspects of the CODECs operation. The sample data is usually, though not necessarily, sent via the CODECs serial port, which is connected directly to one of the DSPs on-chip serial interfaces. The serial connection uses a four-wire bus comprising a data clock, frame sync, data in, and data out lines (Jordan, 1996).

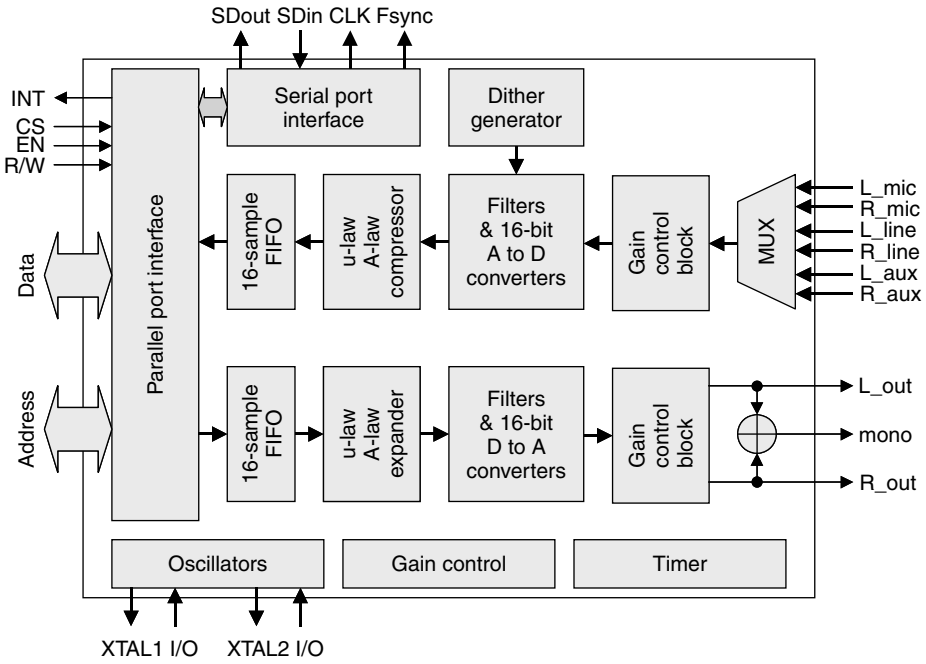

Figure 8. Standard interface CODEC for DSP-based measurement applications.

The CODEC requires only a minimal amount of external support components such as basic I/O buffering and filters, power smoothing, and a crystal clock. The I/O buffering can be made using standard op-amp designs and the filters only need to provide AC coupling that is, an RC filter will suffice. The crystal clocks are used to provide the sample rate for the device and this can be set to operate at any one of a number of standard rates (Crystal Semiconductor Corporation,1994). Because the CODEC incorporates its own sample rate generator, it is not necessary for the DSP to provide this from its internal clock source. Instead, it is common practice in this type of application for the CODEC serial port to be configured such that the CODEC generates the data clock and frame sync signals and the DSP simply synchronizes itself to the CODEC.

1 TOOL SETS IN SUPPORT OF DSP

Design for DSP applications, as with any design, must go through a number of stages and iterations before the final product can be released. For DSP designs, a number of key stages will need to be considered; at a basic level, these can be summarized as algorithm development and design, hardware implementation and software coding and these must be carried out in the context of the end application (Bateman and Paterson-Stephens, 2003). There are, of course, many factors that will influence the path taken for each of these design stages, development cost and time to market being the main driving factors. Many tools are available, which will help the engineer to realize a particular design as quickly as possible and at minimum cost. In particular, tools are available, which will enable algorithms to be simulated at block diagram level in order to verify the design concept (examples include Matlab and Simulink, or Hyperception), see Figure 1. The block diagram can then be automatically translated to a high-level language (HLL), such as C or Ada. The block diagram algorithm to HLL translation can be target specific, that is to say the code generated can be optimized for a particular DSP device (Real-time workshop running under Simulink) (MathWorks–A, 1998). Once the design has been translated, it is compiled and tested on the target device.

The testing and verification process has also advanced somewhat in recent years so it is now possible to monitor, in real time, the operations taking place inside the DSP device. This allows software problems to be identified and resolved as quickly as possible so that the overall design is not delayed (Bateman and Paterson-Stephens, 2003). Standard libraries for software development are also emerging, which means that the design can be built using standard signal processing plug-in functions; for example, in the design of a real-time filter, the engineer can select from a library of standard filter algorithms, add the necessary coefficients to define the filter response, and then finally glue the application together with a small amount of extra software that will manage data flow and other aspects of DSP 'housekeeping.' All this sounds very attractive and in principle the tools are all here and available now to carry out the task as described. However, in reality, the initial cost of setting up this sort of design approach can be high not only in terms of equipment and software costs but also in terms of a high initial learning curve. The final choice of approach will often be determined by other factors not least of all the context of the application, that is, whether the design is likely to be mass produced and sold at a low cost or it is a one-off for research purposes.

2 OVERVIEW OF SELECTED SMALL-TO-LARGE MAINLINE DSP TOOLS

2.1 Visualization tools–algorithm design/verification

Matlab

- Command line and interpreted-code simulation interface

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

© 2005 John Wiley & Sons, Ltd.

ISBN: 0-470-02143-8.

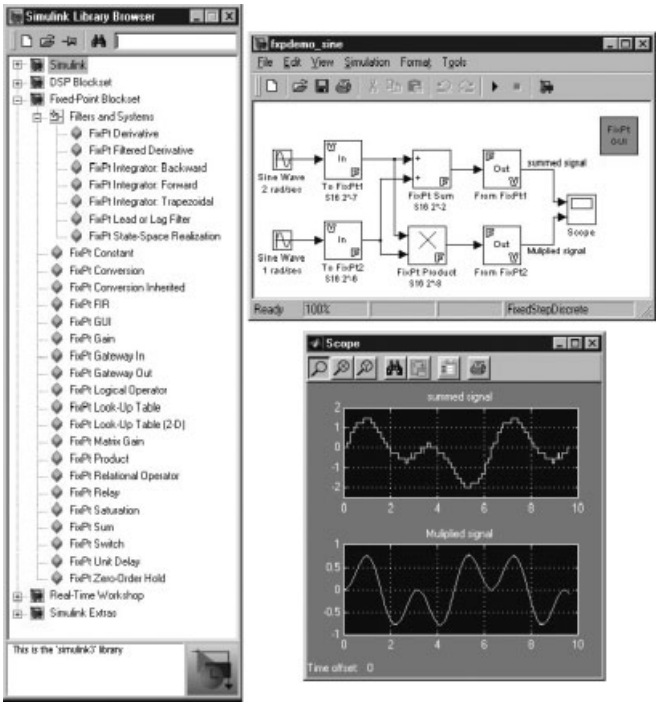

Figure 1. Simulink application modeling screen shot.

- Matrix-based programming language
- Extensive Toolbox support for a range of signal-processing tasks
- Complex graphing/plotting capabilities
- Massive library of support documentation and third party books
- Fast simulations.

Simulink

- 'Graphical front end' for Matlab – intuitive user interface
- All the power of Matlab with extra support for fast simulations
- Extensive range of toolboxes and support libraries
- Real-time mode simulation possible
- Compiled code blocks for very fast simulations
- Interfacing capabilities – able to connect algorithms to hardware
- Compilation of algorithms for target hardware 'Real-time Workshop'.

2.2 DSP system development tools

Visual DSP++ (Analog Devices)

- Can be used with entire range of Analog Devices DSPs
- Integrated design suite used for software and hardware debugging
- Mixed C/C++ and Assembly level programming and debugging
- Easy integration with Simulink target coder
- In-circuit emulation support – real-time debugging
- Support for customized host-control interface designs
- Memory data graphing support – useful for signal processing apps.

Code Composer Studio (Texas Instruments)

- Can be used with entire range of DSPs from Texas Instruments
- Integrated design suite used for software and hardware debugging
- Mixed C/C++ and Assembly level programming and debugging
- Real-time mode debugging – in-circuit emulation
- DSP/BIOS Plug-ins for fast application development/code reuse
- Real-time data exchange to host platform (PC).

3 CHOICE OF DSP TOOLS FOR AN APPLICATION

At the basic level, there are only four things that are required to start developing DSP applications: (i) a low specification host computer – usually windows PC; (ii) a text editor for writing software applications using assembly code; (iii) a low-cost DSP development board that connects to the PC via a parallel or serial cable, see TI-SPRU191 (1996), and (iv) the basic software tools usually supplied with the development board (Bateman and Paterson-Stephens, 2003).

Assuming the user already owns the PC and a simple text editor, the rest can usually be purchased for around $100, and this may or may not include a suitable power supply. Let us start by looking at the last two items from this list, that is, the basic hardware and software tools.

3.1 Basic hardware–a low-cost development board

Most manufacturers of DSP devices offer a low-cost development board, which is intended to be used for a basic evaluation of the technology, see TI-SPRU191 (1996) as an example of this. These boards are usually freestanding and connect to the PC via a slow data link, for example, a serial or parallel connection, see Figure 2.

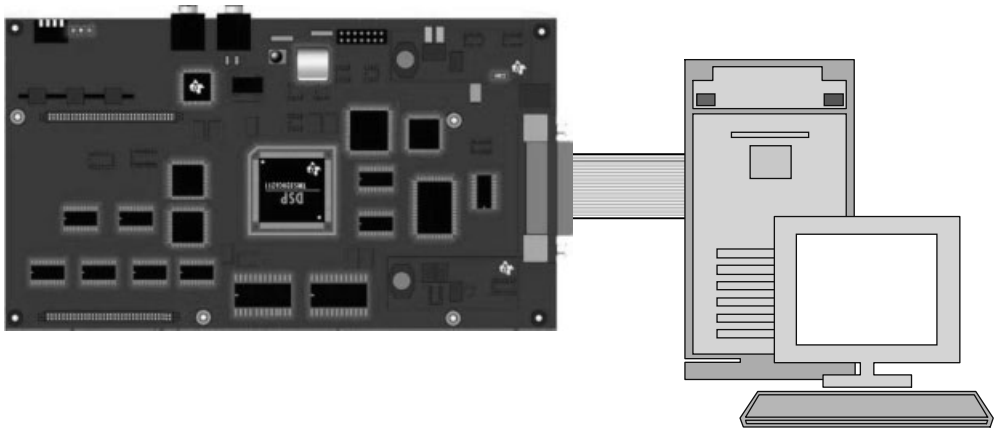

Figure 2. Simple DSP development system.

With the board comes a comprehensive set of software tools for assembling, linking, debugging, and downloading code. Typically, the development board will include data converters so that an audio bandwidth signal can be passed into and out of the DSP device, and generally these are suitable for voice or music applications thus enabling the user to evaluate algorithms using real signals in real time.

3.2 Basic software–a low-cost development environment

In order to get started with DSP software development, a number of basic tools will be needed. These will allow software routines to be written, converted to a form understandable to the DSP, and then downloaded to the target device. Usually, these tools are supplied with a development system as part of the complete package. The following list describes the basic tools required:

- *Basic text editor*: This can be a very simple application such as Windows notepad and is used for writing DSP programs in assembly language.
- *Assembler*: Available from the manufacturer of the DSP device, it is used to convert the users' text-based assembly program into a machine-readable format.
- *Linker*: Organizes the machine-readable code generated by the assembler so that it will match the memory configuration of the target DSP.
- *Debug environment*: Enables software to be tested for the particular DSP device; the debug environment may be in the form of a simulator or an emulator.
- *Downloader*: Often a downloader is provided with DSP development systems so that assembled and linked programs can be transferred to the DSP development board.
- *Hex conversion utility*: Converts assembled and linked DSP code into a form suitable for an EPROM programmer.

An overview of the steps taken during DSP software development is shown in Figure 3. The diagram shows more steps than might typically be required in a basic project; however, these are shown here for completeness (TI-SPRU102C, 1998). At intermediate stages within the diagram, the expected input and output file types are shown.

3.3 More advanced tools

Although the basic setup previously described is fine for the beginner who needs to gain a low-level understanding of the technology and processes involved, the more advanced designer working on a serious commercial project will require development tools that offer many more features (TI-SPRA520, 1999).

All DSP manufacturers offer an extensive range of DSP development tools, for example, Code Composer Studio offered by Texas Instruments, see Figure 4, is a fully integrated software package that can be used for the whole development process in a very similar way to Microsoft Visual C++. Visual DSP++ integrates editor, assembler, and compiler into one package along with extensive features to help manage projects, allow code reuse (via libraries) and target debugging (TI-SPRU303, 1999). In effect, the advanced tool sets integrate all of the stages identified in Figure 1 along with many more features.

4 INTRODUCING DSP TOOLS IN AN ORGANIZATION

Many of the tools and techniques used for designing DSP hardware and/or software will be familiar to engineers

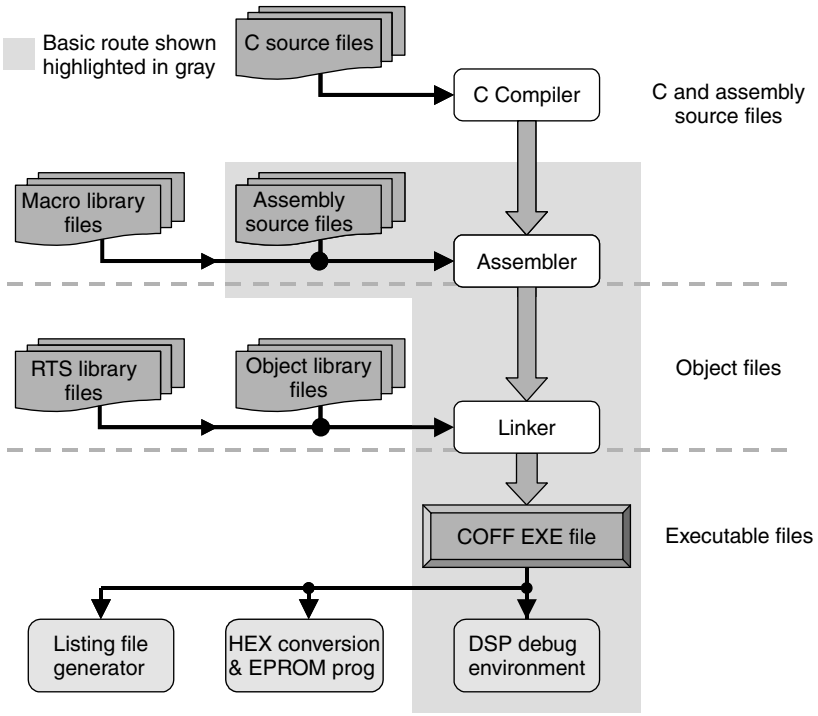

Figure 3. DSP program development flow.

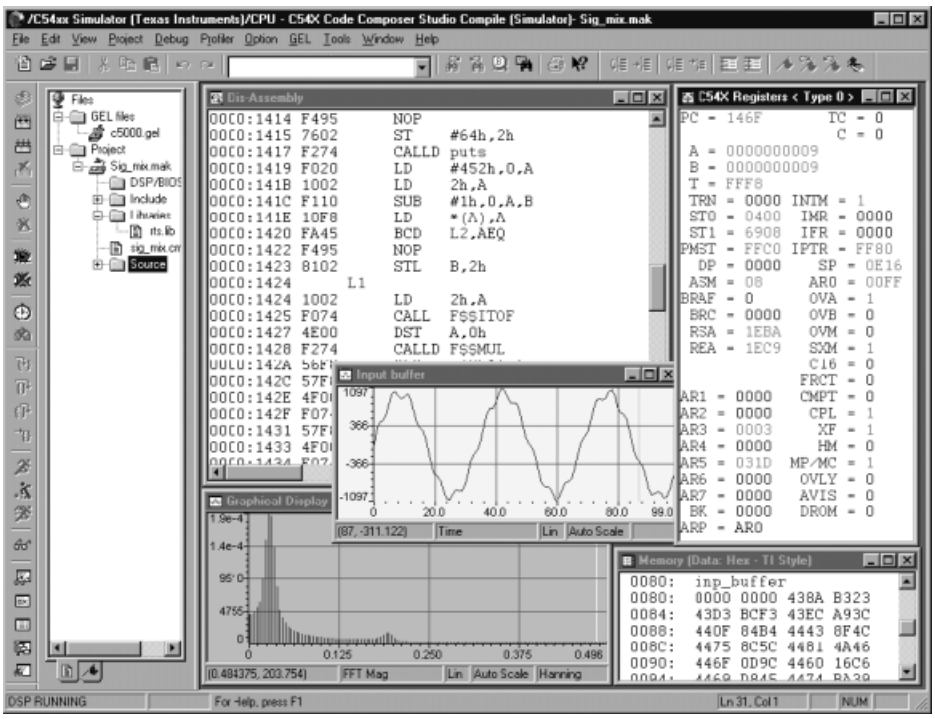

Figure 4. Screen shot of TI Code Composer Studio DSP design interface.

already involved in the design of conventional microprocessor-based electronic products. Similarly, engineers involved in design of analog electronic products, for example, control systems or filter designs, will be familiar with the algorithmic simulation and visualization tools, and complex mathematics. The problem often faced as far as a DSP application design is concerned is the very broad range of skills and knowledge that will be required of the engineer.

In addition to knowledge about the application, the DSP engineer should have a reasonably good grasp of assembly programming, C/C++ programming, hardware design and interfacing, microprocessor architectures, DSP algorithms, and discrete mathematics. That said, the DSP engineer will usually work as part of a design team where each individual will have his or her own spatiality.

When introducing DSP tools into an organization, the choice as to which tools will be the most appropriate is usually predetermined by the choice of DSP device and manufacturer. All DSP manufacturers and a number of third party organizations provide short courses on the use of their specific tools sets and hardware design with their own DSP chips. It is often very worthwhile arranging for key staff to attend manufacturers' own short courses, if for no other reason than to ensure that 'undocumented features' of the development tools can be understood at the outset rather than allowing them to plague a design for a period of time during the development process.

5 LIMITATIONS OF DSP TOOLS

On the face of it, a DSP processor is very similar to a conventional microprocessor; both have address and data buses, a central processing core and memory, and so on. In fact, if a DSP processor is programmed inefficiently without much regard for the subtle differences a DSP hardware architecture has to offer, the DSP will perform pretty much the same as a standard microprocessor. In order to exploit fully the potential speed increases for certain applications, the programmer must be truly aware of what the device has to offer. DSP features such as pipelined operation, multiple data paths and storage, Multiply and Accumulate (MAC) and other arithmetic features/modes of operation, and so on are only accessed when requested specifically by the programmer. When programming a DSP device, the safest path in many ways is to use the native assembly language offered by the manufacturer. Assembly language has the advantage that it can be very efficient and well optimized, and because it is so closely related to the specific DSP architecture, the programmer is likely to exploit the subtleties of the DSP architecture itself. The downside to assembly language is that it is quite difficult to learn, it is device specific and therefore the programmers will need to update their knowledge for each new device, and it is not easy to read and hence not easy to debug.

An alternative to coding using assembly language is to use an HLL such as C or C++; this has the advantage of not being target specific and so the skills of the programmer are more generic and usable across a range of devices. C/C++ code is clearly an industry standard programming language and so many programmers will find this approach to be a very accessible route into DSP programming. HLLs present

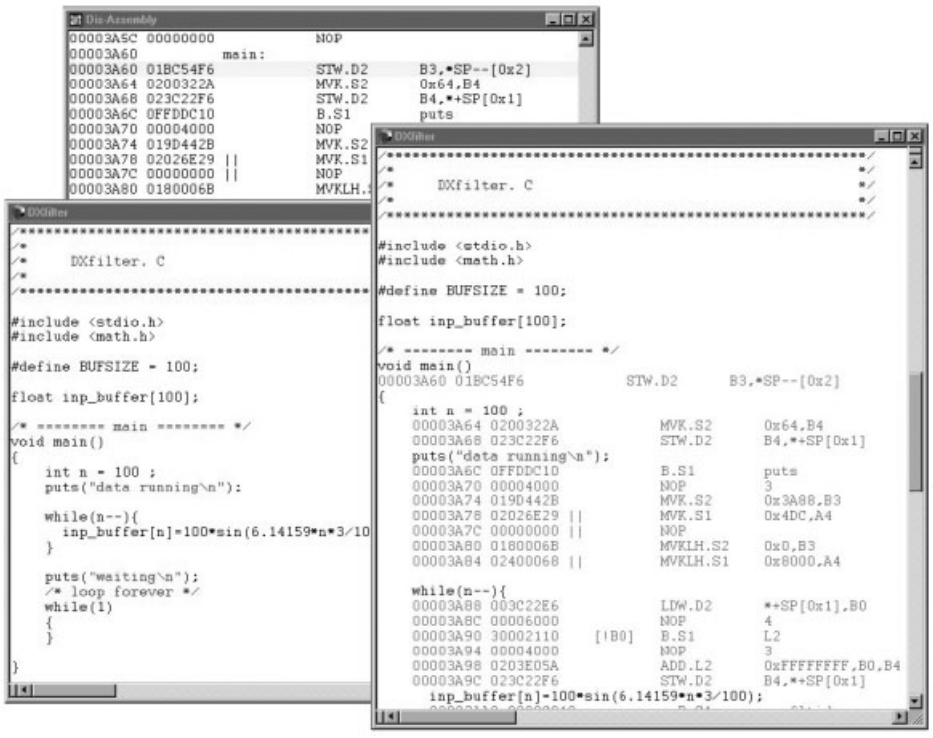

Figure 5. C source debugging using Code Composer Studio from Texas instruments.

their own problems, in particular that of code optimization (Bateman and Paterson-Stephens, 2003). Because HLLs are somewhat abstracted from the target hardware, the compiled code is usually not well optimized for the device. Usually, tool manufacturers provide a range of software switches that can be turned on/off to force the compiler to compile HLL code in a certain way so as to improve optimization. At times, however, the programmer will be required to hand code sections of HLL generated assembly language, see Figure 5. In particular, when designing routines that perform interfacing functions, it is necessary to resort to hand-coded assembly language in order to meet the timing requirements of the interface.

Simulation tools such as Matlab, Simulink, and Hyperception provide a useful platform for developing algorithms and the user to interact with elements of a design before it has been committed to a hardware or embedded software implementation. These are intuitive tools that allow the designer to 'play' with algorithms and to gain a greater understanding of how the final design will operate. These simulation tools work very well and give some good insight into a problem; however, there are potential pitfalls

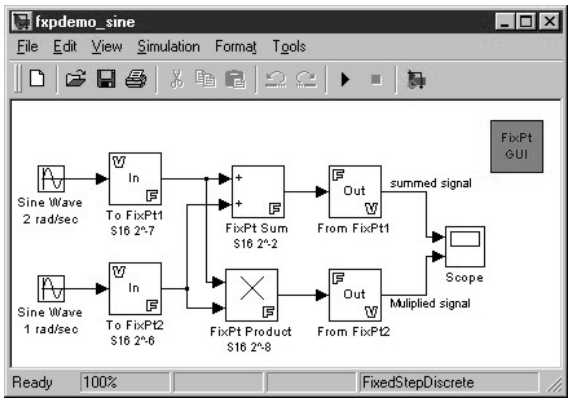

Figure 6. Fixed point DSP simulation tools within Simulink.

(MathWorks-B, 1999). A pertinent example for DSP application design is the effect of fixed point processing and how these are to be considered in the final design. When simulating a design using a visualization tool, such as Simulink, the simulation is performed perhaps using a 64-bit floating point desktop PC. The design may work well in simulation; however, when it is translated over to the target hardware, perhaps a 16-bit fixed point processor, the performance may be somewhat different (MathWorks-C, 1999). Simulation tools usually incorporate features to help incorporate fixed point processing into a simulation, see Figure 6, and this can help resolve any differences.

As far as limitations of design, simulation, and implementation tools are concerned, there are potential problems and pitfalls but if the user takes the time to familiarize themselves with tools, many problems can be avoided.

1 GENERAL PRINCIPLES OF DSP HARDWARE DESIGN

Before proceeding to design any application specific digital signal processing (DSP) hardware, it is important to have a detailed understanding of the intended application. This goes beyond just the sheer number crunching requirements of the selected DSP; it is also important to fully appreciate in detail the I/O requirements and how these may impact on the algorithmic performance of the DSP. While the DSP device must be able to perform specific numerical functions very efficiently, it must also have the capability to interface with other devices and systems so that minimum disruption occurs to the processing core (Bateman and Paterson-Stephens, 2003). Most DSP devices incorporate functional units that can operate with some independence from the core and are able to carry out tasks such as interrupt handling, direct memory accesses (DMA), serial interfacing, and timing operations, (TI-SPRU131d, 1997). In this section, typical system architectures will be presented in order to put many of the DSP facilities into context within different applications from a hardware point of view. Single and multiprocessor architectures will be considered.

1.1 A generalized DSP system

The block diagram shown in Figure 1 represents a standard DSP system architecture in which provision has been made for connecting various peripheral devices.

Looking at Figure 1, it is apparent that in addition to processing signals coming from an external source such as an ADC or CODEC, the DSP may need to handle events originating from a host computer or a user control surface. In normal operation, the DSP runs synchronously with the ADC or CODEC as this provides the regular sampling interval. On arrival of each new sample, the DSP carries out the necessary processing and makes the new output sample available to the DAC or output side of the CODEC. For example, in a professional audio system, the new samples would arrive at a rate of 48 000 per second and the DSP must keep up with this flow of data. If the DSP loses synchronization, then, in the case of this audio example, an audible click would be heard, that is, data would be lost. It is, therefore, imperative that the DSP is able to synchronize with external data flowing into and out of its ports. Taking this audio example a little further, at the same time as samples arriving at 48 000 per second, the DSP may be interrupted by other external devices; the host interface may have new control information updating a particular algorithm; the control surface may have updates from the user requiring a filter response to be recalculated or signal levels to be changed. The host and user events are not likely to be synchronous with the arrival of sampled data and yet the DSP must be

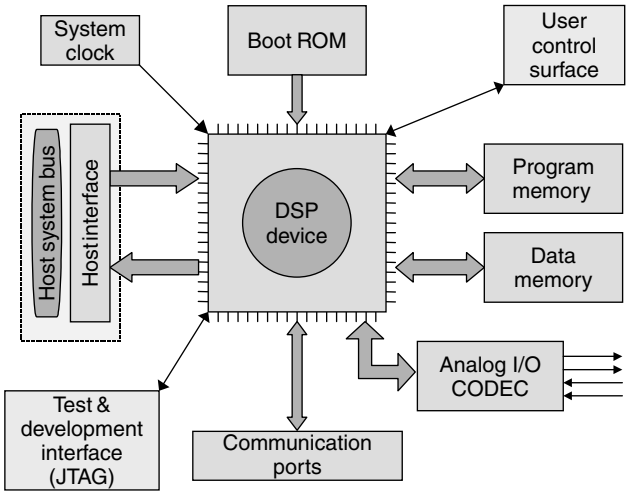

Figure 1. Generalized DSP system architecture.

able to attend to these external interruptions and still maintain full synchronization. There are a number of hardware strategies that can be used by a DSP device to handle transactions with its peripherals. These are summarized briefly as follows.

1.1.1 POLLED I/O

The DSP can POLL external devices to see if they have new data available. In a POLLED system, the DSP simply checks an external pin or memory location to see if a predetermined condition is met, for example, is bit one set high? If the condition is TRUE, then an action can be taken, for example, collect data items from memory. Although the POLLING system is very simple, it does have the disadvantage that the DSP is continually checking for the condition being met rather than getting on with more useful work.

1.1.2 Interrupt driven

All DSP devices incorporate a strategy for interrupting the normal processor flow. External interrupts are provided in the form of a number of physical pins on the outside of the DSP chip each of which will be allocated an individual interrupt number and an associated location in program memory at which a service routine will be stored. The interrupt service routine is usually a short program provided by the user, which carries out a task associated with a particular interrupt.

For example (see Figure 2), if a press button is provided for the user of the DSP system, the button could be connected to an interrupt input pin. When the button is pressed, the DSP is halted from its normal flow and switches to run an alternative routine stored at a different location in memory, called the *interrupt service routine*. On completion of the interrupt service routine, the DSP goes back to where it was prior to the interrupt.

1.2 Multiprocessor systems

Real-time performance for some applications is beyond the capabilities of a single DSP device. In this situation, the only possibility is to use a multiprocessing configuration in which a number of DSP devices are linked together (see Figure 3), and the algorithm is divided into subtasks and distributed among them.

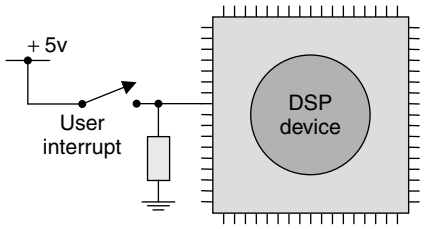

Figure 2. User interrupt.

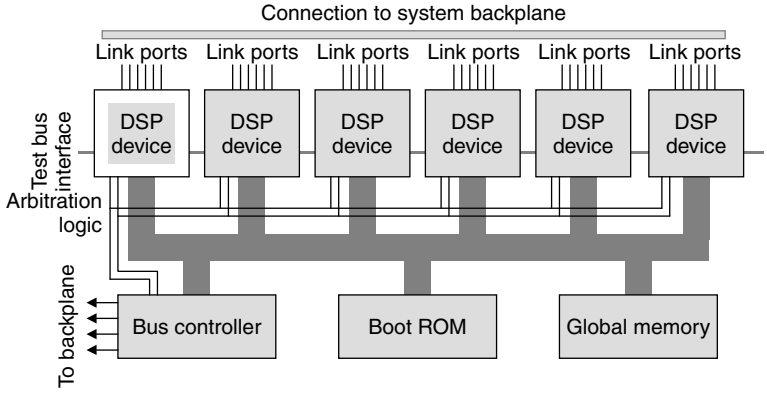

Figure 3. Multiprocessor DSP system design.

Some DSP processors designed with inbuilt multiprocessing features are available. These include devices from Texas Instruments such as the TMS320C4x and C6xxx family. The Analog Devices SHARC family also provides extensive multiprocessing capability through its six serial Link Ports each with a data bandwidth of 40 Mbps.

2 INTEGRATION OF DSP HARDWARE WITH SOFTWARE ELEMENT

The process of integrating the software and hardware elements of a DSP project starts with the generation of source code or a source file. The term *source file* refers to a text-based file written by the programmer, which contains a sequence of instructions; this is the starting point for many programs written for DSP devices. The source file, if written using assembly language instructions, is then converted, using an assembler, into an object file. Object files contain the actual machine readable instructions understood by the particular DSP device targeted. Usually, an object file is said to be relocatable and as such cannot be used directly by the DSP device; instead, it must first be passed through a linker program that produces the final executable DSP program. Although a relocatable program contains all the correct machine instructions, they have not been allocated to specific memory locations within the DSP. One of the functions of the linker is to resolve this memory allocation issue so that all instructions within the final executable program have a specific memory address. The benefit offered by this approach is that relocatable code is not tied to a specific memory structure or even system architecture; therefore, the design, either hardware or software element, can be updated during the life of the product without much limitation (Bateman and Paterson-Stephens, 2003).

The name often used to reference a final executable program is *object module* – note the difference with an object file – the module is the final packaged program that will run on the DSP device. When the object module has been produced, it can be loaded in to the DSP device; this may be via a debug environment hosted on a PC or through the use of an EPROM and a HEX conversion utility. The standard object file and object module format used on the Texas Instruments DSP devices is the COFF format, this stands for Common Object File Format. The HEX conversion utility is used to convert the object module into correctly ordered binary data, which is structured in such a way as to suit the EPROM, EEPROM, or other nonvolatile memory devices (TI-SPRU190b, 1998).

A common approach used in current DSP designs is to use a serial EEPROM to contain the system boot code and any boot-up data that will be required for the application. When the DSP is powered up, the DSP device can be configured to immediately download all of the system code from the serial EEPROM into the DSP's own 'on-chip' memory. The DSP then performs a soft reset and immediately runs the recently downloaded code that is sitting in its memory. One of the benefits of using a serial EPROM like this is that they are often very compact, 8-pin, devices that consume very little PCB real estate and have a very simple 3-wire connection interface (see Figure 4), which keeps the circuit complexity to a minimum.

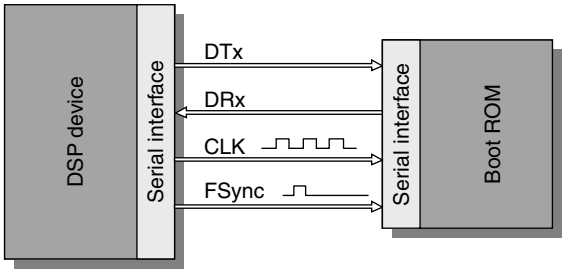

Figure 4. Serial boot ROM using standard 3-wire interface.

3 SUGGESTED PROCESS FOR DSP DESIGN

Every design is different and each engineer will have his or her own preferred methods, but a good starting point for any DSP application is to first consider the basic algorithms that will be required and to design a functional simulation of the system using Matlab and Simulink or similar visualization packages, see Figure 5. This step helps the designer to

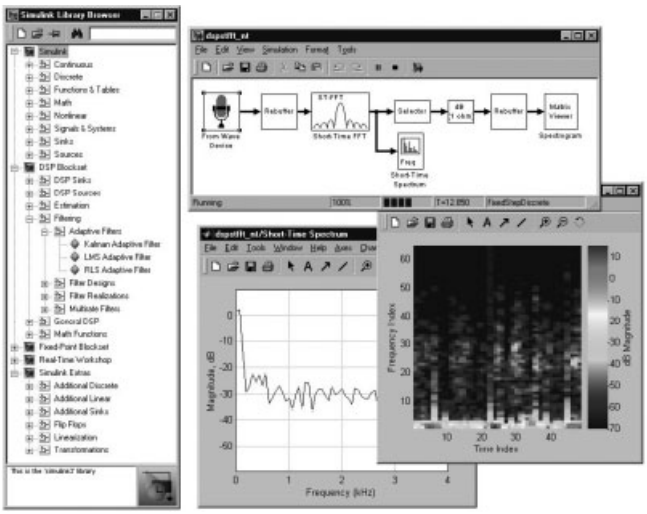

Figure 5. A screen shot showing Simulink while running a basic simulation.

fully understand all of the algorithmic elements and likely number crunching demands of the processor that will need to be used.

The benefit of this initial stage is that the application can be considered in detail without the complications of sometimes unpredictable I/O hardware or the quirks of a specific DSP device. Although this stage is a purely simulated one, it is still possible to make some initial predictions about the various aspects of the final design, for example: the memory storage requirements for filter coefficient tables, data storage, and even code storage requirements.

In order to select an appropriate processor and final system architecture, it is helpful to understand the algorithmic demands as detailed above, and the interfacing requirements for the application must also be considered in detail. For example, does the application require multiple channels of fast analog I/O, a user interface, a host port, or other interfacing mechanisms?

After considering a range of issues about the application, its interfacing requirements and algorithmic demands, it is possible to draw up a broad system specification. This can then be used to help the designer make choices about an appropriate DSP device. Once a device or at least a family of devices has been selected, it is advisable to rework the system specification and to consider in detail how the performance of the algorithms will be affected by the specific architecture of the DSP device selected (Bateman and Paterson-Stephens, 2003). It should be possible, at this point, to make pretty accurate predictions about the number of machine cycles that will be required for each signal processing task taking into account the limitations and overheads inflicted by the I/O, memory, and other hardware structures on the device.

When an appropriate decision has been made about the device to be used, the detailed hardware design can follow. Usually, manufacturers provide very detailed application notes giving recommended hardware configuration and in many cases complete system designs that can be adapted to suit a particular application. This is always a good starting point because much of the initial design has been done, leaving only the application specifics requiring attention. Most manufacturers even provide complete hardware solutions in CAD form so that the initial design can be quickly imported and adapted.

4 TOOLS IN SUPPORT OF DSP DEVELOPMENT

One of the biggest factors in the development of a DSP application is the suitability of the design tools available. In the past, DSP development tools were a rather clumsy collection of different applications that needed to be used in the correct order so that the final design could be realized. Nowadays, DSP development tools have been merged such that initial coding and syntax debugging tools have been integrated into a complex suite usually containing a compiler, assembler, code debugging tool, and a project management tool (TI-SPRU269, 1998). Most of these new integrated DSP development packages allow real hardware to be connected such that code can be tested in real time with 'online' monitoring of performance, this has greatly eased the process of debugging complex software with multiple events occurring in real time.

Code profiling allows the user to investigate in detail the timing of different sections of code within an application. This is particularly useful for complex real-time applications in which multiple threads of execution may be taking place. The designer is able to run the application in real time and investigate where most of the processor time is being spent. The designer can then make choices about optimization of code within specific algorithms in order to bring the final design within the specification of the device and/or application.

Although DSP development tools such as those already described allow very detailed analysis of the code running on the DSP device itself, there is still a useful place for the DSP device simulator in the armory of tools available to the designer. A simulator is simply a software application running on a host computer that simulates all of the function of the target DSP. Simulators do not run in real time, but they are used to run assembly and C code in the same way as the target device. One of the benefits of using the simulator is that it can be easier to test certain elements of an algorithm 'offline' without the distraction of interfacing components and associated software getting in the way. Also, the simulator usually has more detailed tools for profiling code and assessing where efficiency gains can be made.

The mechanism by which DSP hardware can be monitored, probed, and debugged in real time is the JTAG standard and its associated interface. JTAG actually stands for the Joint Test Action Group, which is a working group composed mainly of leading electronic manufacturers who set out to establish a common standard for in-circuit testing and emulation. The result was the IEEE 1149.1 JTAG standard. Of particular interest to the DSP developer is the ability to use the JTAG interface when testing software. In this mode of operation, the DSP device can be single stepped, register values and memory areas monitored, and forced and peripheral devices configured. Integrated packages such as Texas Instruments Code Composer Studio and Analog Devices Visual DSP++ are examples of hosted

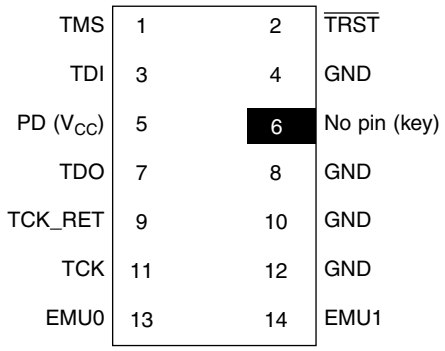

Figure 6. Standard 14-pin JTAG interface connector.

software packages that communicate with target hardware entirely through a fast JTAG emulation port. All aspects of software debugging, loading software, testing, and uploading data to the host are performed via the JTAG link. The JTAG support provided on the target DSP will run in parallel with the operation of the DSP device so that, for example, the value within a target register could be monitored without the need to halt the DSP itself.

The physical connection between the host computer and the DSP's JTAG port is made via a standard 14-pin header, see Figure 6. The header carries serial data between the target device and the host via the TDO (test data out) and TDI (test data in) connectors. The test clock, which is used to synchronize all data transfers, is carried on the TCK connection and a return clock signal is carried on the TCK_RET connection. Pin six acts as key so that the test cable cannot be installed incorrectly and other connection pins such as TMS, EMU0, and EMU1 are used to control various operating modes of the interface.

5 INSTALLATION AND TESTING OF DSP DEVELOPMENTS

There is no substitute for 'in-the-field' testing of DSP designs as is the case for any other design. An application may work perfectly well in principle on the bench back at the design lab, but when it is taken out into the field and tested in its intended environment, many other factors can affect performance. Noise induced onto power supplies, electromagnetic interference and inappropriate/unexpected use by users can all be factors.

The JTAG interface mentioned in the previous section is also useful for in-the-field testing just as it was for the development and debugging stage of the project. Usually, a 14-pin JTAG interface connector will be included on the final DSP board so that in-the-field testing and problem solving can be carried out. The IEEE 1149.1 JTAG standard, in addition to the 'software level' debugging mode, describes a set of rules by which a common test bus system can operate throughout a system level design. The idea of the test bus system is that complex components within a system can be linked to a common bus through which they can be probed and tested while still in circuit. This provides a simple mechanism by which modern systems containing a collection of highly integrated densely packed chips can be tested with relative ease. The JTAG standard allows the user to force conditions within a device as required to perform a particular test, so, for example, using the JTAG interface, a user could force the logic level of certain connection pins on a device to specific value and subsequently observe the resulting operation. This technique is often referred to as *boundary scan*, because the boundary conditions, that is, those of the external connection pins can be monitored and controlled. A subset of the JTAG standard also allows other aspects of a device's performance and operation to be controlled (TI-SPRU173, 1996). Using the JTAG interface, the final DSP system installation can be fully tested and evaluated at software, hardware, and system levels.

1 DIGITAL FILTER CATEGORIES

This is the first article on digital filters. It provides an introduction to their nature and how they are characterized in the time and frequency domains. A general bibliography on the subject is given at the end of this article. Articles **Article 148, General Performance of the Digital Filter, Volume 3**; **Article 149, Low-, High-, and Band-pass Digital Filters, Volume 3**; **Article 150, Finite Infinite Impulse Response (IIR) Digital Filters, Volume 3** and **Article 151, Finite Impulse Response (FIR) Digital Filters, Volume 3** provide detail of types.

A filter is a system that selectively changes the waveshape, amplitude, and phase spectra of a signal in a desired manner. The purposes of the changes are to improve the quality of the signal, for example, to reduce noise, to extract information from the signal, or to separate signals previously combined to make an efficient use of a communication channel.

Filters can be classified in two groups according to signal form:

- *Analog filters* – these filters process continuous signals and are therefore an example of continuous linear systems. They are constructed from linear electrical components.
- *Digital filters* – these are filters formed as sampled data signals. They may be realized by hardware or by suitable programming of a digital computer.

Classification of filters according to the frequency ranges, which are transmitted or rejected, is as follows:

- A *low-pass filter* – has a passband in the low-frequency region;
- A *high-pass filter* – transmits only high frequency input signals;
- A *band-pass filter* – has a passband in a particular frequency band;
- A *band-stop filter* – rejects only a particular frequency band.

Idealized response magnitude characteristics of various types of analog filters are sketched in Figure 1.

A sampled signal has frequency components up to $\omega = \pi/T$ rad s^{-1} and, therefore, the digital filter is classified according to its effect on frequency components in the range $-\pi/T < \omega < \pi/T$. Idealized response magnitude characteristics of various types of the digital filters are sketched in Figure 2.

2 RESPONSE IN THE TIME AND FREQUENCY DOMAINS

A filter may be described either by its frequency response, transfer function, $H(j\omega)$, or by its impulse response, $I(t)$. For example, the impulse responses of Figure 3 have a

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

form of decaying oscillations at a frequency of about ω_0 rad s^{-1}, with zero average value. The corresponding frequency responses will therefore display strong transmission in the region of $\omega = \omega_0$, and rejection of zero frequency inputs.

The pole-zero approach may be used to demonstrate the relationship between the magnitude and phase response of the linear filter. The pole-zero configuration and frequency response characteristic of a typical reactive filter are shown in Figure 4.

Analog filters are composed of passive electrical elements: resistors, inductors, and capacitors. The effect of practical components and terminations is to move the poles and zeros slightly away from the imaginary axis. This means that infinite peaks and zeros will not be observed in practice.

Response characteristics for the elementary low-pass, high-pass, and band-pass filters are shown in Figure 5.

The use of three types of linear electric circuit element, resistors, capacitors, and inductors, enables zeros to be placed anywhere in the s-plane and poles to be placed to the left of the imaginary axis. The use of an active element in a filter obviates the need for inductors. Low- and high-pass digital filters are covered in **Article 149, Low-, High-, and Band-pass Digital Filters, Volume 3**.

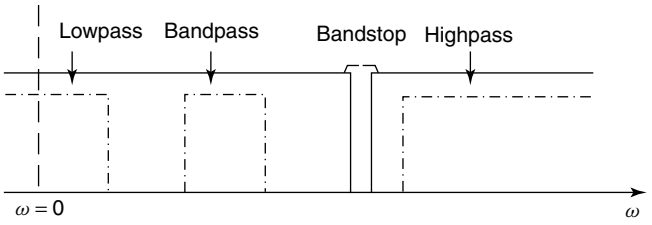

Figure 1. Idealized response magnitude characteristics of various types of analog filters.

3 APPROXIMATION TO THE IDEAL DIGITAL FILTER

The transfer function of a filter is given by

$$H(s) = \frac{1}{a_n s^n + a_{n-1}s^{n-1} + a_{n-2}s^{n-2} + \ldots a_1 s + a_0} \quad (1)$$

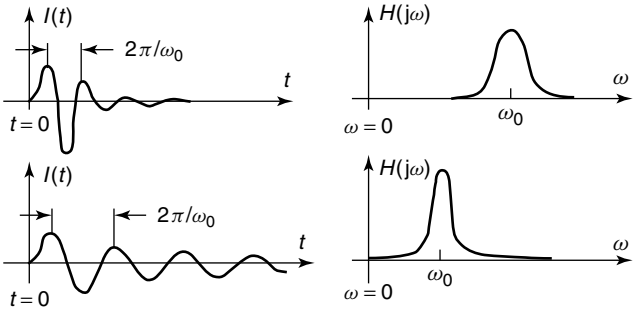

Figure 3. Impulse and frequency responses of two analog band-pass filters.

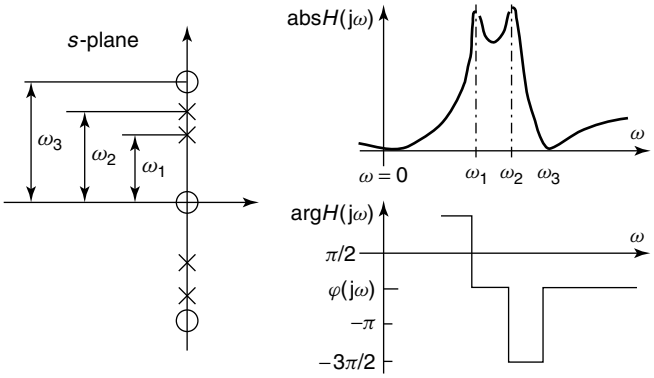

Figure 4. Characteristic of a reactive band-pass filter.

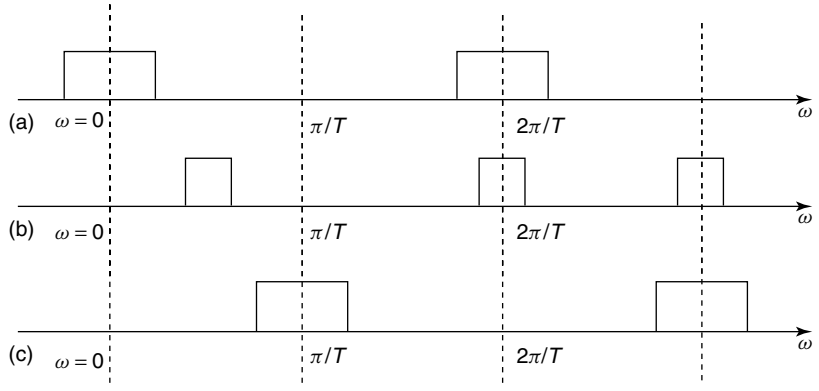

Figure 2. Idealized response magnitude characteristics of digital filters; (a) low-pass, (b) band-pass, and (c) high-pass.

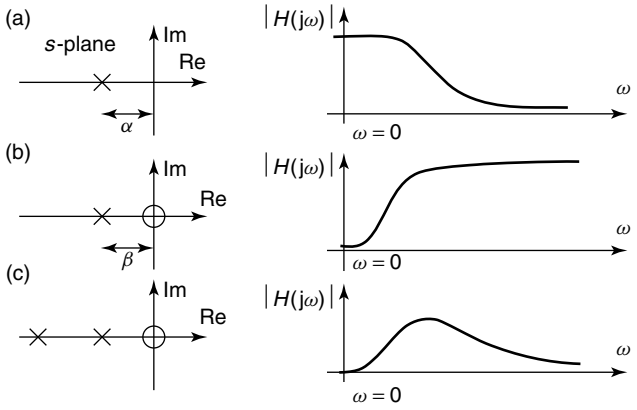

Figure 5. Typical resistors–capacitor (R–C) filter characteristics; (a) low-pass, (b) high-pass, and (c) band-pass.

where the factors of the denominator polynomial represent the poles of $H(s)$. Its frequency response is

$$H(s)|_{s=j\omega} H(j\omega) = \frac{1}{an(j\omega)^n + a_{n-1}(j\omega)^{n-1} + a_{n-2}(j\omega)^{n-2} + \ldots a_1(j\omega) + a_0} \quad (2)$$

and the square of its response magnitude is given by

$$|H(s)|^2 = H(j\omega)H*(j\omega) = H(j\omega)H(-j\omega) = \left\{\frac{1}{a_n(j\omega)^n + a_{n-1}(j\omega)^{n-1} + a_{n-2}(j\omega)^{n-2} + \ldots a_1(j\omega) + a_0}\right\} \times \left\{\frac{1}{a_n(-j\omega)^n + a_{n-1}(-j\omega)^{n-1} + a_{n-2}(-j\omega)^{n-2} + \ldots a_1(-j\omega) + a_0}\right\} \quad (3)$$

This approximates the ideal low-pass filter (Figure 6).

Figure 7 illustrates two types of polynomials having these characteristics. The denominator polynomial should have a magnitude close to 1.0 over the passband and as large as possible over the stopband.

The left-hand figure shows several functions of the form

$$f_1(\omega) = \left[1 + \left(\frac{\omega}{\omega_0}\right)^{2n}\right] \quad (4)$$

where n is a positive integer.

The right-hand plot of Figure 7 shows functions of the form

$$f_2(\omega) = \left[1 + \varepsilon^2 C_n^2\left(\frac{\omega}{\omega_0}\right)\right] \quad (5)$$

where C_n denotes the so-called Chebyshev polynomial of order n in the range $-\omega_0 < \omega < \omega_0$. The value of expression $\varepsilon^2 C_n^2(\omega/\omega_0)$ oscillates between 0 and ε^2 for any value of n.

The use of the polynomials, (4) and (5), gives rise to the well-known Butterworth and Chebyshev filters, (see Figure 8), which are defined by the following squared

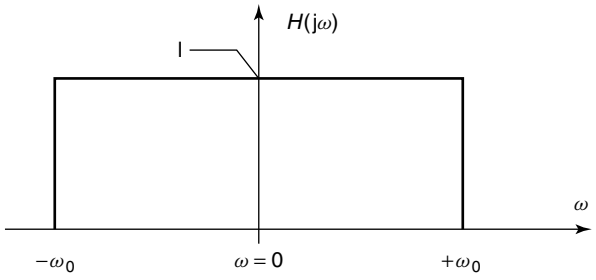

Figure 6. Approximation of the ideal low-pass filter.

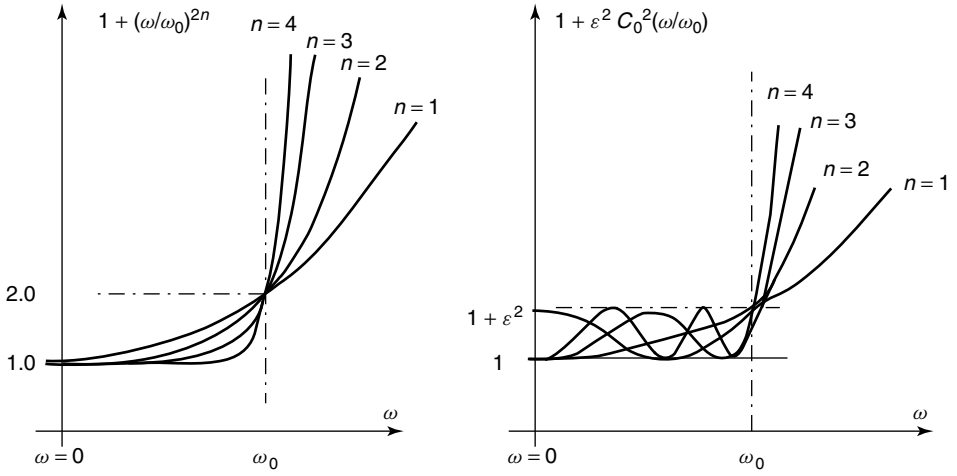

Figure 7. Two types of polynomial characteristics.

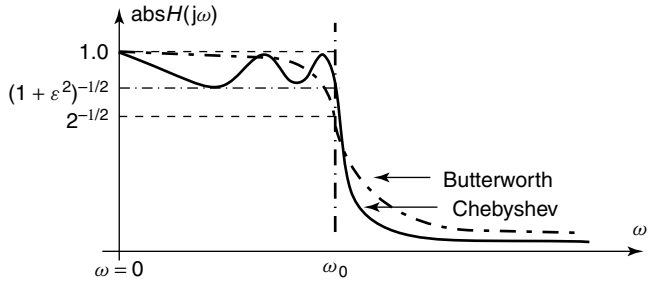

Figure 8. Frequency response, magnitude characteristic of the low-pass Butterworth and Chebyshev filters of fifth-order.

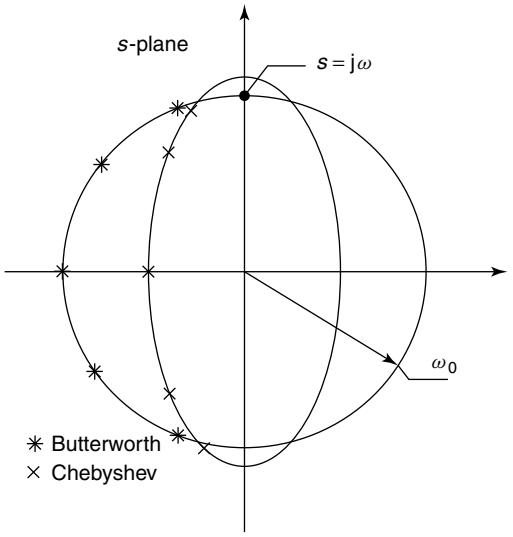

Figure 9. Pole locations of the low-pass Butterworth and Chebyshev filters.

magnitude functions: the Butterworth function

$$|H(\mathrm{j}\omega)|^2 = \frac{1}{[1 + (\omega/\omega_0)^{2n}]} \tag{6}$$

and the Chebyshev function

$$|H(\mathrm{j}\omega)|^2 = \frac{1}{[1 + \varepsilon^2 C_n^2(\omega/\omega_0)]} \tag{7}$$

In the case of the Butterworth filter, we have

$$\begin{aligned} |H(\mathrm{j}\omega)|^2 = H(\mathrm{j}\omega)H(-\mathrm{j}\omega) &\xrightarrow{\mathrm{j}\omega = s} H(s)H(-s) \\ &= \frac{1}{1 + (s/\mathrm{j}\omega_0)^{2n}} \\ &= \frac{1}{1 + (-\mathrm{j})^n(s/\mathrm{j}\omega_0)^n} \frac{1}{1 - (\mathrm{j})^n(s/\mathrm{j}\omega_0)^n} \end{aligned} \tag{8}$$

$$|H(s)|^2 = \begin{cases} \dfrac{1}{1 - (s/\omega_0)^n} \dfrac{1}{1 + (s/\omega_0)^n} \\ \quad = \dfrac{1}{1 - (s/\omega_0)^{2n}} & \text{for even } n \\ \dfrac{1}{1 - \mathrm{j}(s/\omega_0)^n 1 + \mathrm{j}(s/\omega_0)^n} \\ \quad = \dfrac{1}{1 + (s/\omega_0)^{2n}} & \text{for odd } n \end{cases} \tag{9}$$

This function has $2n$ poles equally spaced around a circle of radius ω_0 in the s-plane.

For even n	For odd n
$(s/\omega_0)^{2n} = 1$	$(s/\omega_0)^{2n} = -1$
$(s/\omega_0)^{2n} = \mathrm{e}^{\mathrm{j}2\pi}$	$(s/\omega_0)^{2n} = \mathrm{e}^{\mathrm{j}\pi}$
$s^n = \omega_0^n\ \mathrm{e}^{\mathrm{j}\pi}$	$s^n = \omega_0^n\ \mathrm{e}^{\mathrm{j}\frac{\pi}{2}}$
$s_i = \omega_0\ \mathrm{e}^{\mathrm{j}\frac{\pi}{n}i}$	$s_i = \omega_0\ \mathrm{e}^{\mathrm{j}\frac{\pi}{2n}(i+1)}$
where $i = 0, 1, \ldots, 2n-1$	where $i = 0, 1, \ldots, 2n-1$

(10)

The n poles to the left of the imaginary axis define the filter. It may be shown that the poles of the Chebyshev filter are arranged on an ellipse whose major axis lies along the imaginary axis in the s-plane. The pole locations of the low-pass Butterworth and Chebyshev filters are shown in Figure 9.

1 FORMS OF REALIZATION OF THE DIGITAL FILTER

Digital filters can be realized in two different ways:

- *Hardware* – realized by a digital logic circuit containing storage, delay, and addition–subtraction and multiplication by constants. The advantage of the digital filter is its speed, especially if some of the necessary operations are performed in parallel. Its very costly realization is its disadvantage.
- *Software* – as a program. The filter operates rather slowly in comparison with hardware forms, but on the other hand, this solution is more flexible and inexpensive.

There are two methods of digital filter implementation. The first that one should consider is filtering in the frequency domain. This is an important and widely used approach, which allows great flexibility in the choice of the filter characteristics. The signal spectrum is simply multiplied by the choice of filter characteristic.

2 POLES AND ZEROS IN DIGITAL FILTER DESIGN

The alternative implementation considers filtering in the time domain. The is done by convolution of the input signal with the impulse response of the appropriate filter.

A transfer function, $H(z)$, represents a useful frequency response characteristic. Knowing $H(z)$, it is a simple matter to derive the time domain formula, which describes the operation of the filter. When considering the digital filter, we are concerned with impulse response rather than its frequency spectra; we use a set of z-plane poles and zeros of transfer function, $H(z)$.

If a digital filter and its transfer function have the poles and zeros, as shown in Figure 1, then its response for some frequency ω_1 may be found by drawing vectors from the poles and zeros to the point $z = \exp(j\omega_1 T_s)$. The response magnitude at frequency ω_1 is equal to $a_1 a_2 / b_1$, where a_1, a_2, and b_1 are the lengths of vectors from the poles and zeros to point z.

Point A in the figure represents sinusoidal frequencies $\omega = 0, 2\pi/T_s, 4\pi/T_s, \ldots$ and point B represents frequencies $\omega = \pi/T_s, 3\pi/T_s, 5\pi/T_s, \ldots$ The frequency response characteristic of any digital filter repeats indefinitely at intervals in ω of $2\pi/T$ rad s^{-1}.

Figure 2(a) shows a simple low-pass filter specified by single zero at $z = -1$. At frequency $\omega = 0$, the zero vector has a maximum length of 2.0, and hence, the response amplitude (Figure 2b) must also be a maximum, and it becomes shorter when we move the zero vector anticlockwise around the unit circle. The vector vanishes at point $z = -1$, which corresponds to the sinusoidal frequency $\omega = 2\pi/T$. By considering the phase angle that the zero

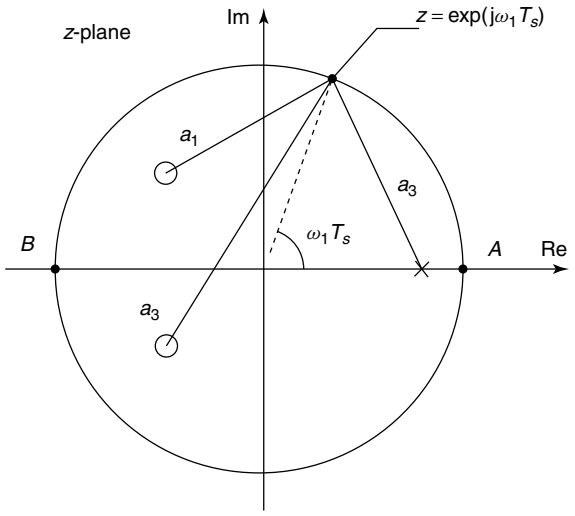

Figure 1. The z-plane poles and zeros of digital filter.

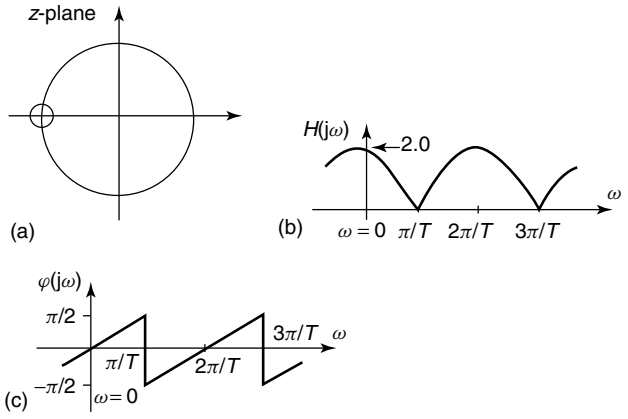

Figure 2. An elementary low-pass digital filter (a) pole-zero configuration; (b) magnitude response characteristic; and (c) phase response characteristic.

vector makes with the positive real axis, we may also infer the filter's phase response (Figure 2c).

The transfer function of this elementary digital filter is $H(z) = (z + 1)$ and equals the transform of the output signal divided by the input. If we write it as $X(z)$ and $Y(z)$ respectively, then $Y(z) = (z + 1)X(z) = zX(z) + X(z)$.

3 IMPULSE RESPONSE OF THE DIGITAL FILTER

The impulse response of a such filter is shown in Figure 3(a). We convolve this impulse response with a typical input signal having successive samples of value. . . $x(n-1), x(n), x(n+1), x(n+2), \ldots$ To calculate the output sample $y(n)$, which coincides with the input samples, $x(n)$, we lay a reversed version of the impulse

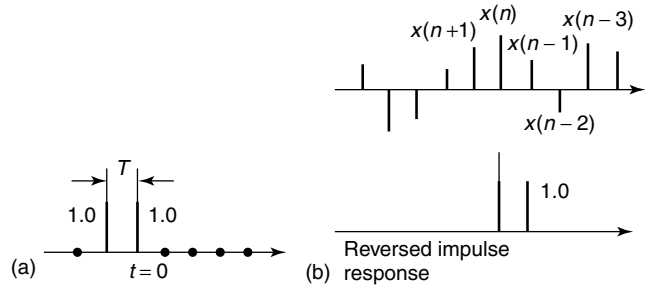

Figure 3. (a) Impulse response of the low-pass filter; (b) derivation of the filter's output by convolution.

response. Cross multiplying point by point and the sum terms gives

$$y(n) = 1 \times x(n) + 1 \times x(n+1) \tag{1}$$

An expression such as this is called a *recurrence formula*.

The filter from the example is 'unrealizable', in the sense that a given output value $y(n)$ depends upon the coincident input $x(n)$ and the next input $x(n+1)$. This difficulty may be solved by dividing $H(z)$ by a term z^m, where m equals the excess number of zeros. This is equivalent to adding m poles at the origin of the z-plane; such poles do not affect the frequency response magnitude characteristic but merely have the effect of delaying the output by m sampling intervals. The new transfer function has the form

$$H'(z) = \frac{(z+1)}{z} = 1 + z^{-1} \tag{2}$$

hence the recurrence formula becomes

$$y(n) = x(n) + x(n+1) \tag{3}$$

which means that any output sample is found by summing the present and previous inputs. For details, refer to **Article 147, Ideal Digital Filter Approximation, Volume 3**.

1 LOW-PASS DIGITAL FILTER

The low-pass filter with a single pole placed at $z = \alpha$ is presented in Figure 1.

If $0 < \alpha \leqslant 1$, then the pole vector will be very small when $\omega = 0$, giving a large response, and relatively large when $\omega = \pi/T$, giving a small response.

The transfer function of the considered filter is

$$H(z) = \frac{1}{(z-\alpha)} = \frac{Y(z)}{X(z)} \tag{1}$$

Hence,

$$(z-\alpha)Y(z) = X(z) \quad \text{or} \quad zY(z) - \alpha Y(z) = X(z) \tag{2}$$

The recurrence formula is therefore

$$y(n+1) - \alpha = x(n) \tag{3}$$

which is equivalent to

$$y(n) - \alpha(n-1) = x(n-1) \tag{4}$$

or

$$y(n) = \alpha y(n-1) + x(n-1) \tag{5}$$

The output sample $y(n)$ is found from the previous output and previous input. A filter, which calculates a new output using one or more previous outputs is called *recursive* and arises whenever a transfer function has a pole placed other than at the origin of the z-plane. It can be also written as a nonrecursive recurrence formula

$$y(n) = x(n-1) + \alpha x(n-2) + \alpha^2 x(n-3) + \alpha^3 x(n-4) + \cdots\cdots \tag{6}$$

2 HIGH-PASS DIGITAL FILTER

A high-pass filter has the transfer function

$$H(z) = \frac{(z-1)}{(z+\alpha)} = \frac{Y(z)}{X(z)} \tag{7}$$

Figure 2 gives its (a) pole-zero configuration, (b) magnitude response characteristic, and (c) impulse response.

From the pole-zero plot,

$$(z+\alpha)Y(z) = (z-1)X(z) \tag{8}$$

The recurrence formula is therefore

$$y(n+1) + \alpha y(n) = x(n+1) - x(n) \tag{9}$$

or

$$y(n) + \alpha y(n-1) = x(n) - x(n-1) \tag{10}$$

giving

$$y(n) = -\alpha y(n-1) + x(n) - x(n-1) \tag{11}$$

The first nine terms of the impulse response are shown in Figure 2(c).

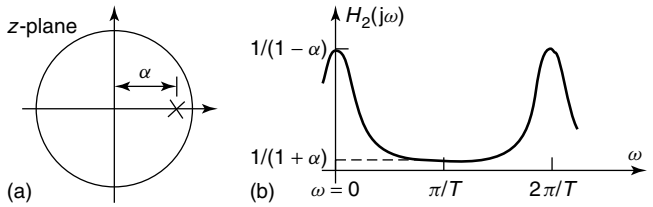

Figure 1. Elementary low-pass digital filter. (a) Pole-zero configuration and (b) magnitude response characteristic.

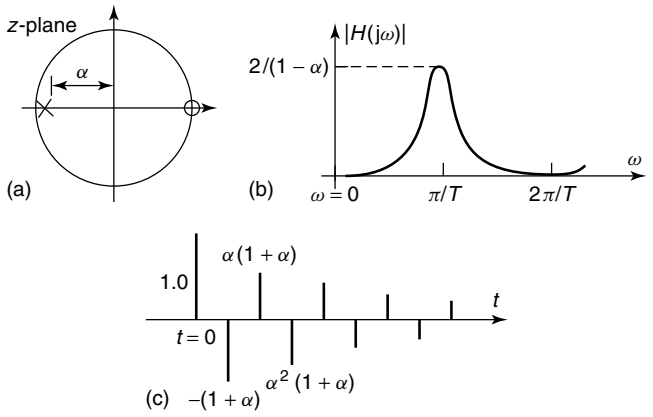

Figure 2. A simple high-pass digital filter. (a) Pole-zero configuration, (b) magnitude response characteristic, and (c) impulse response.

3 ANALYZING A DIGITAL FILTER FROM A POLE-ZERO PLOT

Figure 3(a) shows an example of how to analyze the digital filter with a pole-zero configuration.

The complex conjugate pole pair placed on a circle of radius r, where r is close to unity, gives rise to a band-pass characteristic centered on ω_0 rad s^{-1} (see Figure 3b). Zero-frequency and high-frequency rejection are provided by the zeros at $z = 1$ and $z = -1$. As it is quite often convenient,

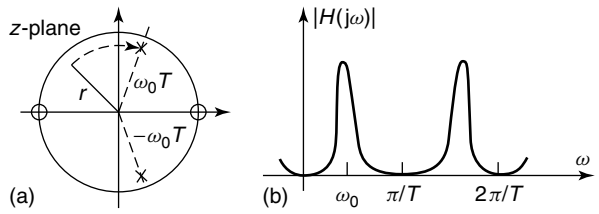

Figure 3. A band-pass digital filter. (a) Pole-zero configuration and (b) magnitude response characteristic.

we express the pole position in polar coordinates; the transfer function is then

$$H(z) = \frac{(z-1)(z+1)}{[z - r\exp(j\omega_0 T)][z - r\exp(-j\omega_0 T)]}$$
$$= \frac{z^2 - 1}{z^2 - rz[\exp(j\omega_0 T) + \exp(-j\omega_0 T)] + r^2} \quad (12)$$

and

$$H(z) = \frac{z^2 - 1}{z^2 - 2rz\cos\omega_0 T + r^2} \quad (13)$$

From this expression, we may derive the recurrence formula

$$y(n) = 2r\cos(\omega_0 T)y(n-1) - r^2 y(n-2) + x(n) - x(n-2) \quad (14)$$

4 BUILDING A DIGITAL FILTER FROM A POLE-ZERO PLOT

For hardware realization (see Figure 4), we choose the following parameter values:

- radius $r = 0.95$
- sampling frequency $f_s = 1\,\text{kHz}$, that is, $T_s = 1\,\text{ms}$

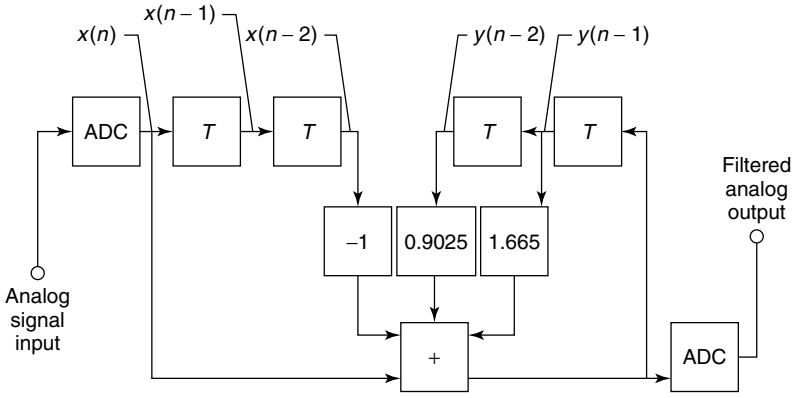

Figure 4. A hardware implementation of the band-pass filter.

- center frequency $\omega_0 = 80\,\text{Hz}$, giving $\omega_0 T = 0.503\,\text{rad}$ or 28.8°.

The recurrence formula becomes

$$y(n) = 1.6650y(n-1) - 0.9025y(n-2) + x(n) - x(n-2) \quad (15)$$

For details, refer **Article 147, Ideal Digital Filter Approximation, Volume 3**.

1 THE INFINITE IMPULSE RESPONSE (IIR)

Any digital filter specified in terms of one or more z-plane poles has the infinite impulse response, IIR. It is a recursive filter, because no infinite impulse response could be implemented in a purely nonrecursive operation.

The recurrence formulae of IIR filters normally involve relatively few terms. It is clear that the IIR of any realizable filter cannot be symmetrical in form and that the IIR filter cannot display pure linear-phase characteristics.

The advantage of its design is that the positioning of just one or a few poles inside but close to the unit circle enables very selective filter passband characteristics to be achieved.

Many practical IIR filters are based upon analog equivalents because analogous filters based upon lumped circuit elements have infinite impulse response. The design problem is to find a suitable transformation for mapping the s-plane poles and zeros of the analog filter representation onto the z-plane.

There are several techniques for deriving a digital filter from an analog one. Two of the widely used ones are as follows:

- Impulse invariance
- Bilinear transformation.

It is possible to choose a suitable z-plane pole-zero configuration for a filter without direct reference to analog designs. The least confusing point of view toward digital filter design is to consider the filter as being specified in terms of angle around the unit circle rather than in terms of analog frequencies.

A problem in determining an appropriate set of specifications for a low-pass digital filter is presented in Figure 1.

Specifications for a required filter often take the form of such a given tolerance scheme. The dashed curve represents the frequency response of a system that meets the prescribed specifications. In this case, there is a passband wherein the magnitude of response must approximate to 1, with an error of $\pm\delta_1$, which can be written as

$$1 - \delta_1 \leq \left|H\left(e^{j\omega}\right)\right| \leq 1 + \delta_1 \quad \text{where} \quad |\omega| \leq \omega_p \qquad (1)$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

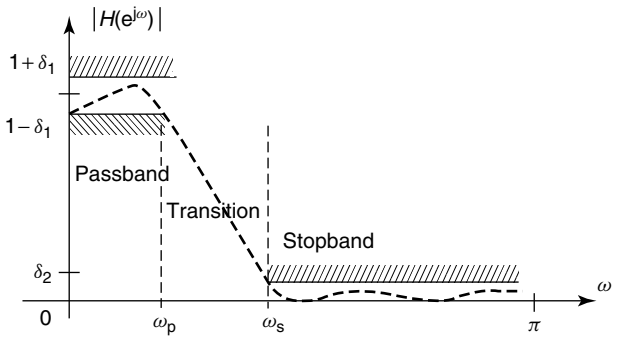

Figure 1. Tolerance limits for approximation of ideal low-pass filter.

There is also a stopband in which the magnitude response must approximate to zero, with an error less than δ_2, for which

$$\left|H\left(e^{j\omega}\right)\right| \leq \delta_2 \quad \text{where} \quad \omega_s \leq |\omega| \leq \pi \mid \tag{2}$$

The passband cut-off frequency, ω_p, and the stopband cut-off frequency, ω_s, are given in terms of z-plane angles.

The next step is to find the discrete-time linear system whose frequency response falls within the prescribed tolerance.

2 DESIGN OF IIR DIGITAL FILTERS FROM ANALOG FILTERS

This method is often used because analog filter design is highly developed. Many useful analog design methods have relatively simple closed-form design formulae. In many applications, it is of interest to use a digital filter to simulate the performance of an analog linear time-invariant filter.

Consider an analog system function given by

$$H_a(s) = \frac{\sum_{k=0}^{M} e_k s^k}{\sum_{k=0}^{N} c_k s^k} = \frac{Y_a(s)}{X_a(s)} \tag{3}$$

where $x_a(t)$ is the input and $y_a(t)$ is the output of the filter, and $X_a(s)$ and $Y_a(s)$ are their respective Laplace transforms. It is assumed that $H_a(s)$ has been obtained through one of the established approximation methods used in analog filter design. The input and output of such a system are related by the convolution integral,

$$y_a(t) = \int_{-\infty}^{\infty} x(\tau) h_a(t-\tau)\, \mathrm{d}\tau \tag{4}$$

where the impulse response, $h_a(t)$, is the inverse Laplace transform of $H_a(s)$.

Alternatively, an analog system having a system function $H_a(s)$ can be described by the differential equation

$$\sum_{k=0}^{N} c_k \frac{\mathrm{d}^k y_a(t)}{\mathrm{d}t^k} = \sum_{k=0}^{M} e_k \frac{\mathrm{d}^k x_a(t)}{\mathrm{d}t^k} \tag{5}$$

The corresponding rational system function for digital filters has the form

$$H(z) = \frac{\sum_{k=0}^{M} b_k z^{-k}}{\sum_{k=0}^{N} c_k z^{-k}} = \frac{Y(z)}{X(z)} \tag{6}$$

The input and output are related by the convolution sum

$$y(n) = \sum_{-\infty}^{+\infty} x(k) n(n-k) \tag{7}$$

or equivalently by the difference equation

$$\sum_{k=0}^{N} a_k y(n-k) = \sum_{k=0}^{M} b_k x(n-k) \tag{8}$$

In transforming an analog system to a digital system, we must therefore obtain either $H(z)$ or $h(n)$ from the analog filter design.

3 IMPULSE INVARIANCE METHOD

This procedure for transforming an analog filter to a digital filter design corresponds to choosing the unit-sample response of the digital filter as equally spaced samples of the impulse response of the analog filter. That is,

$$h(n) = h_a(nT) \tag{9}$$

where T is the sampling period.

The resulting relationship between the response of analog and digital version of a typical low-pass filter is illustrated in Figure 2.

To investigate the interpretation of impulse invariant design in terms of a relationship between the s-plane and the z-plane, consider the system functions of the analog filter expressed in terms of the fraction expansion, so that

$$H_a(s) = \sum_{k=1}^{N} \frac{A_k}{s - s_k} \tag{10}$$

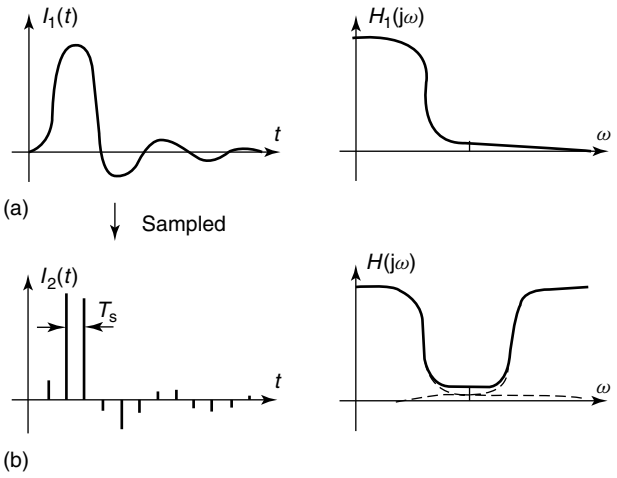

Figure 2. The impulse invariance method. (a) The impulse and frequency response of the analog filter; (b) its digital equivalent. $I_2(t)$ is a sampled version of $I_1(t)$.

The corresponding impulse response is

$$h_a(t) = \sum_{k=1}^{N} A_k e^{s_k T} u(t) \tag{11}$$

where $u(t)$ is a continuous-time unit step function.

The response of the digital filter is then

$$h(n) = h_a(nT) = \sum_{k=1}^{N} A_k e^{s_k nT} u(n) = \sum_{k=1}^{N} A_k (e^{s_k T})^n u(n) \tag{12}$$

The system function of the digital filter $H(z)$ is consequently given by

$$H(z) = \sum_{k=1}^{N} \frac{A_k}{1 - e^{s_k T} z^{-1}} \tag{13}$$

If the analog filter is stable, corresponding to the real part of s_k less than zero, then the magnitude of $e^{s_k T}$ will be less than unity. The corresponding pole in the digital filter will be inside the unit circle, and consequently the digital filter will be also stable. It can be shown that strips of width $2\pi/T$ in the s-plane map into the entire z-plane, as depicted in Figure 3.

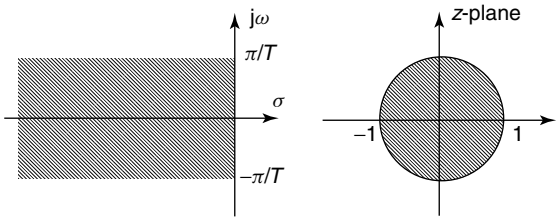

Figure 3. Representation of periodic sampling.

4 DETERMINATION OF A DIGITAL FILTER FROM AN ANALOG FILTER

As an example of the determination of a digital filter from an analog filter by means of the impulse invariance, consider the analog system $H_a(s)$ given by

$$H_a(s) = \frac{s + a}{(s + a)^2 + b^2} = \frac{0.5}{s + a + jb} + \frac{0.5}{s + a - jb} \tag{14}$$

The corresponding transfer function of the impulse invariant digital filter is then

$$H(z) = \frac{0.5}{1 - e^{-aT} e^{-jbT} z^{-1}} + \frac{0.5}{1 - e^{-aT} e^{jbT} z^{-1}}$$
$$= \frac{1 - (e^{-aT} \cos bT) z^{-1}}{(1 - e^{-aT} e^{-jbT} z^{-1})(1 - e^{-aT} e^{-jbT} z^{-1})} \tag{15}$$

from which

$$H(z) = \frac{1 - (e^{-aT} \cos bT) z^{-1}}{1 - 2(e^{-aT} \cos bT) z^{-1} + (e^{-aT})^2 z^{-2}} \tag{16}$$

The digital filter has one zero at the origin and a zero at

$$z = e^{-aT} \cos bT \tag{17}$$

Figure 4 shows the s-plane pole-zero plot for $H_a(s)$ and the z-plane pole-zero plot of $H(z)$, along with the corresponding analog and digital frequency response functions.

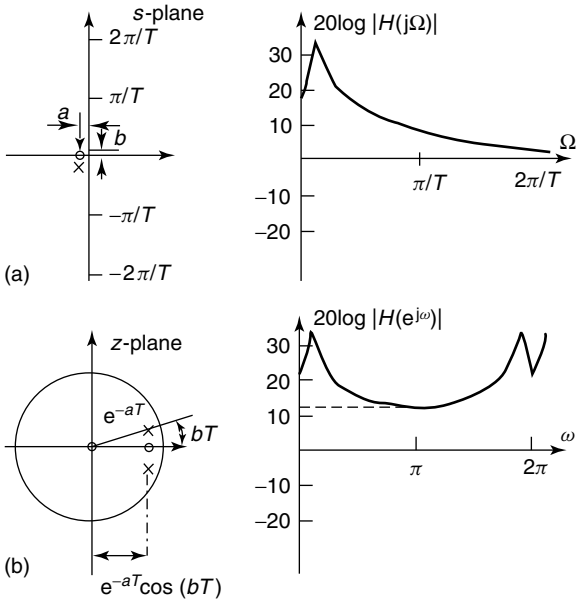

Figure 4. (a) Pole-zero plot and frequency response of a second-order analog system; (b) Pole-zero plot and frequency response of the discrete-time system obtained by sampling the impulse response of the above system.

In this case, the frequency response of the analog system falls off rather slowly relative to the sampling frequency and thus the effects of aliasing are apparent in the digital frequency response.

5 DETERMINATION OF A DIGITAL FILTER TRANSFORM FROM AN ANALOG FILTER

Here is determined the digital filter transform function from the analog filter of the previous case, this time by means of the impulse invariance.

The analog system function $H_a(s)$ given by

$$H_a(s) = \frac{-b}{(s+a)^2 + b^2} = \frac{\text{j}0.5}{s+a-\text{j}b} - \frac{\text{j}0.5}{s+a+\text{j}b} \quad (18)$$

The corresponding transfer function of the impulse invariant digital filter is then

$$\begin{aligned} H(z) &= \frac{\text{j}0.5}{1 - \text{e}^{-aT}\text{e}^{\text{j}bT}z^{-1}} - \frac{\text{j}0.5}{1 - \text{e}^{-aT}\text{e}^{-\text{j}bT}z^{-1}} \\ &= \frac{\text{e}^{-aT}\sin bT}{(1 - \text{e}^{-aT}\text{e}^{-\text{j}bT}z^{-1})(1 - \text{e}^{-aT}\text{e}^{-\text{j}bT}z^{-1})} \\ &= \frac{(\text{e}^{-aT}\sin bT)z^2}{(z - \text{e}^{-aT}\text{e}^{-\text{j}bT})(z - \text{e}^{-aT}\text{e}^{-\text{j}bT})} \\ &= \frac{\text{e}^{-aT}\sin bT}{1 - 2(\text{e}^{-aT}\cos bT)z^{-1} + (\text{e}^{-aT})^2 z^{-2}} \end{aligned} \quad (19)$$

The digital filter has a double zero at the origin.

6 BILINEAR TRANSFORMATION MODEL

The bilinear transformation is an example of the so-called frequency transformation method. A basis of the approach can be clarified by an example. Consider first the function

$$s = \frac{(z-1)}{(z+1)} \quad \text{where} \quad z = \text{e}^{sT} \quad (20)$$

which is bilinear in the sense that both its numerator and denominator polynomials are linear in the variable z.

In order to explain the value of this function in converting an analog filter into a digital equivalent, we need to evaluate its spectrum. This is found by putting $s = \text{j}\omega$, or $z = \text{e}^{\text{j}\omega T}$, which gives

$$\begin{aligned} s &= \frac{\text{e}^{\text{j}\omega T} - 1}{\text{e}^{\text{j}\omega T} + 1} = \frac{\text{e}^{\text{j}\omega T/2}(\text{e}^{\text{j}\omega T/2} - \text{e}^{-\text{j}\omega T/2})}{\text{e}^{\text{j}\omega T/2}(\text{e}^{\text{j}\omega T/2} + \text{e}^{-\text{j}\omega T/2})} \\ &= \text{j}\tan\frac{\omega T}{2} = \sigma + \text{j}\Omega \end{aligned} \quad (21)$$

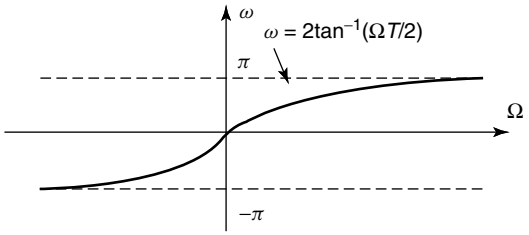

Figure 5. Mapping of the s-plane into z-plane using the bilinear transformation.

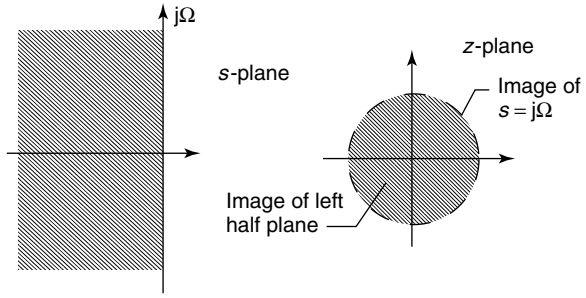

Figure 6. Mapping of the analog frequency axis onto the unit circle using the bilinear transformation.

thus for z on the unit circle, $\sigma = 0$, for which Ω and ω are related by

$$\Omega = \tan\left(\frac{\omega}{2}\right) \quad (22)$$

This relationship is plotted in Figure 5.

In addition to the fact that the imaginary axis in the s-plane maps to the unit circle in the z-plane, the left half of the s-plane maps to the inside of the unit circle and the right half of the s-plane maps to the outside of the unit circle, as depicted in Figure 6.

7 CONVERTING AN ANALOG FILTER INTO A DIGITAL EQUIVALENT FILTER

Suppose the need is to convert an analog filter with transfer function

$$H_a(s) = \frac{1}{s+\alpha} \quad (23)$$

into an equivalent digital filter.

Wherever s appears in $H_a(s)$, replace it by s from (20), giving us the digital filter transfer $H(z)$ to obtain

$$\begin{aligned} H(z) &= \frac{1}{\dfrac{z-1}{z+1} + \alpha} = \frac{z+1}{z-1+\alpha(z+1)} \\ &= \frac{1}{\alpha+1}\frac{z+1}{z+\dfrac{\alpha-1}{\alpha+1}} \end{aligned} \quad (24)$$

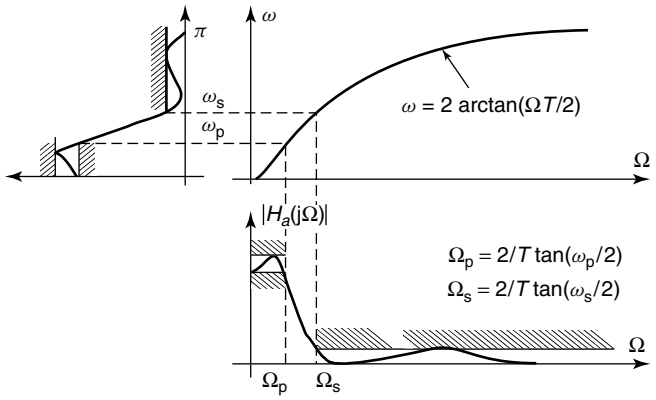

Figure 7. Frequency response and tolerance schemes for analog and corresponding digital filter.

from which the frequency response is given by

$$H(\mathrm{j}\omega) = \frac{1}{\mathrm{j}\tan\omega T/2 + \alpha} \tag{25}$$

The complete frequency response characteristics of the analog filter are compressed into the frequency range $0 < \omega < \pi/T$ in the corresponding digital filter. Figure 7 shows the mapping of an analog frequency response and its corresponding digital frequency response and tolerance scheme.

8 PROPERTIES OF DESIGN OF DIGITAL BUTTERWORTH FILTERS

The squared magnitude function for an analog Butterworth filter is given by

$$\left|H_a(\mathrm{j}\Omega)\right|^2 = \frac{1}{1 + \left(\dfrac{\mathrm{j}\Omega}{\mathrm{j}\Omega_\mathrm{c}}\right)^{2N}} \tag{26}$$

as sketched in Figure 8.

The roots of the denominator polynomial, the poles of the squared magnitude function, are then at

$$s_\mathrm{p} = (-1)^{\frac{1}{2N}}\ \mathrm{j}\Omega_\mathrm{c} \tag{27}$$

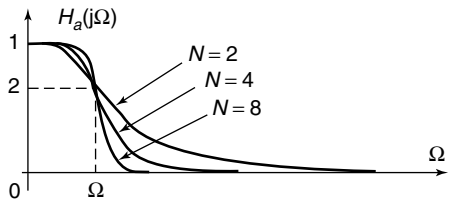

Figure 8. Dependence of the Butterworth magnitude characteristic on the order N.

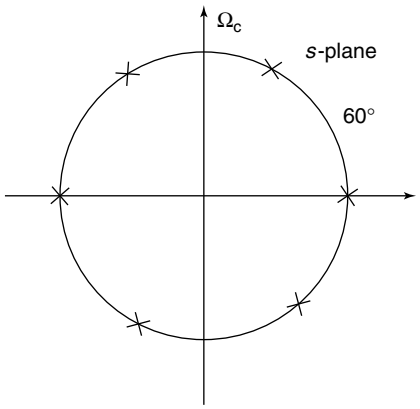

Figure 9. s-plane pole location for a third-order Butterworth filter.

which can be written in the form of poles

$$s_\mathrm{pk} = \left\{ \begin{array}{ll} \Omega_\mathrm{c} \mathrm{e}^{\mathrm{j}\frac{\pi}{N}k} & \text{for } N \text{ odd} \\ \Omega_\mathrm{c} \mathrm{e}^{\mathrm{j}\frac{\pi}{2N}(2k+1)} & \text{for } N \text{ even} \end{array} \right\} \tag{28}$$

where $k = 0, \ldots, N-1$

The properties of a Butterworth filter in terms of poles and zeros are then as follows:

- There are $2N$ poles equally spaced in angle on the circle of radius Ω_c in the s-plane.
- The poles are symmetrically located with respect to the imaginary axis.
- A pole never falls on the imaginary axis.
- A pole occurs on the real axis for odd N but not for even N.
- The angular spacing between the poles on the circle is π/N radians (for $N = 3$, it is indicated in Figure 9).
- The filter is stable when poles occur on the left-half-plane part of the Butterworth circle.

9 DESIGNING A DIGITAL BUTTERWORTH FILTER

Consider the need to design a filter such that the passband magnitude is constant within 1 dB for a frequency below 0.2π and the stopband attenuation is greater than 15 dB for frequencies between 0.3π and π.

If the passband magnitude is normalized to unity at $\omega = 0$, then we require that

$$\begin{aligned} &20\log_{10}|H(\mathrm{j}0.2\pi)| \geq -1 \quad \text{and} \\ &20\log_{10}|H(\mathrm{j}0.3\pi)| \leq -15 \end{aligned} \tag{29}$$

The filter design consists essentially of determining the parameters N and Ω_c to meet the desired specification. For

the Butterworth filter,

$$20\log_{10}|H(\mathrm{j}\Omega)| = 10\log_{10}|H(\mathrm{j}\Omega)|^2 \tag{30}$$

then

$$10\log_{10}\frac{1}{1+(\Omega/\Omega_\mathrm{c})^{2N}} = a[\mathrm{dB}] \tag{31}$$

and

$$1+\left(\frac{\Omega}{\Omega_\mathrm{c}}\right)^{2N} = 10^{0.1a} \tag{32}$$

In our example we have

$$1+\left(\frac{0.2\pi}{\Omega_\mathrm{c}}\right)^{2N} = 10^{0.1} \tag{33}$$

and

$$1+\left(\frac{0.3\pi}{\Omega_\mathrm{c}}\right)^{2N} = 10^{1.5} \tag{34}$$

The solution of these two equations leads to the value $N = 5.88$ and $\Omega_\mathrm{c} = 0.70474\,\mathrm{rad\,s^{-1}}$. The parameter N, however, must be an integer and, consequently, in order for the specifications to be met or exceeded, we round N up to the nearest integer so that $N = 6$.

Then, however, both of the passband and stopband specifications cannot be met exactly. If we substitute $N = 6$ in (34), we obtain $\Omega_\mathrm{c} = 0.7032\,\mathrm{rad\,s^{-1}}$. With this value, the passband specification will be met exactly and the stopband specification will be exceeded for the analog filter. This allows some margin for the aliasing in the digital filter. With the value of Ω_c and with $N = 6$, there are three pole pairs in the left half of the s-plane with coordinates at

- pole pair 1: $-0.1820 \pm \mathrm{j}0.6792$
- pole pair 2: $-0.4972 \pm \mathrm{j}0.4972$
- pole pair 3: $-0.6792 \pm \mathrm{j}0.1820$.

so that

$$\begin{aligned} H_a(s) = {} & \frac{0.120931}{(s^2+0.3640s+0.4945)} \\ & \times (s^2+0.9945s+0.4945) \\ & \times (s^2+1.3585s+0.4945) \end{aligned} \tag{35}$$

Now consider the design of the desired filter above this time using the impulse invariance method.

If we express $H_a(s)$ as a partial fraction and perform a transformation of the above equation, the resulting system function of the digital filter is

$$\begin{aligned} H(z) = {} & \frac{0.2871-0.4466z^{-1}}{1-1.2971z^{-1}+0.6949z^{-2}} \\ & + \frac{-2.1429+1.1454z^{-1}}{1-1.0691z^{-1}+0.3699z^{-2}} \\ & + \frac{1.8558-0.6304z^{-1}}{1-0.9972z^{-1}+0.2570z^{-2}} \end{aligned} \tag{36}$$

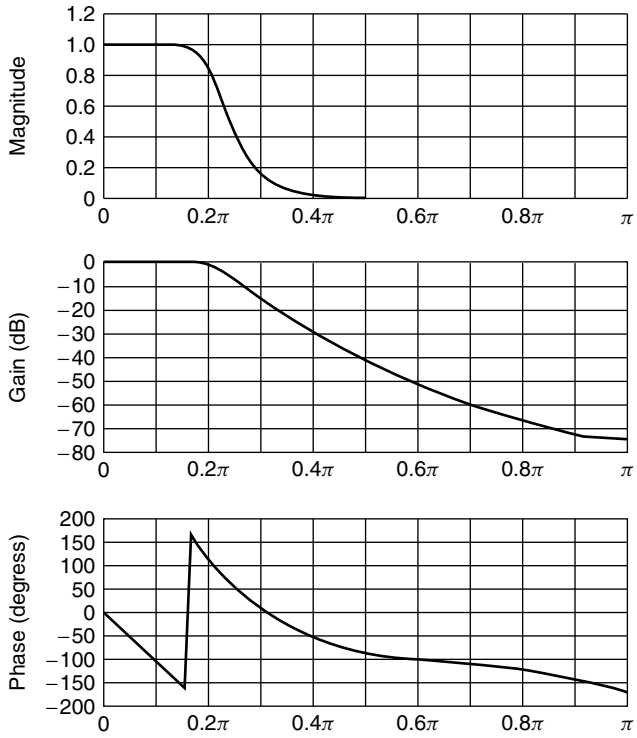

Figure 10. Frequency response of sixth-order Butterworth filter transform by impulse invariance.

It is evident from (36) that the output signal can be derived from the input signal by a recurrence formula. The frequency response of the above system is shown in Figure 10.

Recall now that the filter was designed to exactly meet the specification at the passband edge and to exceed the specification at the stopband edge, and in fact this is the case. This is an indication that the analog filter is sufficiently band limited such that aliasing presents no problems.

10 DESIGN OF A DIGITAL FILTER USING THE BILINEAR TRANSFORMATION METHOD

Given below is the design of a digital filter using the bilinear transformation method.

The digital frequency specification must be prewarped to the corresponding analog frequencies so that with the frequency distortion inherent in the bilinear transformation the critical analog frequencies will map to the correct critical digital frequencies. For the specific filter, we require that

$$20\log_{10}\left|H_a\left(\mathrm{j}2\tan\left(\frac{0.2\pi}{2}\right)\right)\right| \geq -1 \tag{37}$$

and

$$20\log_{10}\left|H_a\left(\mathrm{j}2\tan\left(\frac{0.3\pi}{2}\right)\right)\right| \leq -15 \qquad (38)$$

where we have consequently assumed that $T = 1$. Solving the equations with equality

$$1 + \left(\frac{2\tan(0.1\pi)}{\Omega_c}\right)^{2N} = 10^{0.1} \qquad (39)$$

and

$$1 + \left(\frac{2\tan(0.15\pi)}{\Omega_c}\right)^{2N} = 10^{1.5} \qquad (40)$$

so that

$$N = \frac{1}{2}\,\frac{\log\left[(10^{1.5}-1)\,/\,(10^{0.1}-1)\right]}{\log\left[\tan(0.15\pi)\,/\tan(0.1\pi)\right]} = 5.305 \qquad (41)$$

N must be chosen as 6. If we determine Ω_c by substituting $N = 6$ into (39), we obtain $\Omega_c = 0.76622$. For this value of Ω_c, the passband specifications are exceeded and the stopband specifications are met exactly. In the s-plane, 12 poles of the squared magnitude function are uniformly distributed in angle on a circle of radius 0.76622, as shown in Figure 11.

The transfer function in the s-plane corresponding to the left-half-plane poles is

$$H_a(s) = \frac{0.20238}{(s^2 + 0.396s + 0.5871)\times(s^2 + 1.083s + 0.5871)\times(s^2 + 1.4802s + 0.5871)} \qquad (42)$$

The transfer function $H(z)$ for the digital filter is then obtained by applying the bilinear transformation to $H_a(s)$

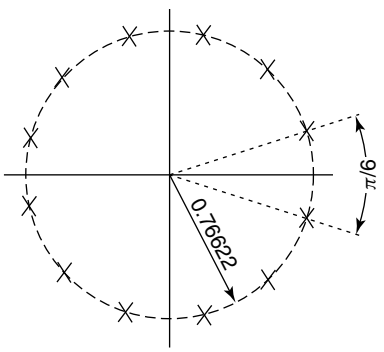

Figure 11. s-plane locations of sixth-order Butterworth filter.

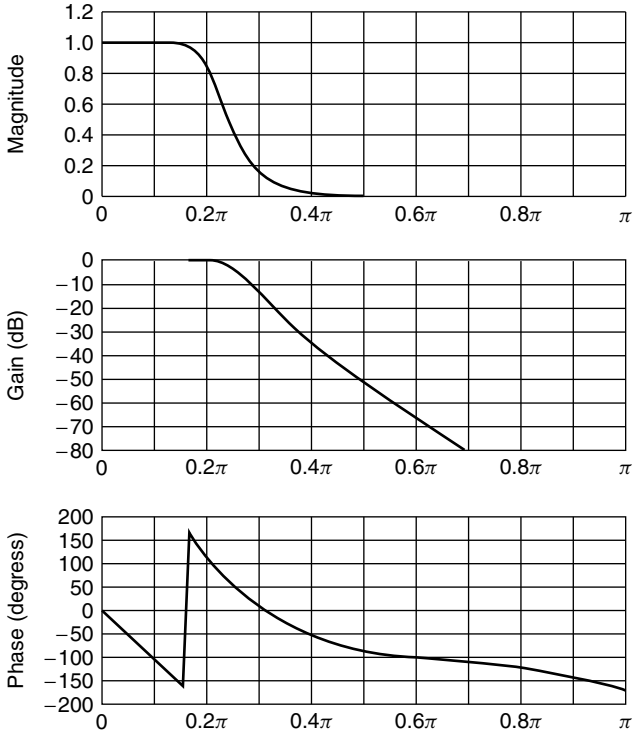

Figure 12. Frequency transfer of sixth-order Butterworth filter transformed by bilinear transformation.

with T chosen as unity, with the result that

$$H(z) = \frac{0.0007378(1 - z^{-1})^6}{(1 - 1.2686z^{-1} + 0.7051z^{-2})\times(1 - 1.0106z^{-1} + 0.3583z^{-2})\times\frac{1}{(1 - 0.9044z^{-1} + 0.2155z^{-2})}} \qquad (43)$$

The magnitude and phase of the digital frequency response is shown in Figure 12.

At $\omega = 0.2\pi$, the magnitude is down 0.5632 dB and at $\omega = 0.3\pi$ the magnitude is down exactly 15 dB.

It should be noted that the magnitude function in Figure 12 falls off much more rapidly than the one in Figure 10. This is because the bilinear transformation maps the entire jΩ axis of the s-plane onto the unit circle. Since the analog Butterworth filter has sixth-order zero at $s = \infty$, the resulting digital filter has a sixth-order zero at $z = -1$.

1 OUTLINE OF DIGITAL FILTER WITH FINITE IMPULSE RESPONSE (FIR)

A digital transversal filter is a filter, which has m delay stages, $(m+1)$ positive or negative multipliers, and an adder or summing junction. It is nonrecursive, with a time domain recurrence formula given by

$$y(n) = a_0x(n) + a_1x(n-1) + a_2x(n-2) + \cdots\cdots + a_mx(n-m) \quad (1)$$

and

$$y(n) = \sum_{i=0}^{m} a_i x(n-i) \quad (2)$$

The filter impulse response is just made up to the multiplier coefficient sequence a_0 to a_m, and is finite in duration.

The disadvantage of a nonrecursive finite impulse response (FIR) filter is that it requires many more delay and multiplier elements than a recursive filter. However, the filter has significant advantages. For example, an impulse response, which is finite in duration, can also be symmetrical in form. This produces a pure linear-phase characteristic; there is no phase distortion. It does not have to be linear phase, but most practical designs incorporate this advantage, which is not available in analog filters. The filter is also inherently stable, since it does not involve feedback from output to input.

2 THE MOVING-AVERAGE FILTER

A simple form of digital filter in which all the multipliers are equal is often called a *moving-average filter*.

As an example, consider the transversal filter in which all multipliers are equal. We use 19 delay and 20 multipliers equal to 0.05.

The transfer function, as a sum of finite power series, is given by

$$H(z) = \frac{(1-z^{-20})}{(1-z^{-1})} = \frac{(z^{20}-1)}{z^{19}(z-1)} \quad (3)$$

The filter has 19 poles in origin and $z = 1$. The zeros of the function are uniformly distributed in angle on a unit circle in the z-plane and the angular spacing between the zeros on the circle is $\pi/10$T rad. The first transmission zero is at $\omega = \pi/10$T. The characteristics of this particular design are shown in Figure 1.

3 FIR DESIGN BASED ON WINDOW FUNCTION

Digital filter design starts from an ideal desired frequency response specification such as

$$H_d(e^{j\omega}) = \sum_{-\infty}^{\infty} h_d(n)e^{-j\omega n} \quad (4)$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

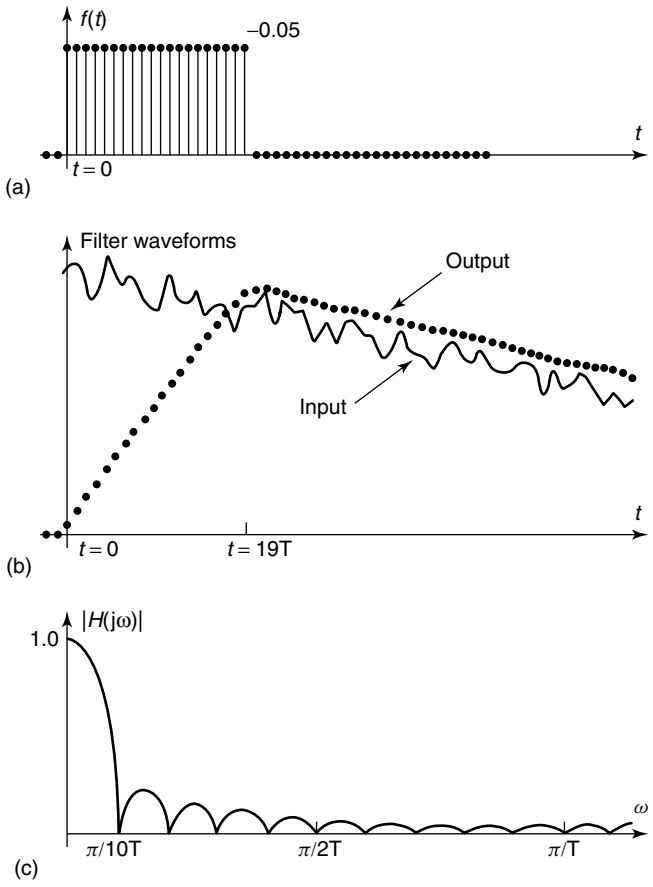

Figure 1. A moving-average filter (a) impulse response, (b) typical input and output waveform, (c) frequency response magnitude characteristic.

The equivalent impulse response may then be found by the inverse discrete Fourier transform, and it is used to define the multipliers of the digital transversal filter.

$$h_d(n) = \frac{1}{2\pi}\int_{-\pi}^{\pi} H_d(\mathrm{e}^{\mathrm{j}\omega n})\mathrm{e}^{\mathrm{j}\omega n}\,\mathrm{d}\omega \tag{5}$$

The impulse response will often contain an unacceptable number of terms. It is possible to simplify the impulse response by ignoring the smaller terms.

$$h(n) = \begin{cases} h_d(n), & 0 < n < N-1 \\ 0, & \text{elsewhere} \end{cases} \tag{6}$$

Such truncation is equivalent to multiplying the function by a rectangular observation window; it causes spreading of the frequency domain characteristic. An alternative solution to the truncation problem is to select a more effective window function, $w(n)$, such as a Hamming, Hanning, or Keiser window.

$$H(n) = h(n)w(n) \tag{7}$$

Now follows some commonly used window functions. These are specified by the following equations:

Rectangular window function

$$w(n) = \begin{cases} 1, & 0 \le n \le N-1 \\ 0, & \text{elsewhere} \end{cases} \tag{8}$$

Bartlett window function

$$w(n) = \begin{cases} \dfrac{2n}{N-1}, & 0 \le n \le \dfrac{N-1}{2} \\ 2 - \dfrac{2n}{N-1}, & \dfrac{2n}{N-1} \le n \le N-1 \end{cases} \tag{9}$$

Hanning window function

$$w(n) = \begin{cases} \dfrac{1}{2}\left[1 - \cos\left(\dfrac{2\pi n}{N-1}\right)\right], & 0 \le n \le N-1 \\ 0, & \text{otherwise} \end{cases} \tag{10}$$

Hamming window function

$$w(n) = \begin{cases} 0.54 - 0.46\cos\left(\dfrac{2\pi n}{N-1}\right), & 0 \le n \le N-1 \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

Blackman window function

$$w(n) = \begin{cases} 0.42 - 0.5\cos\left(\dfrac{2\pi n}{N-1}\right) \\ \quad +0.08\cos\left(\dfrac{4\pi n}{N-1}\right), & 0 \le n \le N-1 \\ 0, & \text{otherwise} \end{cases} \tag{12}$$

Windowing can be applied at different stages of spectrum estimation:

- to the time record, called *linear windowing* in the time domain,
- to the results of the Discrete Fourier Transform called *linear windowing* in the frequency domain.

4 TRANSVERSAL FILTER DESIGN BY THE WINDOW METHOD

To illustrate the techniques, now consider the design of a low-pass filter, which takes as its starting point an ideal low-pass filter characteristic $G_1(\omega)$ with a cutoff frequency of $\omega_0 = \pi/4\mathrm{T}$ (Figure 2(a)).

The impulse response $I(t)$ is symmetrical about $t = 0$ and of sampled $(\sin x)/x$ form (Figure 2(b)). We next decide how many impulse response terms we can accommodate in the final design, and multiply by a window function with this number of terms.

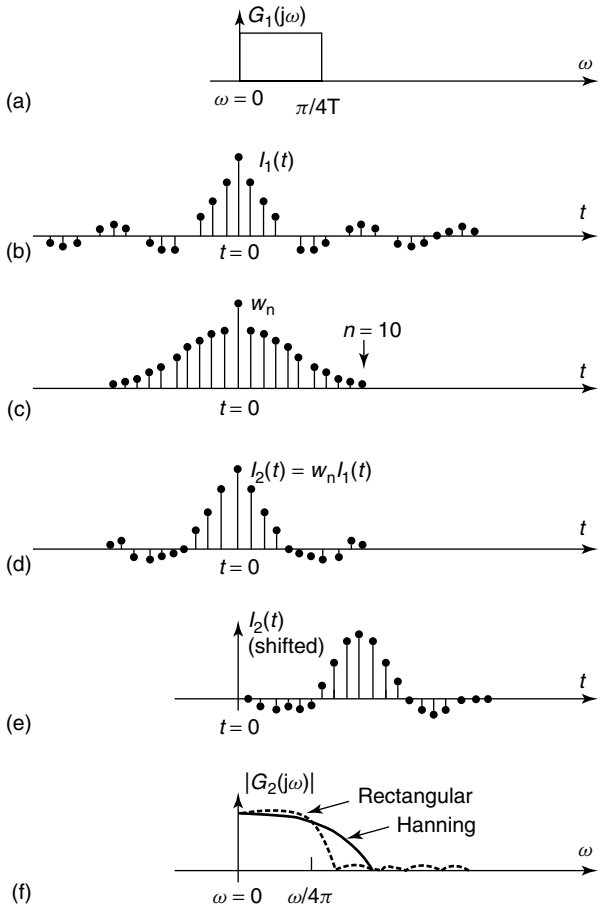

Figure 2. Transversal filter design by window method.

A Hamming window can be used that is defined as:

$$w(n) = \begin{cases} 0.54 + 0.46\cos n\pi/N, & -N < n < n \\ 0, & \text{elsewhere} \end{cases} \tag{13}$$

This has $(2N - 1)$ terms. Use 21 transversal multipliers so that $N = 11$. The impulse response can be shifted forward (Figure 2(e)) so that it begins at $t = 0$. This makes the filter physically releasable and converts the original zero-phase filter into a pure linear-phase one. The resulting frequency response magnitude characteristic is shown in Figure 2(f).

5 DIGITAL FILTER WITH LINEAR-PHASE SPECTRUM

This time, the design filter has to achieve a linear-phase spectrum.

The desired frequency response is defined as

$$H_d(e^{-j\omega}) = \begin{cases} e^{-j\omega\alpha}, & |\omega| < \omega_c \\ 0, & \text{elsewhere} \end{cases} \tag{14}$$

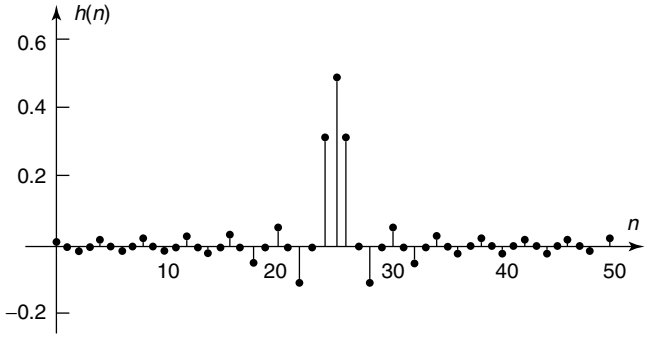

Figure 3. Truncated impulse response of an ideal low-pass filter. (Delay is 25 samples, total length is 51 samples and cutoff frequency is $\omega_0 = \pi/2$.)

The corresponding impulse response is

$$h_d(n) = \begin{cases} \dfrac{1}{2\pi}\displaystyle\int_{-\omega}^{\omega} e^{j\omega(n-\alpha)}\,d\omega \\ \dfrac{\sin[\omega_c(n-\alpha)]}{\pi(n-\alpha)}, n \neq \alpha \end{cases} \tag{15}$$

Clearly, the impulse response has infinite duration. To create a finite duration linear phase causal filter of length N, it is necessary to define $h(n) = h_d(n)w(n)$ and $\alpha = (N-1)/2$. Figure 3 shows a plot of $h(n)$ for a rectangular window where $N = 51$, and $\omega_c = \pi/2$.

6 SUMMARY OF DIGITAL FILTER METHODS

It is useful to summarize the methods and techniques presented in this part on digital data filtering. It started with a comment on filter classifications. Several types of filters have been distinguished according to the signal form and frequency range.

It continued with the description of the filter in the frequency domain by its frequency response transfer function, and in the time domain by its impulse response. The Butterworth and Chebyshev filters have been presented as examples of an ideal filter approximation.

The general performance of digital filters has been outlined using two different methods of digital filter realization and two different ways of the filter implementation. The method of filter amplitude and phase spectra estimation from its zero-pole configuration has been presented.

Low-pass and high-pass filters are described as typical examples of the digital filters in the z-plane. Their magnitude response characteristics have been considered. The problem of determining an appropriate set of specifications with a low-pass filter as the example has been given.

Filters with infinite impulse response, IIR, and filters with finite impulse response, have been described. Since many

practical IIR filters are based upon analog equivalents, the design problem is to find a suitable transformation for mapping the s-plane poles and zeros of the analog filter into the z-plane. The impulse invariance method or bilinear transformation has been introduced. The design principles and procedures for both methods have been presented. Several examples of low-pass Butterworth filter design have been shown.

The coverage also includes the concept of the moving-average filter as an example of an FIR filter. FIR filter design based on a window function is the most useful form. Design examples have been given.

1 DATA AND INFORMATION

Data are the basic elements used to represent the formation or measurement of facts, which are described by numbers, characters, assertions and so on, in a digital form. Data by themselves have little if any meaning. Only processed data gives meaningful information, as represented in Figure 1. The raw material to gain knowledge is information, which is extracted from data.

Consider the example of the manufacture of a light bulb to illustrate this transformation from data to information. The information required is whether the lamp is either too bright or too dull. Two pieces of information are required to perform the assessment. In the first place, a standard brightness is required and in the second, the actual brightness must be measured. Obtaining information about the lamp's brightness means that knowledge about the lamp has been acquired and a specification of uncertainty becomes possible. In a wider context, this knowledge can assist in production control so helping in running the business, in improving health and safety, or in making strategic decisions about long-term planning among many other possibilities. Such a view means that information is necessary to control almost everything. Hence, control is central to the question of data and information. More on the differences between data, information, and knowledge is given in **Article 13, Signals, Information and Knowledge, and Meaning, Volume 1**.

2 BASIC ORGANIZATION OF THE STORED PROGRAM COMPUTER

The stored program computer (Conger, 1999; Gaonkar, 1999; Karalis, 1997; Wilkinson and Makki, 1992), which is an indispensable component in measurement systems (Lang, 1987, 1991; Morrison, 1997) is also important in measurement systems design (Sydenham, Hancock and Thorn, 1989). A common basic architecture for a stored program computer, which is shown in Figure 2, consists of three main subsystems. A *central processing unit*, or CPU, executes instructions. The set of instructions make up the instruction set. Instructions, which are to be executed in a prescribed manner, form part of a program stored in main memory.

Main memory may be divided into two parts. A primary memory is used to store the program to be executed as well as the data to be operated on. This primary memory, which is normally of a semiconductor form, is referred to as *random access memory*, or RAM. It consists of a volatile, *read/write memory*, or R/W memory, and a nonvolatile *read only memory*, or ROM.

Secondary memory, which is often called a backing store, may have different recording forms. Of the three kinds of magnetic recording forms, the first kind is called the *hard*

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

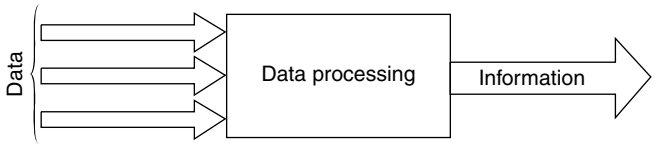

Figure 1. A processor converts data to information.

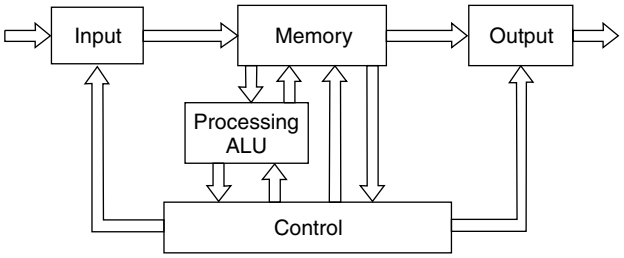

Figure 2. Architecture of a stored program computer.

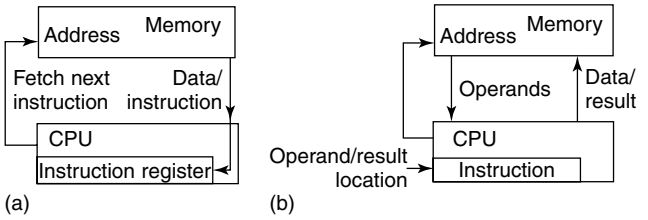

Figure 3. The fetch principle in (a) and the execute principle in (b) of stored program operation.

disk drive, or HDD, which is the main operational form of secondary memory. The other two magnetic recording forms are either removable floppy disk drives or removable tape drives. Removable floppy diskettes may be used for transferring programs and data from one computer to another. Originally, they took the form of 5.25-inch platters. Later, the 3.5-inch high density disk, first developed by

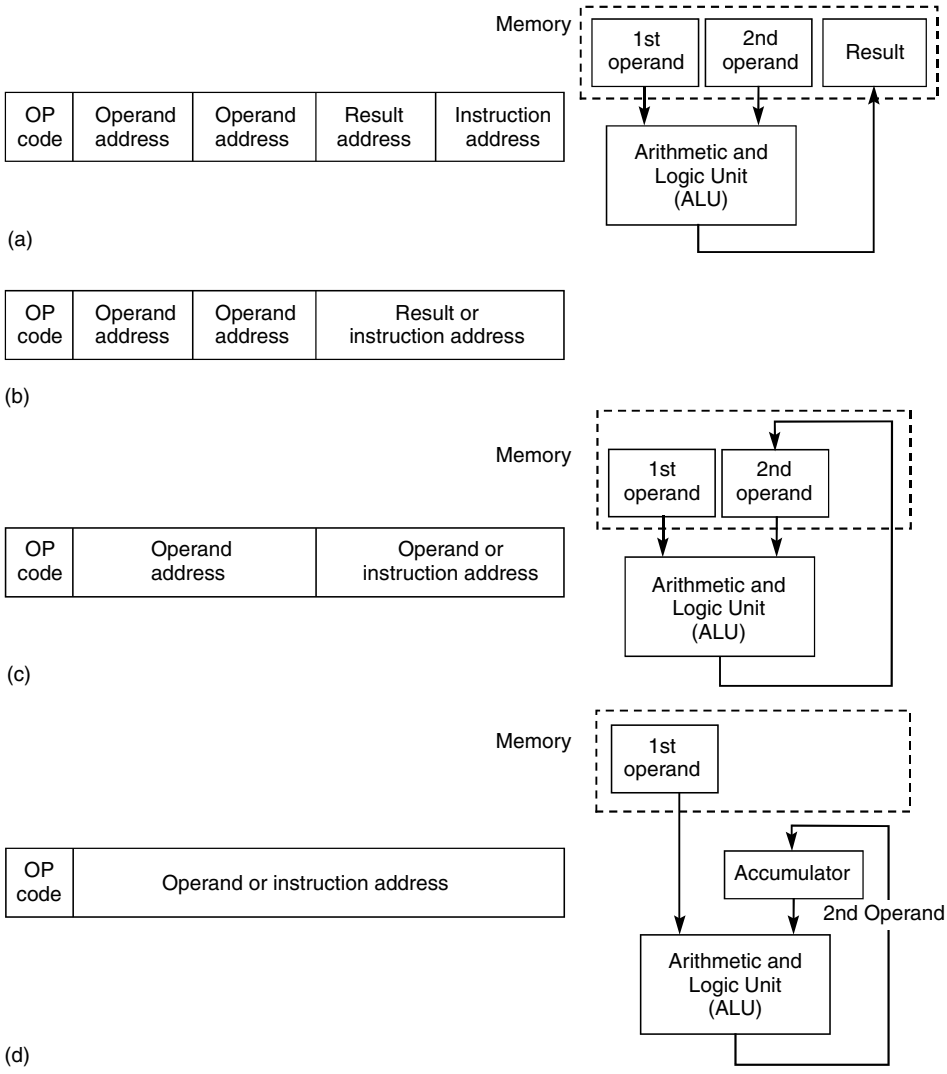

Figure 4. The four macroinstruction formats.

the Sony Corporation, became the most common form of removable media for backing store.

Unfortunately, these media are not all interchangeable or even compatible with the 3.5-inch, 1.44 Mb type.

Tape systems are almost all exclusively used for the purposes of backing up either the complete contents or selected parts of HDD contents. This is mainly used for data security purposes. However, it can also be used as a means of fast recovery of original Operating System, or OS, installations in the event of irrecoverable system crashes. INPUT DEVICES and OUTPUT DEVICES are interfaces to video display units, or VDUs, floppy disk drives, and other peripherals.

The basic mode of operation, consisting of two separate control cycles as shown in Figure 3, are

- FETCH CYCLE when instructions are fetched,
- EXECUTE CYCLE when the instruction is processed.

More details are given in **Article 154, Internal Operation of the Microprocessor, Volume 3**.

Instructions are executed sequentially. The memory is used to store both the program and data. It should be noted that alternative computer architectures are possible. These depend on data availability and not the order of the instructions. Thus, they can operate concurrently and are known as *data flow computers*.

3 PURPOSE AND FORMAT OF MACROINSTRUCTIONS

A number of instruction formats are available depending on the machine design and the compromises made. The most general format is shown in Figure 4(a), where an operational code, or op-code, is specified along with the addresses of the Arithmetic and Logic Unit, or ALU, source operands, and the destination of the result. The next instruction address can also be specified. Thus, data transfer and control can occur together. This format is used for microprogramming, which is a sequence of microinstructions used to execute one top level machine instruction.

If the program control and data processing instructions are separated, it is possible to reduce the instruction fields by one. Figure 4(b) shows this format of separate control and processing instructions.

A further reduction is possible if the destination address is assumed. Figure 4(c) can be interpreted as '*take operands 1 and 2 from the addresses given and return the result to operand 2 address*'. This is somewhat restrictive since memory data is overwritten. An alternative approach is to include a separate register to store the result. This is called the *accumulator*.

The presence of the accumulator, as shown in Figure 4(d) can be used to produce a one-address instruction format, where one of the source operands comes from instruction and the other is the accumulator. The result is returned to the accumulator. In practice, a register file is used for providing a number of detectable registers determined by the op-code.

1 DATA WIDTH AND ADDRESS RANGE IN COMPUTER BUSES

Figure 1 shows a typical microprocessor architecture consisting of an arithmetic logic unit (ALU), accumulator and register file, which contains the *stack pointer*, or SP, and the *program counter*, or PC. Microcomputers usually handle 8, 16, 24, 32 or 64 bit wide data words. It is obviously uneconomical to choose a 32-bit bus for use in a system intended for 8 bits (Holdsworth, 1987; Lang, 1991; Rangan, Sarama and Mani, 1983; Tocci and Laskowski, 1987; Wilkinson and Makki, 1992). Component level buses, which are merely extensions of the local processor bus to a back-plane, normally have 16 to 20 address lines giving 64 kB to 1 MB of addressable RAM. Although an 8-bit bus system may be adequate for small process or machine tool systems, it is totally inadequate for modern business applications, which usually include versatile graphic facilities. Hence, allow at least 24 address lines up to say 32 or even 64.

The external data bus and external address bus are buffered by a data buffer, or DBF register and an address buffer, or ABF register, while instructions are loaded into the instruction register, or IR, for use by the control unit. Data transfer between registers occurs via an internal or local processor bus. Control lines from the control unit are available for interfacing to external devices.

2 INSTRUCTION SET

The instruction set for the processor can be divided into the following:

- TRANSFER: movement of data from one location to another such as register or memory locations,
- ARITHMETIC AND LOGICAL: ADD, SUB, OR, AND, NOT, and so on,
- SHIFT AND ROTATE: moving each bit in a binary number,
- JUMP/BRANCH: alters sequence of instructions including program control determined by conditions of the last ALU result,
- INPUT/OUTPUT: transfer from processor registers to external devices,
- CONTROL: interrupts, bit test, external conditions affecting the instruction flow.

3 EXTERNAL BUSES – SYNCHRONOUS AND ASYNCHRONOUS TRANSFERS

Information must be distributed or transferred within the system. The various bus signals, which are used for this purpose, are divided into three main groups. One group, called the *data bus*, is used to carry data from and to various locations within the system. This data needs to be

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

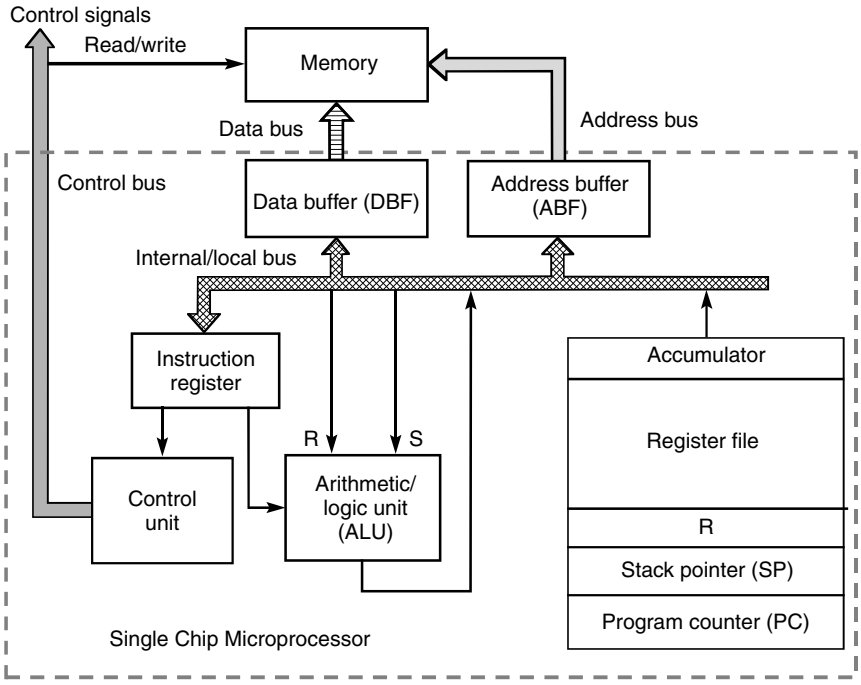

Figure 1. Operational organization of a microprocessor using a single address instruction format.

directed. For this reason, a second bus called the *address bus* is essential. The whole system needs to be controlled. A control bus carries the control signals utilized by the system to direct, time, and order the sequential proceedings of program execution.

The basic methods of information transfer use either SYNCHRONOUS bus transfers or ASYNCHRONOUS bus transfers. Reliable data transfer requires a data transfer protocol or defined set of rules. Three main problems must be overcome. When a master gates several parallel data or address lines with the signals, lack of synchronism causes problems. This is called *skew*. These problems are compounded by the differences in the rise times of each separate line signal. Moreover, the switching point of bus transceivers must be taken into account.

In synchronous bus transfers, synchronization of master and slave is timed as in Figure 2(a) using the circuit of Figure 2(b). Information on the direction of transfer, to or from the processor, the transfer timing, and whether it is a memory or input/output operation, is required. Data are placed on the parallel bus lines. After a delay, which is sufficient to cover the maximum skew and rise time differences, a stable strobe pulse is generated. The processor generates a request signal, together with data and address signals. When the appropriate device receives these signals, data is accepted or generated. The slave responds by completing a write operation to memory or some other interface. Although the timing is known in advance and taken into account by the processor, the processor must

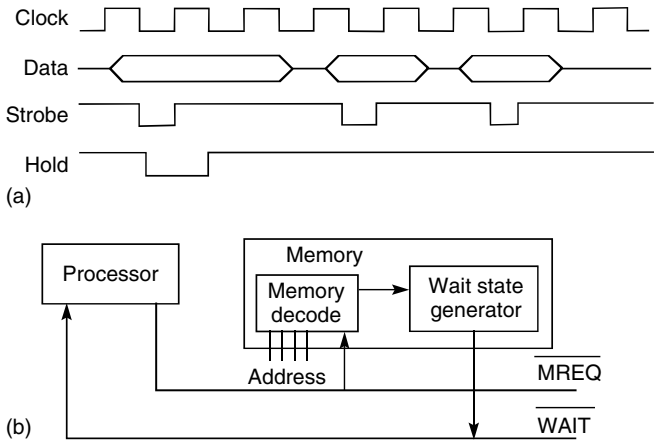

Figure 2. Synchronous protocol with hold and wait cycle: (a) signal timing diagram and (b) organization of the Z80.

not operate faster than the speed of the slowest device. However, since this can be restrictive, introducing a wait signal, or ready signal, can alleviate this problem. A wait state generator, contained within the slow memory being accessed, activates the wait line to the processor causing it to introduce dummy clock cycles in the middle of the data transfer period. Hence, when the slave is slow, it generates a hold pulse telling the master to insert wait cycles until the slave action is completed. Performance is limited by two main factors. In the first case, a clock pulse cannot be changed once it has been defined. This implies that

the system cannot take advantage of faster circuits as they become available. In the second case, slow devices need to be synchronized. Hence, a hold pulse has to be generated very quickly. This requires fast logic so that the master can decide whether to proceed with the next data cycle or to insert dummy wait cycles.

The above information is provided by control signals, which are usually active low or '0'. For example, in the Z80, the signals are $\overline{\text{RD}}$, $\overline{\text{WR}}$, $\overline{\text{MREQ}}$ (memory request), $\overline{\text{IORG}}$ (input/output request).

In the Motorola 6800 series, they are VMA or valid memory address, R/$\overline{\text{W}}$, E or ϕ. E or ϕ is the general processor clock with which timing is synchronized.

4 OVERCOMING PROBLEMS IN THE SYNCHRONOUS PROTOCOL

Problems that occur in the synchronous protocol are overcome by the inclusion of full handshaking signals: data strobe (DS*) and data acknowledge (DK*). The operations proceed in the sequence outlined in Figure 3(a). Two control lines are utilized. One from the processor initiates the start of data transfer, while the other, from the destination, which is the memory in this case, triggers completion of the transfer. Thus, the total transfer time is always dictated by the returning signal, whose absence would indicate a failure in the peripheral device. Compare this to WAIT state generation in which failure to generate is ignored by the processor. After first placing data on lines, the master waits until its own transmitter skew effects have settled and asserts DS*. When the slave sees DS* asserted, it waits until its own receiver skew effects have settled. It then waits for a long enough time either to accept the data or to place new data on the relevant lines before asserting DK*. Meantime, the master holds data steady until it sees DK* asserted. When this occurs, it then releases both data and DS* or waits until it has accepted the slave's data before releasing DS*. The slave holds its data until it sees DS* released. Finally, it then removes its data before releasing DK* in preparation for the next cycle. The data transfer rate is automatically adjusted to allow the fastest possible rate for the receiver and transmitter modules involved. The disadvantage of this method is that extra control signals are required. Propagation delays of these extra control signals may slow the speed of processor operation.

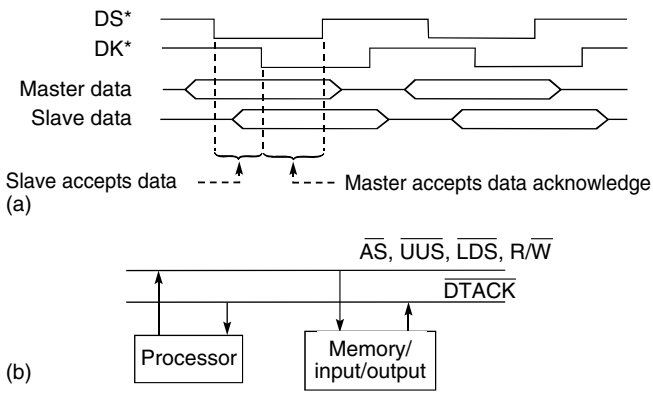

Figure 3. Asynchronous protocol: (a) signal timing diagram and (b) organization of the Motorola 6800.

In the case of the Motorola 6800, both synchronous and asynchronous signals are present. The asynchronous are $\overline{\text{AS}}$ (address strobe), $\overline{\text{UDS}}$ upper data strobe D08-D15, $\overline{\text{LDS}}$ lower data strobe D01-D07, R/$\overline{\text{W}}$, $\overline{\text{DTACK}}$ data acknowledge. The synchronous signals are similar to those of the 6800.

1 FETCHING AND EXECUTING

The operation of the processor can be divided into two cycles known as FETCH and EXECUTE (Conger, 1999; Gaonkar, 1999; Karalis, 1997; Heffer, King and Heath, 1981; (**Article 153, Single Address Instruction Microcomputer, Volume 3**); Wilkinson and Makki, 1992). It should be noted that all of the following operations are essentially register-to-register transfers. They are synchronized to the system clock. Figure 1 shows the control timing pulses, or T states, being derived from the system clock.

In the FETCH cycle, instructions are brought from the external primary memory to the internal instruction register of the processor. There are several distinct steps in this procedure. The output address is placed on the address bus, while appropriate control signals are established on the control bus. The instruction is transferred from the data bus to the instruction register after a suitable delay or alternatively after WAIT states or data acknowledge. When this is completed, the program counter is incremented by 1. Subsequently, other instruction bytes are fetched if required.

To illustrate the EXECUTE cycle, consider the implementation of the Z80 instruction LD A, (100). Firstly, the address 100 is placed onto the address lines, while the control signals are placed on the control bus. Data is loaded into the processor, before subsequent internal bus transfer to register A. If the instruction were LD (100), A the data would be transferred from register A via the internal bus to the data bus.

2 REGISTER TRANSFER LOGIC, OR RTL

The transfer of data between registers can be specified using a register transfer notation. For example, transferring the contents of register B to register A could be indicated by

$$\mathrm{A} \longleftarrow \mathrm{B}$$

Such a notation has found application in hardware description languages, or HDLs. They can be used to describe the operation of complex digital systems in which other techniques such as state diagrams are inappropriate.

Prefixing the transfer with a colon can include control signal operation

$$\mathrm{T1}\colon \mathrm{A} \longleftarrow \mathrm{B}$$

Thus, transfer takes place when T1 is high. Also

$$\mathrm{T1} \times \phi\colon \mathrm{A} \longleftarrow \mathrm{B}$$

indicates transfer when both T1 and ϕ are high.

Arithmetic operations in the ALU can also be specified. Thus, if register B goes to the ALU R-BUS and C to the L-BUS, then an ADD operation gives

$$\mathrm{T1}\colon \mathrm{A} \longleftarrow \mathrm{B} + C$$

Internal processor operation can be specified in terms of this notation. As an example, consider the Z80 processor. Assume that the control signals are generated by the loading of one bit registers corresponding to $\overline{MI}$ (Instruction fetch),

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

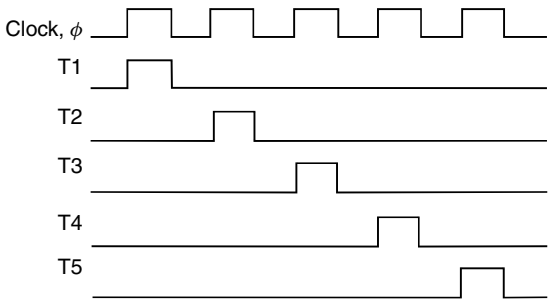

Figure 1. Control state timing for the instruction execute phase.

$\overline{MREQ}$, $\overline{RFSH}$ (dynamic RAM refresh), $\overline{RD}$, and $\overline{WR}$ Processor control inputs include ϕ (system clock) and $\overline{WAIT}$. Registers are loaded on the rising edge of the specified control signal, that is, T1, T3, T3, and so on.

For *instruction fetch*, the following transfers would be required;

FT1: ABUS ⟵ ABF ⟵ PC, 91- ⟵ 0

FT1: PC ⟵ PC + 1

FT$\overline{1}$: $\overline{MREQ}$ ⟵ 0, $\overline{RD}$ ⟵ 0

FT3: IR ⟵ DBUS

FT3: ABUS ⟵ RI, $\overline{MREQ}$ ⟵ 1, $\overline{RD}$ ⟵ 1, $\overline{M1}$ ⟵ 0, $\overline{RFSH}$ ⟵ 0

FT3: $\overline{MREQ}$ ⟵ 0, R ⟵ R + 1

FT4: $\overline{MREQ}$ ⟵ 1

FT1: $\overline{RFSH}$ ⟵ 1

For a *memory-to-register read* of the form LD A, (100)

ET1: ABUS ⟵ ABF

ET1: $\overline{MREQ}$ ⟵ 0, $\overline{RD}$ ⟵ 0

ET$\overline{3}$: $\overline{MREQ}$ ⟵ 0, $\overline{RD}$ ⟵ 1, A ⟵ DBUS

To obtain a *literal* of the form LD A, n from PROGRAM MEMORY, the following would occur after the op-code had been fetched.

ET1: ABUS ⟵ ABF ⟵ PC (PC points to next instruction byte)

ET1: PC ⟵ PC + 1

ET$\overline{3}$: $\overline{MREQ}$ ⟵ 0, $\overline{RD}$ ⟵ 0

ET$\overline{3}$: $\overline{MREQ}$ ⟵ 1, $\overline{RD}$ ⟵ 0, A ⟵ DBUS

A *write-from-a-register* such as LD (100), A

ET1: ABUS ⟵ ABF

ET$\overline{1}$: $\overline{MREQ}$ ⟵ 0, DBUS ⟵ DBF ⟵ A

ET2: $\overline{WR}$ ⟵ 0,

ET$\overline{3}$: $\overline{MREQ}$ ⟵ 1, $\overline{WR}$ ⟵ 1

T1′ DBUS ⟵ Zhigh (T1 of next cycle)

Arithmetic operations can also be described. These include ADD A, B, which uses the following operations.

ETl: ALUR ⟵ A

ET2: ALUS ⟵ B

ET3: A ⟵ ALU

Conditional microoperations might also be required, for example, interrogating the $\overline{WAIT}$ line until it goes to 1. Others are required for implementing conditional branch instructions depending on the STATUS of the ALU. In register transfer logic (RTL), a typical statement is

T2: IF $\overline{WAIT} = 0$ THEN T2 ELSE T3

T3:

The T2 cycle is repeated until $\overline{WAIT} = 0$.

1 INPUT AND OUTPUT–PROGRAMMING AND TYPES

There are four parts to a microprocessor system, the microprocessor, which is an integrated circuit, or IC, central processing unit, or the microprogram, data memory, which is also usually fabricated in IC technology, and the input/output circuitry. The last two topics will now be considered.

Data transfer to and from the input/output devices, using processor machine instructions, requires that checks be made to ascertain that the I/O device, or input–output device, has data ready before a read, and is ready to accept data before data is sent. This is known as handshaking (Heffer, King and Heath, 1981; Holdsworth, 1987; (*see* **Article 153, Single Address Instruction Microcomputer, Volume 3**); Tocci and Laskowski, 1987; Wilkinson and Makki, 1992). A status register, which is polled, can be used to indicate the state of readiness of the interface (Doyle, 1999).

The two types of I/O are parallel I/O, or PIO, and serial I/O, or SIO. In PIO, data is sent in parallel at 1 bit per line. Common interfaces such as PIOs and versatile interface adapters (VIAs) have the necessary processor interfaces for controlling the I/O device, interrogating its status, interrupting the processor, and sending an interrupt vector. Handshake lines such as data strobe/acknowledge, or STB, and data ready, or RDY, ensure controlled data transfers at the port input.

For SIO, the information is sent along one wire. It consists of a number of bits separated in time. The following terms, which are described in more detail in **Article 165, Introduction to Networked Instrumentation, Volume 3**; **Article 166, Instrument Interconnection, Volume 3**; **Article 167, Asynchronous and Synchronous Interface Protocols, Volume 3**; **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**; and **Article 169, Voltage and Current Loop Transmission, Volume 3** relate to serial transmission.

- *Simplex*: data is sent in one direction only,
- *Half duplex*: data is sent in both directions one at a time,
- *Full duplex*: data is sent in both directions simultaneously.

Serial signals may also be transmitted synchronously or asynchronously. In the synchronous serial interface, a block of characters is transmitted one bit at a time without stop-bits. It is 20 to 27% faster than asynchronous transmission for the same bit rate. Synchronization characters, such as insert 3 characters are sent at the start and end of transmission, and periodically in between characters. The synchronizing characters must not be valid characters. In ASCII, or American Standard Code for Information Interchange, the SYN (0010110) character cannot be used. Parts available include USARTs, or Universal Synchronous/Asynchronous Receiver/Transmitters and SIOs.

The ASCII coded signal shown in Figure 1 is a standard asynchronous format. Transmission rates up to

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

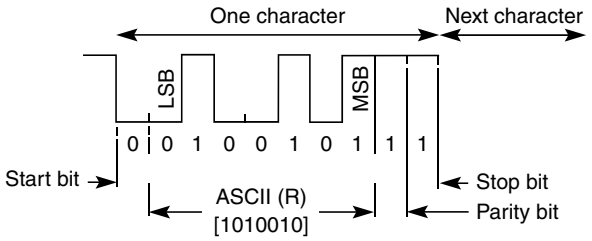

Figure 1. An ASCII coded signal.

9600 bps or 960 characters per second are common for video terminals. Parts used include universal asynchronous receiver/transmitters, or UARTs, or asynchronous communications interface adapters, or ACIAs, for microprocessors.

2 INTERRUPTS AND INTERRUPT SERVICING

Programmed I/O has the disadvantage that the processor must continually poll the I/O status register to see if data has to be sent or received. This slows down the processor. An alternative is to interrupt the processor during normal execution, causing it to service the I/O device. Special signals, such as *interrupt request* and *interrupt acknowledge*, are needed. Figure 2 shows the signaling lines and the interrupt handling scheme.

Interrupts are suited to unsynchronized I/O and randomly occurring I/O. It is especially suited to the multiprocessing environment, where several programs are interleaved. Interrupts can also be used to respond to internal processor hardware conditions such as ALU overflow.

An interrupt service routine, or ISR, is an integral part of every program, which allows the sequence of program operation to be suspended temporarily in an orderly manner. When one of the number of possible requests for interrupt servicing is acknowledged, the ISR may be initiated. Interrupt requests may be due to the following:

- An *unconditional jump* to a known location. This may be fixed in the processor design and activated as nonmaskable interrupts. Several locations may be available.
- In *vectored interrupts*, a jump address is provided to the processor by

  1. defined memory location *holding SR address,*
  2. interrupting device *providing SR address as a vector.*

Multiple interrupts may be caused if several devices are used to interrupt the processor. A priority interrupt number must be given to each so that simultaneous interrupts can be resolved. Priority can be established by the following:

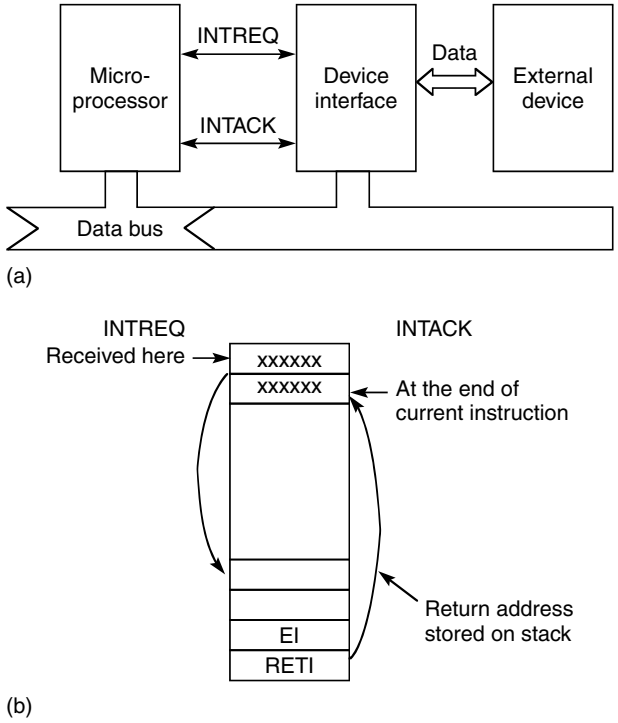

Figure 2. Interrupts in microprocessors: (a) interrupt request signals; and (b) interrupt handling.

- *Polled interrupts*: All interrupt requests are wire-OR'ed together for a single interrupt request, or INTREQ. The processor acknowledgment involves polling the devices to see which has sent INTREQ. This includes the following:

  1. The use of an INT FLAG on each device, which is set on INT. Processor checks flags in order of priority.
  2. The use of an INTERRUPT REQUEST REGISTER with bits set for each device. Set order of priority of bits in register.

- *Daisy chained interrupts*: One of the interrupt control lines passes through each device.

  1. *Daisy chained interrupt acknowledge*: As shown in the circuit of Figure 3, the highest priority is closest to the processor that receives the request directly. The interrupting device blocks the interrupt acknowledge, or INTACK, from the processor to devices with lower priority. Vectored ISRs can be used to identify the interrupting device.
  2. *Interrupt request*: The lowest priority device is closest to the processor. There is a common acknowledge to all devices.

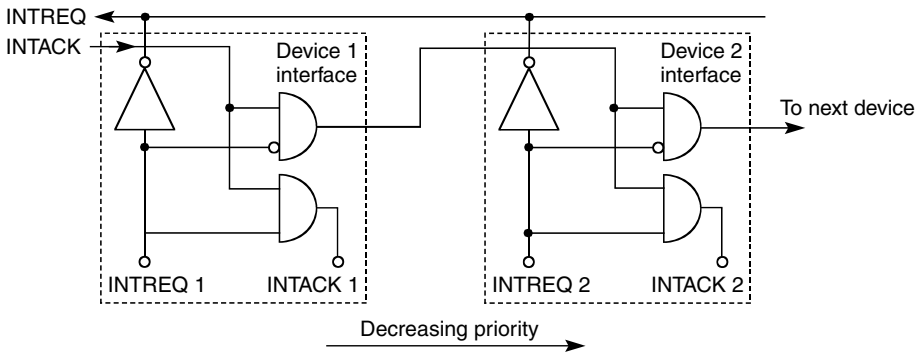

Figure 3. Handling interrupts using the daisy chained method.

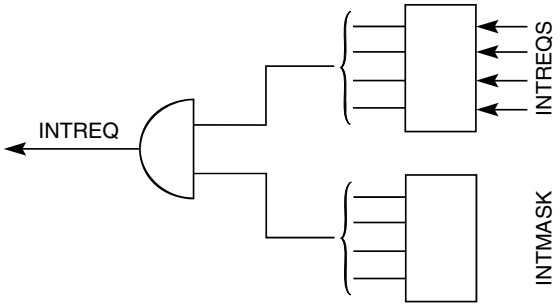

Figure 4. Added flexibility using an interrupt mask.

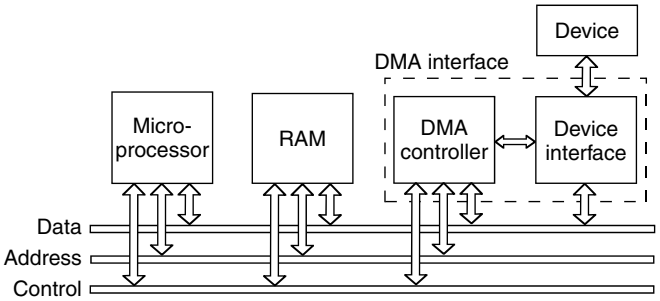

Figure 5. Use of a DMA controller.

Figure 4 illustrates the added flexibility of INTERRUPT MASKING. Higher priority devices can be selectively enabled immediately after accepting an INTREQ.

Interrupt controllers are devices that can

- handle multiple interrupts outside the processor,
- can support eight levels cascadable to more,
- can also supply interrupt vectors,
- can operate with fixed or rotating priority.

Rotating priority means that after the highest priority interrupt is serviced, it is then given the lowest priority. The next to highest becomes highest and so on. Priority therefore rotates thus preventing an interrupt dominating at the expense of others, which might not be serviced at all. This technique is also used in multiple bus-master systems.

3 DIRECT MEMORY ACCESS

Processor controlled transfers, such as memory to I/O, means that the processor cannot do other things. The speed of transfer is limited by the execution times of machine instructions. For large amounts of data, this is time consuming. A *direct memory access*, or DMA, controller, in the structural arrangement given in Figure 5, may be used as an attractive alternative. It is programmed from the processor by receipt of the starting address in memory plus the number of bytes to be transferred. The controller first captures the system data, address, and control buses, followed by transfer of the required number of bytes before signaling the processor that transfer is complete. The processor, which relinquishes the bus on receipt of a bus request, or BREQ, at the end of the current instruction, cannot use the bus again until transfer is complete. To allow the processor to continue operating, the DMA controller can 'steal' processor cycles, called *processor stealing*, to allow program execution.

The controller can operate in a variety of ways to

- fetch setup addresses and byte counts held in external memory,
- take data from source and compare it with the contents of a preloaded DMA register to find a data match,
- detect when a data match is not found. This is useful in memory testing where the same word is loaded into each location. If a different word is detected, an error is present at that location.

DMA is useful for devices such as magnetic disk memory units where a data block must be transferred as a constant stream and at a rate dictated by the shaft speed of the disk.

1 INTRODUCTION TO MEMORY MANAGEMENT SYSTEMS

When running large programs or when operating on data files that do not fit completely into the available primary memory, a memory management scheme must be implemented to control the transfer of information between the system's secondary, or disk memory, and primary or random access memory (RAM).

In simple systems such as microprocessors running MSDOS, a technique known as OVERLAYING is applied where existing programs are overwritten. A large software package is divided into a MAIN FILE and several OVERLAY FILES, which overwrite the main file. It may be necessary to restore the main file from time to time. Thus, a common problem is caused by interaction between program sections in different overlay files, which can cause disk threshing owing to excessive disk to memory transfers. Also, errors in different overlays can be difficult to detect.

2 PRIMARY AND SECONDARY MEMORY WORD BLOCK TRANSFER

In more sophisticated management systems, automatic replacement of memory blocks in primary memory with blocks obtained from secondary memory is desirable. Such systems require both the actual address used by the memory units and the program address produced by the processor. Translation between the two addresses is achieved by hardware and software. During program transfer, actual memory addresses may change but the program addresses used by the processor will remain the same. The two types of systems deal with memory in the form of pages of memory or segments of memory.

In paged or virtual memory systems, the actual address is the real address and the program address is the virtual address. A page is a memory block of fixed length of 128, 256, 512, 1024 words. An address is composed of a page number and a line number. Thus, there are two fields in the address as shown in Figure 1(a).

Memory management units, or MMUs, must provide hardware to translate the virtual page number into a real page number. This hardware works only on the primary memory. For secondary memory, software replacement algorithms are required to transfer pages from secondary to primary. The hardware checks to see if the page is in primary memory. If not, software must search secondary memory from which data is transferred to either a blank page or overwrites an existing one. Note the number of virtual addresses can exceed the actual number of available addresses in both memories as shown in Figure 1(b).

Address translation is achieved using one of two techniques. In direct mapping, as shown in Figure 2(a), all

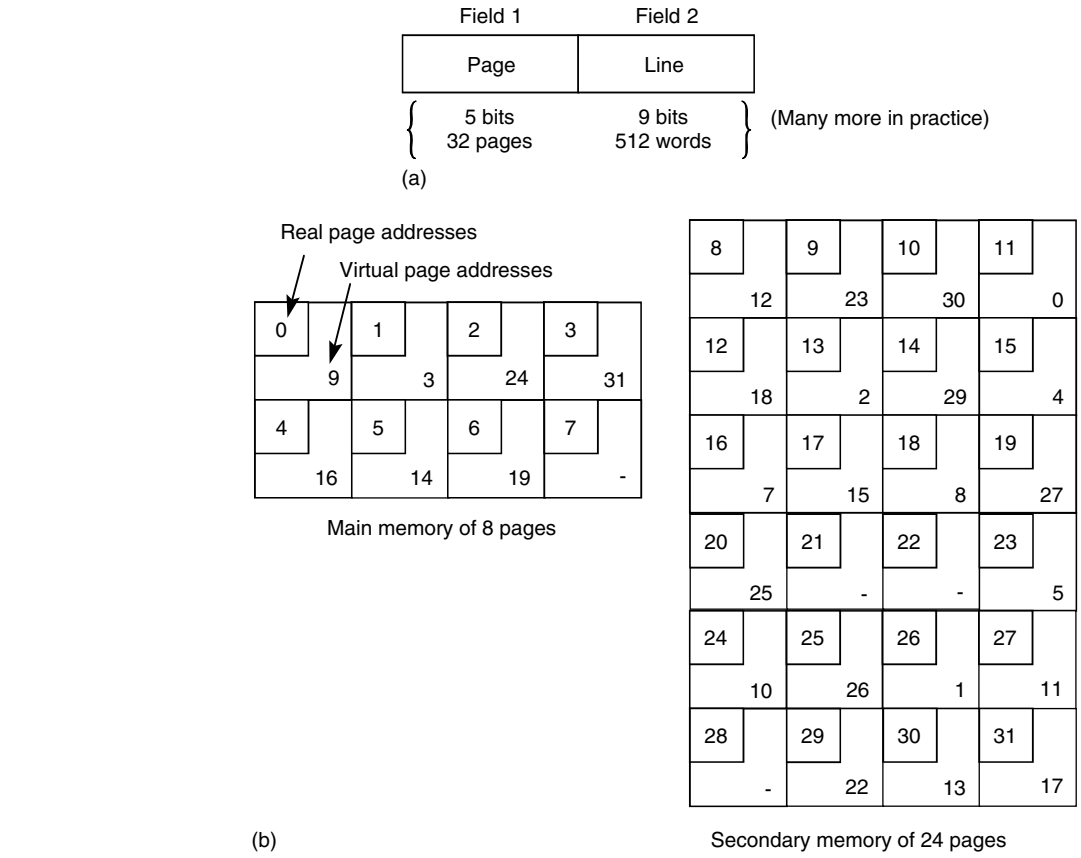

Figure 1. Memory management: (a) the two-field address structure and (b) translation of virtual to real page number.

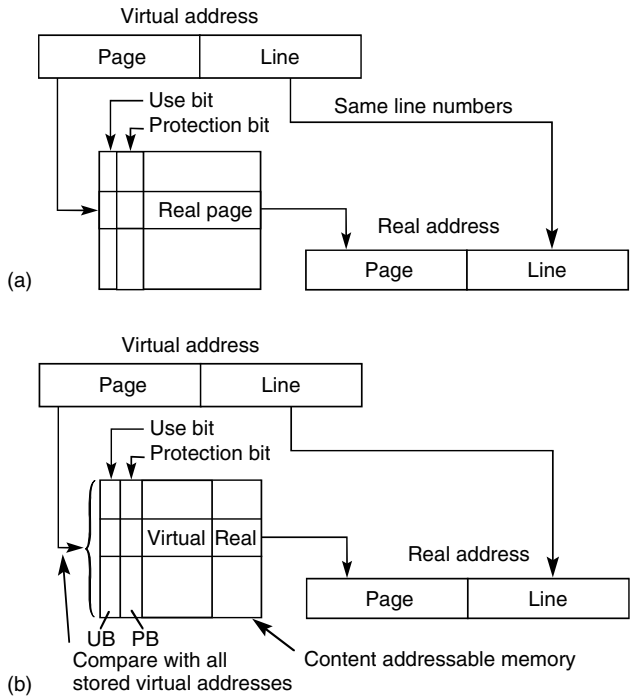

Figure 2. Address translation methods: (a) the direct mapping method and (b) the associative mapping method.

the real page addresses are stored in high speed RAM whose addresses correspond to the virtual page addresses and whose contents provide the real page addresses. The line numbers are the same in both the real and virtual page. Associative mapping uses a content addressable memory, or CAM, as shown in Figure 2(b). Here, a location is identified by its contents. The input data word is applied to the inputs of the CAM, which simultaneously compares data in all memory locations. The location containing the data is flagged as output. This memory, which uses bipolar technology, is fast, with access times of typically 30 ns. However, it is expensive. It is linked to a RAM, which contains the real addresses. Thus, the processor sends the virtual address; it is compared with all others, and if a match is found, the real address is accessed from the RAM.

3 REPLACEMENT ALGORITHMS

The transfer of data between primary and secondary memories can be achieved using a number of software algorithms. In random replacement, pages to be replaced in primary memory are chosen at random. This is not very good, since most programs access locations in proximity to each other.

First-in-first-out-replacement (FIFO) is an effective strategy for replacement. The incoming page replaces the page that is resident longest in memory. A rotating pointer identifies the real page in primary memory on a list where replacement has to take place. If a page fault occurs, which means the page is not in primary memory, the virtual page address at the pointer location is replaced by the new virtual page address. The counter is then incremented to the next location. Note that in a direct mapping scheme, the contents of the new virtual page address would be loaded with the real memory address of the pointer. In an associative scheme, the new virtual page address would be stored at the location corresponding to the real memory address, in essentially the same way.

First-in-not-used-first-out-replacement is a modification of the first-in-first-out-replacement, described above. It avoids unnecessary transfers of recently used data. A use bit is included, which is set if a page is referenced after initial loading (use bit = '0'). When a page fault occurs, the use bit at the current pointer location is checked. If it is 1, the bit is reset and the pointer incremented to the next location, where the bit is again checked. If the bit is zero, the location is loaded with the virtual address. Transfer of pages between primary and secondary memory then occurs and the counter is incremented.

Least recently used replacement, or LRU replacement, makes use of a list of the virtual page addresses held in primary memory. The list is updated by shifting every existing list line down by one when each new page is inserted at the top of the list as it is brought from primary. The page at the bottom of the list is then replaced. If, however, the page accessed is already on the list, it is moved to the top of the list, its preceding pages are moved one location down, while those after remain unchanged. Note that the actual pages are not reordered in primary memory. If many pages are accessed, then implementation is difficult. In one scheme, a counter is held for each page and regularly incremented. If the page is accessed, it is reset. The page with the highest count is replaced. It is expensive in hardware. In an alternative scheme, associative memory is used to record the primary memory pages. It is used for the top 16 or 32 entries while the rest are held in the RAM. This scheme essentially implements the list.

Some general points are worth emphasizing. The use bit can be incorporated into the virtual address translation table together with protection bits; for a read-only page, retain page in primary memory. The page size is typically 512 words and is a compromise. A small page means that (a) the transfer time is short and (b) there is a large selection of different pages in primary memory. Hence, a large page table is required. The minimum page size is constrained by disk sector size. For small pages, an increased proportion of information is required for sector identification. For a large page size, transfer times are long and there is an increase in unused space at the end of each page. This is called *internal fragmentation*.

4 SEGMENTED SYSTEM

As shown in Figure 3, the memory space is divided into different sizes of blocks, or segments, at contiguous locations. This technique may be better when programs and data are generated in various sizes. Segments can overlap, with the segment address consisting of a number plus a displacement, or offset, within the segment. The offset and segment are added together to form the real address. The logical address is the virtual address and the physical address is the real address.

Translation of logical addresses uses a segment table and direct mapping, as shown in Figure 4. The segment table can include protection bits in the form of a length field

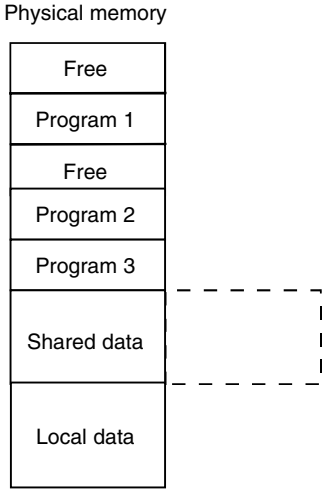

Figure 3. Division of memory into contiguous blocks.

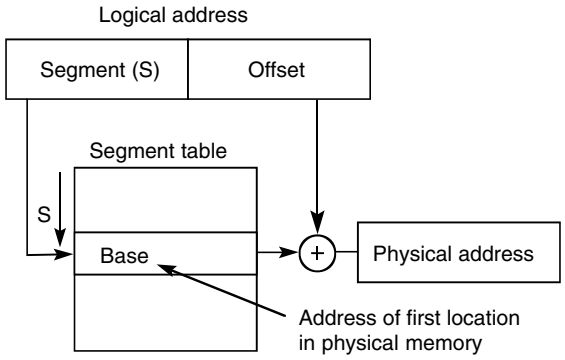

Figure 4. Addition of segment number to segment table.

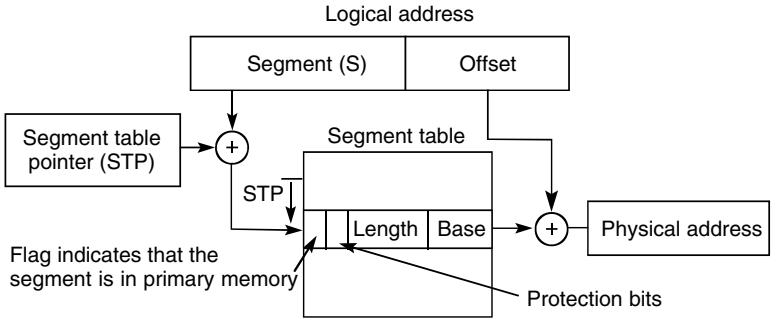

Figure 5. Translation of logical to real address.

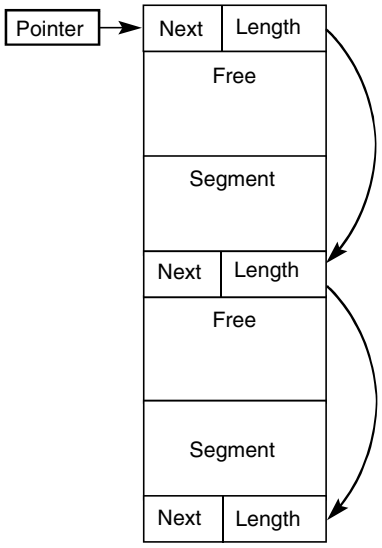

Figure 6. Implementation of the first fit algorithm.

so that referencing beyond a segment is prevented. Several segment tables can also be used.

In Figure 5, the segment number, S, is added to the segment table pointer (STP) to reach the correct address in the segment table. A flag is used to indicate that the segment is in primary memory. The offset is compared with the segment length and if the offset is greater, a segment error signal is generated. Otherwise, the segment base address is added to the offset to access the physical memory location.

Replacement algorithms, although similar to the pages system, must take account of the varying segment lengths. Care must also be taken to prevent external fragmentation by leaving a lot of unusable spaces.

For the first fit algorithm, a word that points to the next free space in memory and the length of the current space, as shown in Figure 6, is stored at the beginning of each free space in memory. A pointer, P, points to the first free space. If a replacement is required, the next/length word is read. If the length is greater than the segment to be inserted, transfer takes place with the next/length word inserted at the end. Meantime, the length is changed to indicate the remaining space. The next in the word of the previous free space is changed to point to the new next. If the length is less than the new segment, the space is ignored and the next space is checked until one of sufficient length is found. To prevent external fragmentation, a minimum residual free space can be specified.

1 SINGLE THREAD SYSTEMS

In many systems, where only one processor is used for program execution, there is only one program counter. Presently, there is a tendency to include coprocessors in dense program execution systems. When this is the case, the program execution time, T_{prog}, is then

$$T_{\text{prog}} = T_{\text{c}} \times \sum_{\text{i}=1}^{N} I_{\text{i}} \overline{C_{\text{i}}} \tag{1}$$

where T_{prog} is the program time, T_{c} is the cycle time, which depends on the architecture, I_{i} is the number of times instruction i is executed, which depends on both the program and the architecture, and $\overline{C_{\text{i}}}$ is the number of cycles or instructions, which depends upon the architecture. All of the variables determining T_{prog} depend upon the architecture of the system used while the indexing also depends upon the program.

Acceleration may be achieved at the manufacturing or realization level of the processors. The most commonly used manufacturing technique is the Very Large Scale Integration, or VLSI, process. For example, the Intel 80386 IC operating at 16 MHz has 275 000 transistors (100 mm^2), the MC68030 integrates an MC68020 CPU with an MC68851 MMU.

It is also possible to implement acceleration techniques at the system implementation level. The various elements involved in data manipulations together with their typical access times and capacities are shown in Figure 1. A number of terms should be explained first. Latency is the total time between the start of an operation and the availability of a result. The bandwidth is the number of operations per second, expressed as say 40 Mbytes/s over a bus or 2 MFlops/s for floating-point operations. The time taken to respond to a memory request is called the *memory latency time*.

Caches improve memory latency provided they are high-speed (∼50 ns). *Memory bandwidth* is also important. For example, a memory produces one byte in 100 ns and 8 bytes in 800 ns. Another produces the first 2 bytes in 200 ns and thereafter 2 bytes in 50 ns giving a total for the 8 bytes of 350 ns. Which is better? This introduces the concept of pipelining, or interleaving memory paths. Parallelism where wide data paths or multiple paths are used, is also important. Execution Latency is the delay associated with arithmetic operations. Having other processing units such as multipliers and coprocessors can solve this problem. Execution bandwidth is again effected by pipelining and

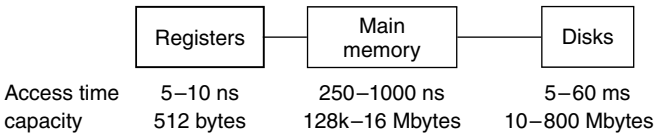

Figure 1. Illustration of memory latency for registers, main memory, and disks.

parallelism. Pipelining ensures that independent operations and instructions are processed simultaneously. This means that execution of the next instruction should start before the first has finished. For example, adding two floating-point numbers should be executed in the manner illustrated in Figure 2.

2 ACCELERATION OF MAIN MEMORY AT THE ARCHITECTURAL LEVEL

This is illustrated in Figure 3. It is based upon using special purpose processors for signal processing where the ALU and multiplier are on a single chip. Another approach used reduces the hardware complexity by using reduced instruction set computers, or RISC, so that the numbers of unique instructions, addressing modes, and data types are lower. Eliminate large microprogrammed controllers. Migrate complex functions to the compiler and away from execution time. It is possible to accelerate main memory using

- multiple memory paths,
- interleaving partitions,
  - low-level interleaving,
  - high-level interleaving.

Multiple memory paths use the Harvard architecture of Figure 3(a) instead of the von Neumann architecture, where instructions and data are mixed and share a common memory. The Harvard uses two memory paths, one for instructions and the other for data. It is usually implemented internally with data and instruction caches, while externally it appears as a von Neumann machine.

Memory may be divided into multiple physically independent modules, as shown in Figure 3(b) and (c). Memory interleaving partitions are then utilized with either low-order interleaving, illustrated in Figure 3(b), or high-order

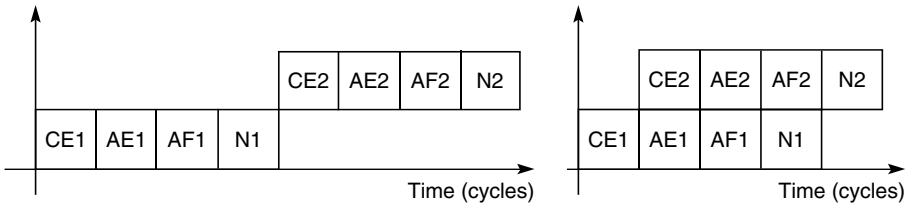

Figure 2. Principles of execution latency.

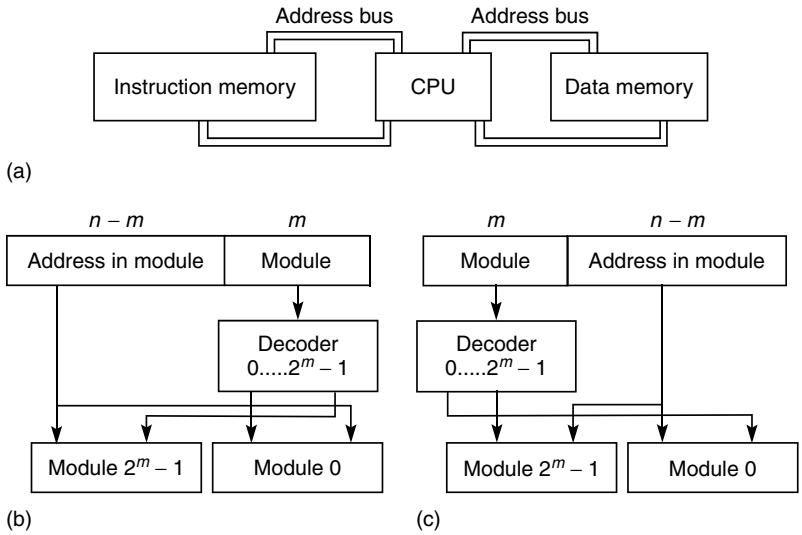

Figure 3. Acceleration of main memory using accelerating structures at the architectural level: (a) multiple memory paths, (b) low-order interleaving, and (c) high-order interleaving memory.

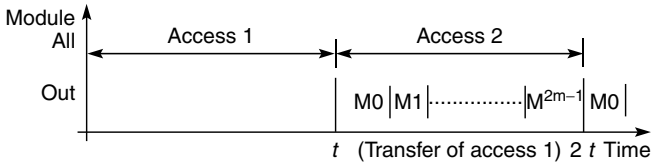

Figure 4. Speeding up memory access.

interleaving, illustrated in Figure 3(c). Low-order interleaving puts consecutive addresses in consecutive modules. It supports spatial locality and is good for vector elements and successive instructions. However, the failure of a module is catastrophic. In high-order interleaving, the data is in one module. In this method, shown in Figure 4, the address space is split into M contiguous parts. It does not support spatial locality since all are successive, easy to expand, and have fault tolerance. Low order is preferred in memories such as caches because it has spatial locality.

To speed up memory access, all the modules have to process memory requests simultaneously as in Figure 4. For low-order interleaving, simultaneous access is possible. High-order $n - m$ bits are sent to the modules at the same time with buffering of the output from each module. The low-order bits activate a multiplexer to select each module output in turn with the second memory access overlapping with the multiplexer accesses.

If all M words are accessed, memory access time is divided by M, the total number of modules. For nonsequential access to different modules, this scheme breaks down.

Concurrent Access overcomes the low efficiency of nonsequential access by offering to each module different high-order addresses, which are processed at the same time. Buffers now hold the memory addresses for each module allowing each to operate independently. A maximum speedup of M is again possible and the modules can be accessed at random. However, a memory control unit is required.

3 CACHE MEMORY

These are high-speed buffers between the main memory and the processor memory. Their success depends on locality. If the entire working set of a process can be placed into the cache, a substantial increase in performance can be achieved.

Purposes of Cache Memory are now discussed. There is usually a mismatch in the speed between transfers in primary and secondary memories, the latter being much slower. There is also a speed mismatch between primary memory access and processor operation times because the processor can operate faster. Having a cache of high-speed

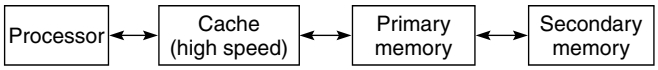

Figure 5. Structural principle of cache memory.

bipolar memory resident between the primary memory and the processor as shown in Figure 5 can reduce this problem.

The cache of limited capacity (512 words), which contains the current processor instructions and data, is updated as required, by reading from the primary memory. Outputs from the processor, which are then copied to the primary memory, can also update the cache. The cache works because the principle of locality applies, that is, instructions, and to a lesser extent data, are accessed locally to each other, and program loops are common. Thus, there are many cache references to each primary reference. If the first reference is obtained from primary memory and transferred to cache in time M s, and there then follows n references by the processor to cache in access time m s, the average access time, T_a, is

$$T_a = \frac{(M + n \times m)}{n} \tag{2}$$

Note the assumption that the output from primary goes to cache first before being accessed by the processor. In practice, output could go to both. Also, note that write operations to cache must be copied to primary memory at some stage. This will slow average transfer times.

For $M = 400\,\text{ns}$, $m = 50\,\text{ns}$ and

$n = 10$, then $T_a = 90\,\text{ns}$ rather than 400 ns.

To match the speed of data transfer to the cache, the primary memory is interleaved so that a number of words are accessed concurrently. The memory is divided into a number of modules, usually a power of 2, and the primary addresses are numbered across the module as shown in Figure 6. The number of modules is chosen to match the

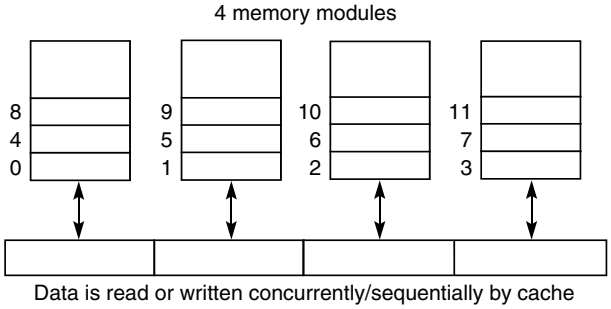

Figure 6. Numbering of primary addresses across the memory modules.

cache to which each word is transferred sequentially. Thus, for the example above, 8 memory blocks would be required having an access time per word to cache of $M = 50$ ns. For $n = 10$ the average access time, T_a, is now equal to 55 ns.

An important parameter in cache operations is the probability that the required word is in cache and is of the order of 0.8. A *hit* occurs when a cache location contains the required data, otherwise a miss results. The hit ratio, h, is

$$h = \frac{\text{the number of times the required word is found in cache}}{\text{the total number of references}} = \frac{\text{the number of hits}}{\text{the total number of references}} \quad (3)$$

Example A cache operates with a hit ratio of 0.85. Using the memory parameters as before with $M = 400$ ns and $m = 50$ ns, calculate the access time, T_a. Assume that the cache is loaded before the processor is accessed.

Solution:

$$T_a = \frac{(15 \times 400 + 15 \times 50 + 85 \times 50)}{100} = 100 \text{ ns} \quad (4)$$

4 OPERATION OF THE CACHE

A TAG is a memory address. Each entry in cache consists of a line of data, which can be several memory words, as represented in Figure 7. For an M-way interleaved memory, a cache line can be M words or $2M$ words or $4M$ words. TAGS are matched in the address field. If a hit, then select byte in line and update line status, which reflects reference, for example, write. If a miss, send the real address to main memory. During read from main memory, the cache selects a line in cache to be replaced. For virtual memory, a memory management unit, or MMU, is needed for address translation for cache and memory access.

The translation can be performed serially as shown in Figure 8(a). The alternative is to do it in parallel, as in Figure 8(b). This is called D-displacement. An extra field

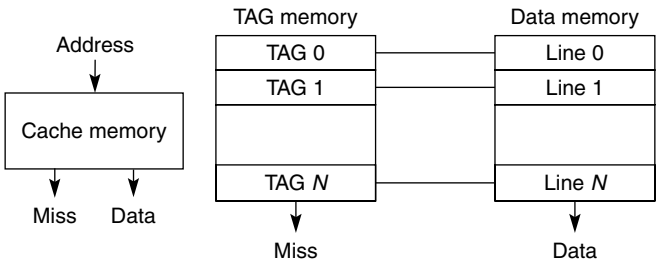

Figure 7. Cache memory TAG principles of cache operation.

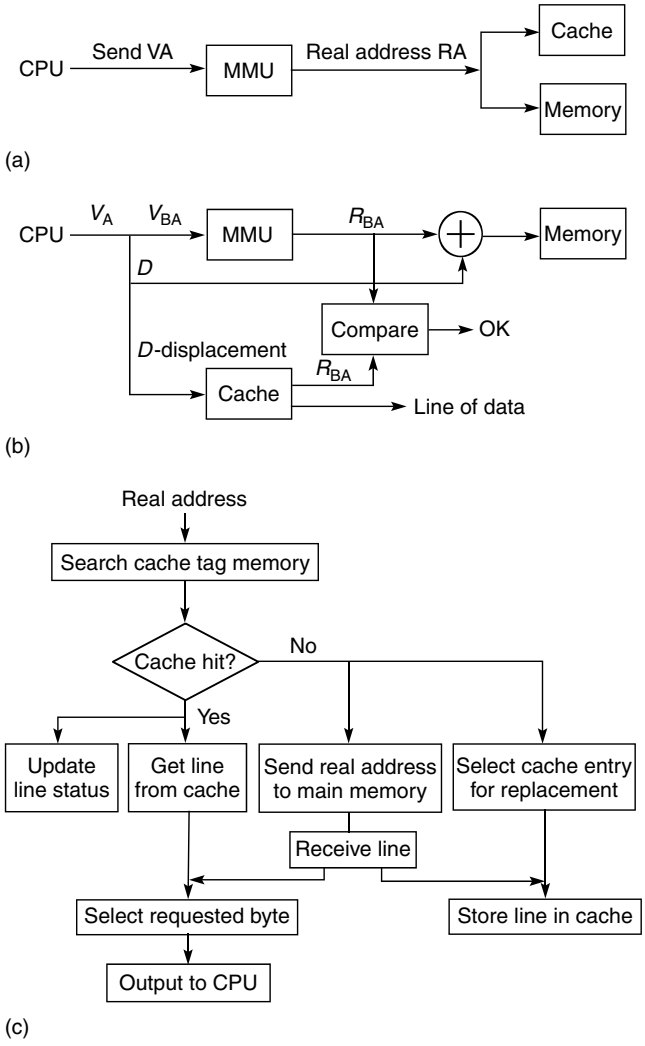

Figure 8. Operation of the cache: (a) serial, (b) parallel, and (c) typical flow of instructions.

is needed to hold R_{BA}. These assume that the cache is in the real address space, which is the most common.

The flow diagram for cache operation is given in Figure 8(c). When the real address is specified, the cache TAG memory is searched. If there is a hit, the line status is updated and the line is fetched from the cache. Subsequently, the operation, which is straightforward, selects the requested bytes and sends them to the CPU. If there is a cache miss, the real address is sent to main memory and the cache entry is selected for replacement. The main memory receives the real address, the receive line is activated and the line is stored in cache, and the requested bytes are selected.

In cache design, two hit ratios are of interest. The cold-start hit ratio applies to an initially empty cache, while the warm-start hit ratio applies when a process already has data in the cache.

Line size and cache size are the two most important factors regarding hit ratio. Long lines improve the spatial locality but it takes time to move them. For microprocessors, typical sizes are 16 to 64 bytes. A large number of lines improves the temporal locality up to a point. When greater than the working set, this will not result in a decrease in the miss ratio.

5 MEMORY FETCH POLICIES

There are various strategies in determining what lines should be fetched from main memory and loaded into the cache. Demand fetching fetches the line when it is needed. This is always implemented to some degree, but a measure of prefetching can improve matters. Prefetching tries to fetch lines, which are going to be needed in the near future. In high-speed caches, it is the line immediately following the fetched line i, that is, line $i + l$. Hence, fetch line 1 and prefetch line $i + l$. There are a number of policies that can be implemented. One is always prefetch, which tries to prefetch a line whenever line i is referenced. This increases memory traffic by about 80%. An alternative is to prefetch-on-a-miss, that is, when a cache miss occurs, line i is fetched and line $i + l$ is prefetched. Another more common method is tagged-prefetch, which prefetches on a miss and on the first reference to a prefetched line. This increases memory traffic up by 10 to 20% for the same miss ratio as always prefetch.

6 CACHE MAPPING SCHEMES – PLACEMENT POLICIES

Cache is smaller than main memory, so that a few lines map into each cache line. It is necessary to decide where to put data lines in the cache. Primary memory is hardware mapped into the cache by three main ways.

7 CACHE MAPPING SCHEMES – DIRECT MAPPING

Direct mapping is shown in Figure 9(a). A TAG field in the processor address is used to identify a page in primary memory, while an INDEX field finds the word within the page. Thus, words with different tags (pages) but the same index will share the same location in cache. To see if a word is in cache, the tags are compared. If the tags are the same, the word is read, otherwise the word is accessed from primary memory. For interleaved memories, a block of words can be transferred to cache as shown in Figure 9(b). Note that common blocks in different pages occupy the same cache locations. Take as an example a main memory

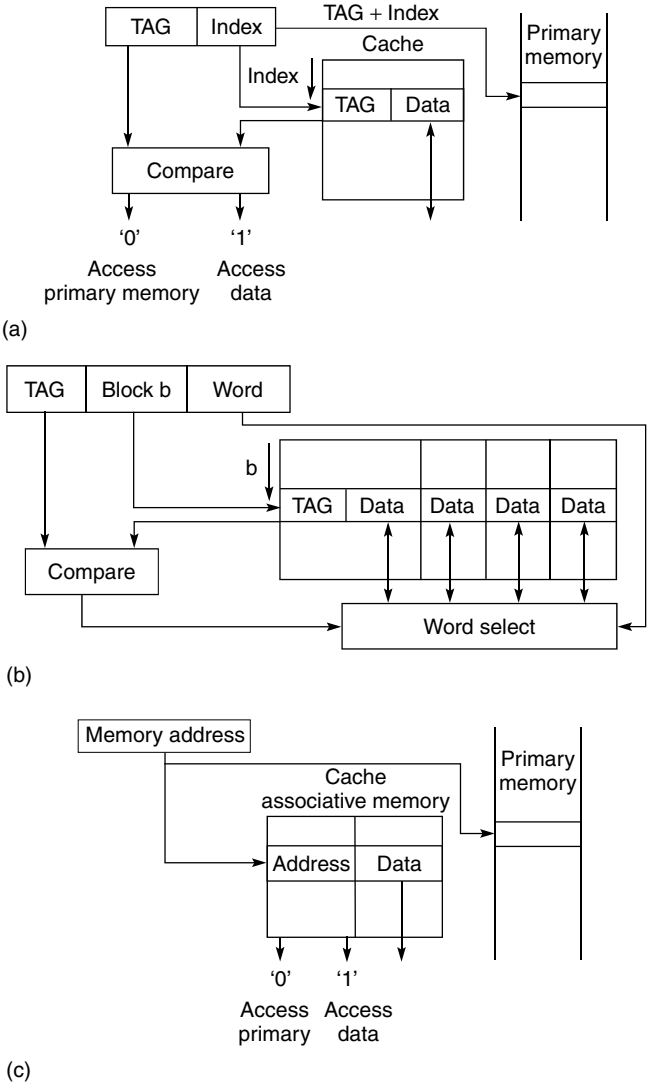

Figure 9. Mapping schemes for cache memory: (a) direct type for noninterleaved, (b) interleaved, and (c) associative type.

consisting of 1 MB with a 20-bit address, and a 16 kB cache with 16 bytes per line. Thus, there are 64 klines in main memory and 1024 lines in the cache. In direct mapping, line i is placed in line (i modulo 1024) in the cache. The advantage of this method is that associative comparison is not needed and the replacement of lines is trivial. However, the cache can only contain one of the 64, or 26, lines that map into each cache line one at a time.

8 CACHE MAPPING SCHEMES – ASSOCIATIVE AND SET-ASSOCIATIVE MAPPING

Associative mapping, shown in Figure 9(c), uses a content addressable memory, or CAM, to compare the incoming

address with all the cache addresses simultaneously. If the address is present, the data is read, otherwise it is accessed to the cache from primary memory and overwrites data. This scheme is expensive since words are stored in the CAM. An alternative is to store a block so that the block address is compared associatively reducing storage requirements. In both cases, during block or word replacement, the existing block or word must be chosen either on a random first-in-first-out or least recently used basis.

Fully associative cache is used when any line can reside at any location and is found by comparing the tag contained in the address field with the tags held in the cache. It has the highest hit ratio but may be slower due to the comparator hardware required for the matching. It is expensive to implement, but this could change with developments in VLSI.

Set-associative mapping, as illustrated in Figure 10, allows a block of data with the same index but different tags to be stored. It combines the advantages of direct mapping with fully associative placement. To find the required word, the tags are compared associatively and the required word is found. The cache is partitioned into a number of sets, S, containing a number of lines, L. The sets are directly mapped while the lines in each set are associatively mapped. Thus, for example, given that the number of lines per set is chosen to be $L = 4$, then the number of sets $S = M/L = 256$, where M is the number of lines in main memory. To find a line, the middle 8 bits of the address are used to find the set of line i such that it is placed in set (i modulo S) or (i modulo 256). The 8-bit tags within each set are then associatively mapped. Note that each set can contain any one of 256 lines. However, since each set has 4 lines, then 4 out of these 256 can be stored at the same time. This is better than direct mapping. Since the associative search is only over L elements, rather than M, it is much less costly than a full-associative cache. Note also that for $S = l$, the cache is fully associative, while for $L = l$ (one line per set) the cache is directly mapped.

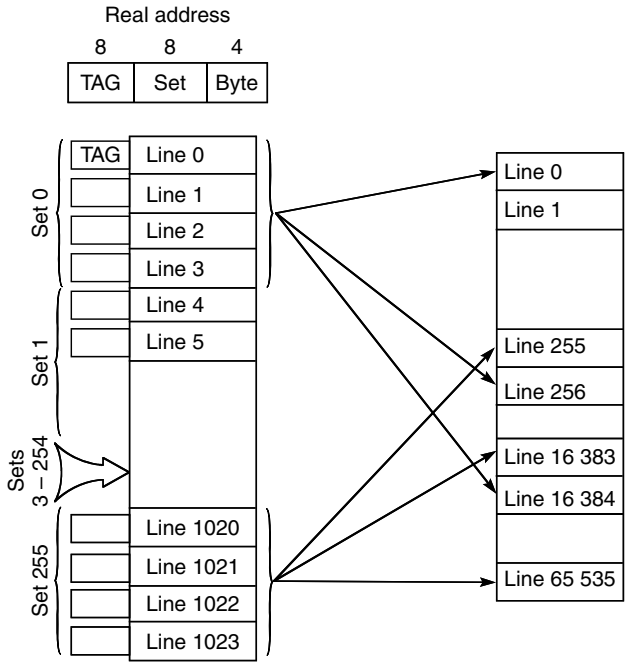

Figure 10. Cache mapping using the set-associative method.

9 CACHE MAPPING SCHEMES – REPLACEMENT POLICIES AND MEMORY UPDATE

Replacement policies: When a cache miss occurs and the cache is full, the question of which line to replace arises. This requires a cache replacement policy. The same techniques that were used for management of the main memory can be applied. However, since usage of the cache operates at maximum speed, such techniques must be implemented in hardware. Also, for simplicity, fixed sized partitions are used with each process occupying either the whole or a fixed area of cache. There are two approaches. One is based on the usage of line and the other ignoring the usage. LRU takes account of when the line was last referenced and has the highest hit ratio but is costly to implement. Random and FIFO policies are two nonusage based methods. Statistics show that the influence of placement is greater than that of replacement. For direct mapping, replacement is trivial. For a fully associative cache, replacement is difficult.

Main memory update: If data in cache is replaced by a write operation, information will be lost if the line has been modified and not updated in the main memory. It is necessary to ensure that any data written to cache is also written to main memory so that I/O operations such as DMA can operate on primary memory. There are two commonly used update policies.

Write-through: In this approach to memory update, every write operation from the processor always transmits changes to the cache and main memory. Although this takes time, there are usually some reads to cache. Hence, writes to primary memory can take place while the cache reads take place. This method is good for multiprocessor systems with multiple caches.

Copy-back also called write-back: There are three versions of this method. In the first two, a cache line is only transmitted to main memory if it is to be replaced in the cache. In always-copy-back, no account is taken of whether the line has been modified. In flagged-copy-back, a line is

copied only when it has been modified as indicated by a 'dirty flag'. This policy means that the main memory can contain 'stale' data, which will be lost if there is a processor or cache failure. The third method of writing to cache is known as *write-back*. Here, updating occurs during block replacement time. A tag bit indicates when a block has been updated. If a block has to be transferred into an existing block location, the old block is checked to see if it has been changed. If so, it is transferred to the primary memory.

Optimization of the cache is an important design consideration. Factors to be taken into account are hit ratio, access time on a hit, and delay time on a miss. A large cache gives a low miss ratio but a high cost. Note that if there is a write-miss, with the write-through policy, it is not specified whether the line is copied to cache. On copy-back the written line is usually copied to the cache on a write-miss.

1 SINGLE CHIP MICROPROCESSORS

A typical single chip microprocessor has the architecture given in Figure 1. The instruction set is based on the standard 6800 instructions with additional functions. The central processing unit CPU has seven registers available to the programmer as shown in Figure 1. The two 8-bit accumulators, A and B, can be used by some instructions as a single 16-bit accumulator called the *D register*, which allows a set of 16-bit operations even though the CPU is technically an 8-bit processor.

Two index registers are available that may be used along with register D to perform fast 16-bit arithmetic operations. Two 16-bit by 16-bit divide instructions are also included.

2 MICROPROCESSOR-BASED DATA ACQUISITION

Microprocessors and microcontrollers form the heart of all modern acquisition systems. The microprocessor, which generally performs control, data handling, and data processing functions, requires external peripherals. Interfacing to these peripherals is achieved using a bus oriented connection consisting of a control bus, an address bus, and a data bus as shown in Figure 2. The external peripheral ICs (integrated circuits) handle input–output, I/O, operations, communications using Asynchronous Communications Interface Adapter, or ACIA, and external memory of both the read-only memory, or ROM, and random-access memory, or RAM, types.

The microcontroller unit, or MCU, which combines all these functions into one IC, thus simplifies the system design. This reduces costs and board space. A typical block diagram for an MCU is shown in Figure 3. The MCU example given in the figure, which is the Motorola 68HC11A8, is one version of the very popular 68HC family of microcontrollers. This controller, which is manufactured using the high density complementary metal oxide semiconductor, or HCMOS, IC technology, is an advanced 8-bit MCU with sophisticated on chip peripheral capabilities. Although the nominal bus speed is 2 MHz, it may operate at ultralow frequencies for reduced power applications. Note that the central subsystem is still a microprocessor.

The MCU I/O capability is grouped into ports. A port may be configured as a general I/O, similar to the VIA, or may have a specific function, such as serial communications, analog to digital converter, or ADC, input. Ports B and C may operate in single chip mode, where the MCU application requires no additional external memory, or in expanded mode, where external memory may be added. The latter requires the definition of an address bus, by combining ports B and C, and a data bus. Note that the data bus is multiplexed with low byte address lines to reduce the number of IC pins. The versatility of this configuration allows the device to interface, or be configured, to suit many applications.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

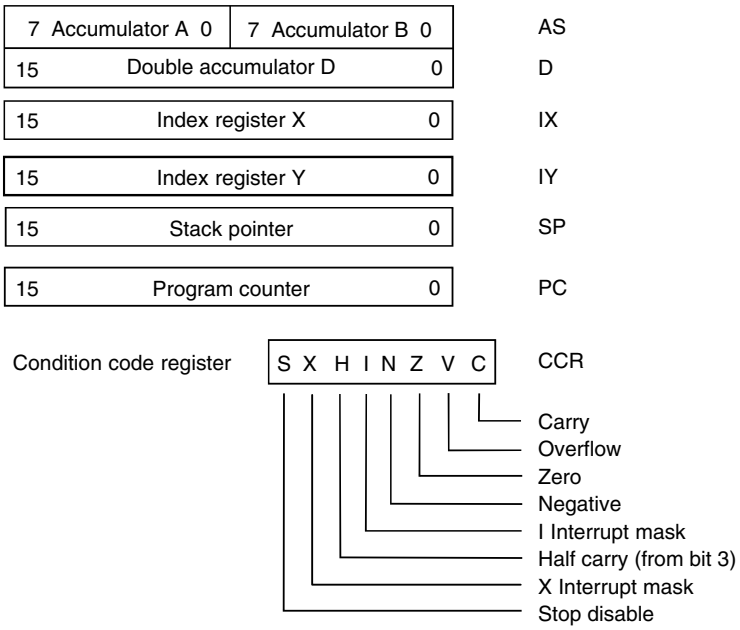

Figure 1. The programming registers in a microprocessor or microcontroller.

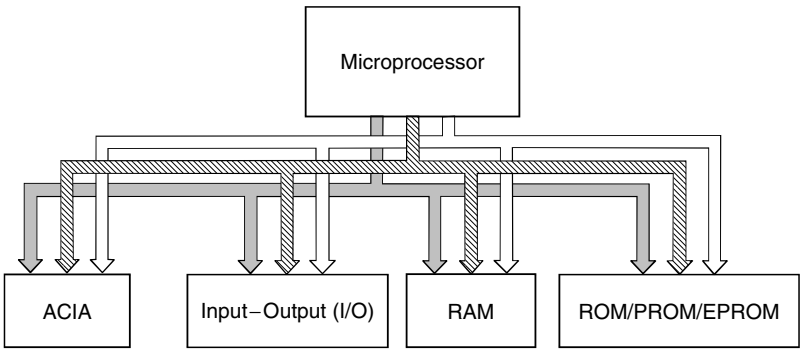

Figure 2. A microprocessor controlled data acquisition system.

The MCU also includes a 16-bit free running timer with three input capture lines, five output-compare lines, and a real time interrupt function. An 8-bit pulse accumulator subsystem can also count external events or measure external periods.

The version shown here also has an onboard 8-channel analog multiplexor, or MUX, feeding an 8-bit ADC. This allows up to eight individual analog sensors to be monitored by one MCU. Conversion is initiated under software control.

The device also includes an asynchronous serial communications interface, or SCI, and a separate synchronous serial peripheral interface, or SPI. Adding suitable line drivers allows a communication capability directly from the MCU for RS 232/RS 422, which are described in **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**. The SCI generates standard communication formats with 1 start bit, 8 or 9 data bits, and a stop bit, as previously illustrated in **Article 155, External Operation of the Microprocessor, Volume 3**. An on chip baud rate generator derives standard baud rate frequencies from the MCU oscillator. The SCI system can be used to connect a CRT or personal computer to the MCU. Alternatively, several widely distributed MCUs can use their SCI subsystems to form a serial communication network. This clearly allows remote data processing/information extraction as well as local data capture.

Self-monitoring circuitry is included on chip to protect against system errors. A computer operating properly watchdog system, or COP, protects against software failures. A clock monitor system generates a system reset in case the clock is lost or runs too slow. An illegal op-code detection circuit provides a nonmaskable interrupt if an illegal op-code is detected.

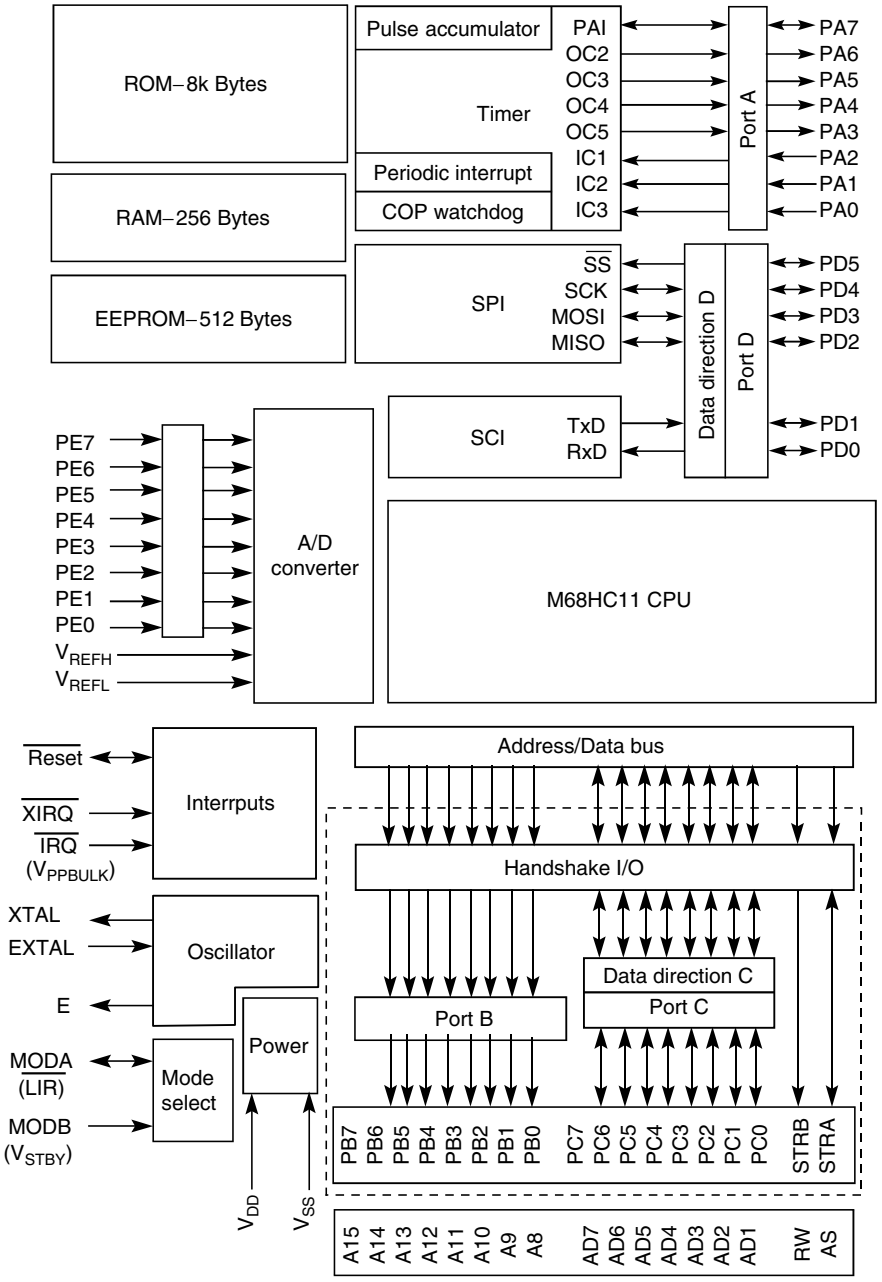

Figure 3. The Motorola 68HC11A8 microcontroller.

Two software controlled power saving modes of operation, WAIT and STOP, are available to conserve power. These modes make the 68HC11 family especially attractive for automotive and battery driven applications.

3 INTRODUCTION TO SPECIAL PURPOSE DIGITAL PROCESSORS

Digital systems of increasing complexity are playing a vital role in the processing of information. The reasons for this are as follows:

1. digital systems are less prone to error;
2. numerical accuracy depends on the number of variables, or bits, used;
3. information can be both numerical and nonnumerical;
4. a structured approach can be used by breaking the main task into a series of subtasks;
5. a general purpose system (computer) can be specified, which can be programmed for a particular task; and
6. VLSI technology has made the realization of complex systems cost-effective.

From an engineering point of view, the description and design of digital systems require the development of suitable models. For simple digital sequential networks, a systems model based on the state description of the system can be used with its concepts of output function and state transition function. For other systems, performing complex computations, an algorithmic model, which breaks down a complex digital computation into a sequence of primitive computations, becomes attractive. The algorithms themselves can be fixed by the hardware, or if storage is available they can be changed by programming. Such algorithmic models can be used for the specification, simulation, and implementation of complex digital systems.

The algorithmic model can be used at several levels of the system depending on the nature of the primitive computations. These range from (a) the hardware level, where logical operations are implemented by hardwiring networks of switching components; (b) the firmware level, where primitive computations involving hardware-like logical operations are implemented as microprograms; and (c) the software level, where language statements are executed in the computer.

A typical computer system consisting of memory, control, and processing elements has already been described in **Article 152, Fundamentals of the Stored Program Digital Computer, Volume 3**. The *data*, *control*, *processing*, *and I/O* structures of this system are all important. Arithmetic processing elements in the form of bit-slice components will be now introduced.

4 BIT-SLICE DEVICES AND ELEMENTS

Large scale integration, or LSI, of digital logic functions has led to higher switching speeds, due to shorter lead lengths, and higher reliability due to minimization of the number of interconnections. From an economic point of view, large scale use of a device is desirable (cf application specific integrated circuits or ASICs). This has led to microprocessors/computers on a chip and special purpose bit-slice elements, which are the building blocks of computer systems.

Bit-slice elements are fixed width computer hardware elements that range over 4, 8, 16, and 32 bits. A bit slice forms the basis of large computer systems, since they can be paralleled up. For speed, they are implemented in Bipolar Technology, which includes ECL, LSTTL, and ASTTL. Examples are 74LS481, MC10800, (ECL), and AMD 2901 (LSTTL). They can also be used for other applications such as signal processing. To be realized as a digital system, they require control logic. The use of bit slices allows partitioning of the system into a set of LSI building blocks of fixed words of width 4, 8, and so on to implement words in vertical slices of 8, 16, 32, and so on. This approach provides a reduction in the pin-out of the chip, a realization in LSI or VLSI, and a universal building block.

Bit-slice elements give the advantages of flexibility and speed when designing large systems with high performance. The trend has been to introduce higher levels of integration into bipolar families so that word length increases to 8, 16, and 32 bits. In the latter case, the ASS832 from TI (Texas Instruments) uses Advanced Schottky technology to obtain a 75-ns instruction execution. The structure of bit-slice elements may be organized to allow operation in either serial or parallel modes as in Figure 4. The serial modes are very similar to the conventional Von Neumann architecture. In the parallel units, many of the acceleration mechanisms already described in **Article 157, Data Acceleration in Computers, Volume 3** are used.

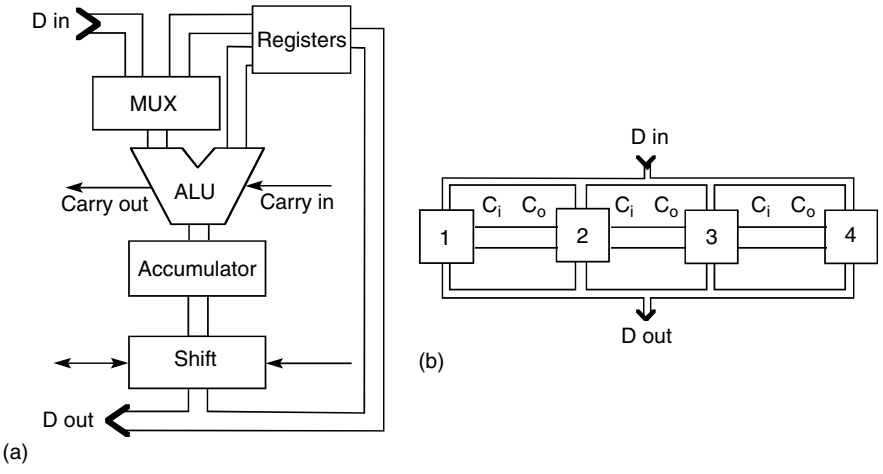

Figure 4. Architecture for typical bit-slice processors: (a) serial and (b) parallel.

A comparison with microprocessors is appropriate. In the first place, microprocessors are not bit-slice devices. They are LSI stored program computers, whose hardware consists of registers, ALU (arithmetic logic unit) and control unit, with fixed instruction sets. Since microprocessors are made in MOS and CMOS technology, they are generally slower than bit-slice elements, which are fabricated in bipolar technology.

5 THE FIRST BIT-SLICE PROCESSOR AMD 2901

Although this was one of the first *slices*, it is an important one since its general structure, which is shown in Figure 5, established the architectural structure of future devices. It was used in the DEC system 2020 and Data General Nova 4. It is a 40-pin LSI chip implemented in LSTTL with 500 gates. It has a 4-bit wide slice and an 18-word RAM. Any two of its registers are selectable on A and B data busses by a 4-bit control input. Note that the A register is read only, while the B register is read and write. Its ALU, which has three arithmetic and five logical instructions, R and S, has inputs for connection to R-A reg., D bus (external, 0 *S*-A reg, B reg, Q reg, 0).

The Q reg, which is designed for multiplication on the basis of shift and add, can be fed from the ALU or from itself with a shift up or down. It can shift the ALU output before loading into B reg. The ALU output can go to the external Y Bus, Q reg., or the Register Array with a shift, and can also output A reg contents to theY bus.

There are nine control lines for controlling (a) ALU Function (b) ALU Source Data (c) ALU Destination. Other control lines allow Y bus data enable ALU carry-in, ALU carry-out, and carry look ahead signals.

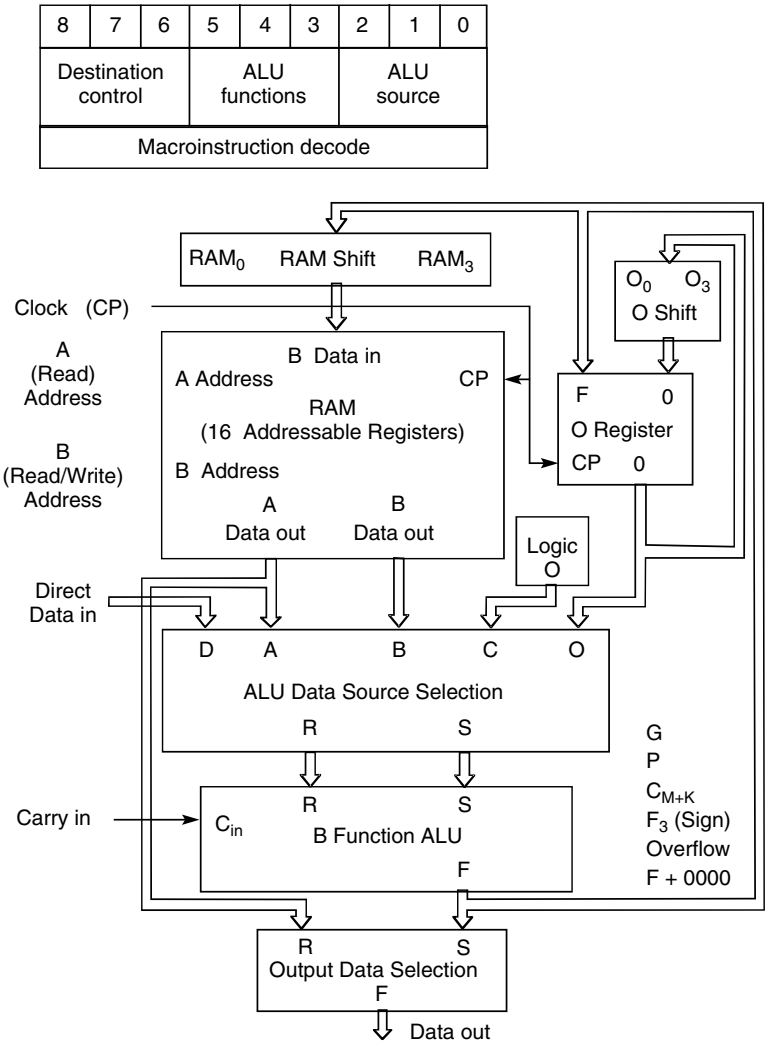

Figure 5. Functional block diagram of the AMD 2901.

The operation of the slice occurs within one cycle of the clock, which is sometimes referred to as a *microcycle*. Hence, data is taken from the RAM, the ALU operates on the data, which is then shifted and reloaded into the RAM registers: all within one microcycle. Different edges of the clock are used to prevent race hazards. Thus, the slice can be considered as a 'micromachine' that changes state every microcycle.

1 SOFTWARE DEVELOPMENT LIFE CYCLES

There are a number of software development life cycles (SDLC) or methodologies, which apply to both the functional and object-oriented approaches. The major ones used are the Waterfall, Spiral, Rapid Prototyping, and Cataract forms. These are little different to those used, in general, in the engineering of systems and they have been the basis of many of those developed; *see also* **Article 63, Outline of Systems Thinking, Volume 2**; **Article 64, Executing A Measuring System Design, Volume 2**; **Article 65, Life Cycle Concept, Volume 2**; and **Article 66, Phases of System Life Cycle, Volume 2**.

All of the forms of life cycle follow the following basic steps:

- Determine what has to be produced – this is generally the time in which the need is identified and the requirements written.
- Produce it – the design and implementation phase. This might also include developing prototypes and concept demonstration models.
- Test it – the test and evaluation step is to determine that the software meets its requirements.
- Deploy it – field it and use it.
- Operate and maintain it – this is the time in which latent defects show up and need to be corrected. Changes may also be suggested to improve or add functionality, which would then be incorporated in later releases of the software.

The alternative life cycles used in software development are now outlined to reveal their differences.

1.1 The waterfall methodology

The basic software development life cycle is known as the *Waterfall Methodology*. It follows the basic sequence of 'requirements, design, build, test, and operate'. It is known as the Waterfall, because when drawn, the process flow across the drawing looks like a waterfall. The waterfall methodology works very well if three conditions are met:

1. requirements are known before design begins;
2. requirements do not change while the design, build, and test phases take place; which generally means the
3. time frame is relatively short.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

These conditions are generally met when developing software for specific test and evaluation situations.

However, the waterfall methodology fails miserably if any of these three conditions are not met – which is usually the case if the project has substantially new issues involved.

As a consequence, the waterfall methodology has largely fallen out of favor, being replaced in software development by some sort of spiral or rapid prototyping methodologies. What is generally not noticed is that if the spiral is stretched out in a linear manner, it forms a series of small waterfalls.

1.2 Spiral and rapid prototyping methodologies

The spiral methodology Boehm (1988) implicitly added risk and risk mitigation to the basic waterfall methodology. Other rapid prototyping methodologies focus on converging the capabilities of the product to meet the requirements of the customer at the end of the product development cycle.

1.3 The cataract methodology

The Cataract Methodology (Kasser, 2002) combines the best of several methodologies and implicitly adds configuration management to the development process. It incorporates an initial Build version, Build Zero, which contains the same initial two phases, requirements and design, of the waterfall methodology with the exception that there is recognition that

- all requirements are not finalized at the Software Requirements Review (SRR) stage;
- additional requirements will become known as the project progresses;
- design and implementation decisions will be deferred and made in a *just-in-time manner* (Davies, 1998; Kasser, 2000). These decisions must also be made so as to maximize the 'don't care' situations (Kasser, 2001).

The work in Build Zero is to

- identify the highest priority requirements;
- baseline an initial set of user needs and corresponding system requirements;
- complete the first draft of the Test and Evaluation Management Plan (TEMP);
- document the assumptions driving the need for the software;
- develop the work breakdown structure (WBS) to level the workload across the future Builds and implement the highest priority requirements in the earlier Builds (Denzler and Kasser, 1995).

Build One, and each subsequent Build phase, is a miniature waterfall process in itself, hence the use of the term 'cataracts' to designate the methodology. The requirements for each Build are first frozen at the Build SRR. Then the design effort begins. Once the design is over, the Build is implemented and the software turned over for integration with the previous Builds.

While the design team does assist with the integration, their main effort is to start to work on the design of the next Build. Once the first Build has been built and is working, the 'requirements – design – integrate – test – transition and operate' stages of the SDLC commence for the second Build.

This cycle will continue through subsequent Builds until the software is decommissioned, although the contract may change from the development organization to the maintenance organization. Each Build is an identical process but time delayed with respect to the previous one. Each successive Build provides additional capabilities.

2 DEVELOPING THE SOFTWARE REQUIREMENTS FOR A MEASURING SYSTEM

Requirements articulate the implementation of a need. In this instance, the need is to measure something over some period of time with some degree of accuracy under certain conditions.

According to Juran (1988), the ideal unit of measure has the following characteristics:

- It provides an agreed basis for decision making. Different people view things differently and have different priorities. The metric must allow a meeting of minds between all interested parties.
- It is understandable. Technical metrics are normally understandable, but metrics of management or personal effectiveness are not. This may be because words do not have standardized meanings or may require an educational background that is lacking.
- It applies broadly in use to determine whether an improvement has occurred. Percentages and ratios apply to many situations and facilitate comparisons.
- It is susceptible to uniform interpretation. The units used and types of errors must have been defined with appropriate precision.
- It is economical to apply. There is a trade-off between the cost of making the measurements and the value of having them. The cost may depend on the precision, so care must be taken to specify the correct precision.

- It is compatible with existing designs of sensors. If you cannot measure it, there is little point in defining it as a metric.

Questions to be asked and answered when developing the requirements for a needed measuring system include:

- What is to be measured (temperature, pressure, voltage, current, etc.)?
- What is the degree of accuracy needed?
- Are the resources to make the measurement available (or can they be made available when needed)?
- What is the measurement data going to be used for? There is no need to measure something if the results are not going to be used.
- How will the software be tested to verify the requirements for sensitivity and accuracy are met?

It is imperative to develop good requirements; the penalty of not doing so can be considerable extra cost and time to change the software to correct errors appearing later when they are costly to fix. It is much better to find errors early. This, however, contrasts with the fact that the many requirements for novel systems can often be found only from a journey of discovery as the project develops. More on requirements is found in **Article 3, Measures and Metrics; Their Application, Volume 1**; **Article 67, Principle of Concept of Operations (ConOps), Volume 2**; and **Article 69, Requirements Allocation, Volume 2**.

3 DOCUMENTING REQUIREMENTS

Requirements can be documented in various ways including:

- *Text mode requirements*: the traditional statement of the form 'the software shall do X in response to Y within time T'.
- *Drawings and flowcharts*: process charts, timing or waveform diagrams, and Unified Modeling Language (UML) drawings.

Requirements are a means, not an end. There is nothing divine about requirements; they are just a convenient poorly used tool for translating user needs into the software that should be built.

They are generated as an intermediate work product in the software development process and are developed to provide formal communication between the stakeholders.

Writing text-based unambiguous requirements for combinatorial and sequential scenarios in the form of imperative construct statements is difficult. Timing and state diagrams are often used within the context of the Requirements Document (RD) to provide the necessary information. Sutcliffe, Galliers and Minocha (1999) proposed reducing human error in generating requirements by analyzing them using an approach of creating scenarios as threads of behavior through a *use case* and by adopting an object-oriented approach.

There is no single best way to document requirements. Requirements are a tool. In this instance, they are used to communicate the need to the developers and testers. Whatever format best acts as the communications medium is the 'right' way to use requirements.

Dedicated requirements extraction and management software tools are available, their use being, because they are costly and take considerable time and resources to deploy, more for the larger-size projects where requirements can number in the thousands and thus need a sound entry, modeling, recording, and tracking system in order to allow many people to work on them simultaneously.

4 CODE DEVELOPMENT

The IEEE 12207 Standard for code development describes the process for developing software. The process employed should be a tailored version of the standard appropriate to the size of the project developing the software. In general, the larger the project, the more people there will be working on it, bringing a greater need for the degree of formality applied. This work systematically converts the requirements into appropriate software computer code using whatever computer language(s) that has been selected for the project.

Selection of which language to adopt will usually be decided by the

- code already used in the project
- experience of the contractor doing the work
- dictates of the customer
- appropriateness of the language for the task at hand
- maintenance issues
- flexibility to interface to other software suites.

Efficient code building needs availability of suitable development tools for code generation from higher-level languages, with debugging tools and documentation aids all running on appropriate development-computing machines.

Experienced coders may appear to be overly expensive but are usually the most economic way to go as their speed and accuracy of development will be better than what can be obtained by the less experienced. The error rate will be lower with the consequence that the regression effort will be reduced as less repairs are needed.

5 REVIEWS

A key issue that brings control to code development is the 'work done' review process, for it flushes out potential problems at a time when they are cheap to fix.

According to Kasser (1998), reviews are not held to do work on the project but they too often degenerate into that form of meeting; that is best done in other types of meetings.

A review is a meeting held to provide visibility into the state of a product or process and to formalize approval of decisions previously made. It is not a time to present surprises or controversial design changes. As such, the general rules for running and chairing effective meetings apply. For example, there should be a prepublished agenda giving the issues and order of discussion. Well-prepared documentation should be made well before the meeting.

Any phase in the SDLC can be considered as a series of activities that take place between two milestone reviews – a 'start' milestone and an 'end' milestone. For example, the software design phase takes place between the SRR and the Software Design Review (SDR). Each milestone review covers two sets of work:

- work accomplished prior to the milestone (products completed, resources consumed);
- work to be accomplished before the next milestone review (products planned, resources available).

The products produced for the 'end' milestone are tested against the

- products-planned section of the 'start' milestone – the one before the current milestone;
- specifications for the specific products.

At each milestone, look at the work done now and at what is then planned to accomplish before the next review.

Take steps to ensure the necessary information is available to the meeting and that all concerned are not holding back on tardy issues in the hope that the difficulties they currently have will clear by the next meeting. A major source of project failure is lack of finding out problems early enough.

Reviews are an integral part of the SDLC. Each review focuses on the issues related to the particular phase. There are two kinds of reviews in the SDLC – formal and informal.

These reviews contribute to effective software development because they show progress. Customers want to see results quickly and equate results with software or hardware prototypes. Consequently, they tend not to allow enough time for analysis and design.

By taking part in the formal reviews and with the right team relationship in the informal reviews, the customers will see progress as the project progresses through the early stages (preproduction) of SDLC. They will also share the discovery process that is always associated with new projects and appreciate the difficulties as they arise.

Reviews serve as milestones to demonstrate progress in the completion of some work. The major formal reviews include the SRR, Preliminary Design Review (PDR), SDR, Operational Readiness Review (ORR), and so on, as are set up for the project. Informal reviews are mostly peer reviews when colleagues check each other's work. Reviews can also be thought of as being critical tests carried out in a way that lessens embarrassment over shortcomings.

Consider reviews from the perspectives of testing. The earlier the testing can be performed in the SDLC, the greater the reduction in the penalty costs of not doing it right the first time. Testing is done at well-established checkpoints through the SDLC. These check points include:

- *Concept reviews*: Verify that the conceptual software will meet the needs of the customer. Many times, people state problems in terms of particular solutions that may not meet their needs when subsequently researched and analyzed.
- *Implementation (management) plans*: Verify that adequate resources have been scheduled and sufficient planning has been performed to maximize the probability of successful completion of the tasks defined.
- *Requirements reviews*: Verify that the requirements have fully documented the customer's need as well as what can be done at that point.
- *Design reviews*: Verify that the design meets the requirements, namely, that nothing has been added or left out and that all interfaces will work correctly.
- *Code walk-throughs*: Verify that the code meets the module specifications, namely, that nothing has been added or left out.
- *Test plan reviews*: Verify that the tests, as planned, will exercise every requirement and will not waste effort testing for undocumented requirements.
- *Test procedure reviews*: Verify that the test procedures conform to the test plans without additions or subtractions.

Informal reviews are slightly different to formal reviews. However, to be effective, the following 'P' items need to be considered for formal reviews:

- *Prerequisite*: The product to be discussed in the review must be available for study before the review. The minimum is 24 h, perhaps longer, depending on people's schedules.

- *Peers*: The presenter, coordinator, and reviewers must be peers during informal reviews to allow free discussion and improve the tendency to discuss the problem, not the person. If management is absent, then, in theory, there will be no one to impress or be intimidated by.
- *Product item*: This must be small enough to be completely reviewed within one hour.
- *Period of time*: The time spent discussing each subitem must be limited to a few minutes.
- *Pact*: Consensus is to be reached by the team during the review as to the disposition of discussion items. A healthy coalition of activity is essential as each kind of skill integrates to produce the whole.

For effective formal reviews, only the 'Prerequisite' and 'Product item' issues are essential.

These reviews shown here, in general, cover items that are not discussed at the Configuration Control Board level. However, they do take place in a formal or informal manner in the process of implementing change requests – see Section 8.

6 TESTING THE SOFTWARE

The code should be built and tested in phases. It should not be left to be tested at too long a period.

The ideal implementation for test and evaluation of software is to build it from the user interface to the measurement software. This allows the users/operators to use the completed parts of the software to test sections developed later. This approach ensures that the software is 'user friendly'. There are enough instances of software being released that is so clumsy to use that it is obvious that the people who wrote the code never used it.

Software is a partial system product and needs to be tested just like the whole system product that will be tested using the software. The following are examples of the attributes of software that need to be tested (Hughes, 2000):

- *Correctness*: Extent to which a program satisfies its specifications and fulfills the customer's requirements.
- *Reliability*: Extent to which a program can be expected to perform its intended function with the required precision when called upon to operate in stated conditions.
- *Efficiency*: Amount of computer resources required by the software when executed.
- *Integrity*: Extent to which access to the software or data by unauthorized persons can be controlled.
- *Usability*: Effort required for learning, operating, preparing input, and interpreting output.
- *Maintainability*: Effort required for locating and fixing an error in an operational program.
- *Testability*: Effort and expediency required for testing a program to ensure that it performs its intended function.
- *Flexibility*: Effort required for modifying an operational program.

Depending on the circumstances, not all parameters for testing may be required. For example, if the program is going to run on a personal computer in a stand-alone environment, with no other program running at the same time, there is little point in testing to determine the actual resources used by the program as long as it performs in a satisfactory manner.

All effective meetings need a suitable set of metrics to gauge success and progress – *see* **Article 3, Measures and Metrics; Their Application, Volume 1** – consider now metrics used for reviews. Reviews form an important part of the communications process between the developer and the customer. Both parties participate to ensure that the work is proceeding correctly, that is, the contractor is producing the system that the customer wants.

One metric for reviews could be the number of Review Item Discrepancies (RID) generated during or following a review. Since reviews with the same name (i.e. SRR) have different levels of complexity depending on the size of the system being reviewed, comparing numbers may not be useful. RIDs are commonly used, but while they do point out deficiencies in the products delivered at the time of the review, the absence of RIDs is an ambiguous condition. It is possible to produce an operations concept review that will receive zero RIDs. This is possible by discussing the concept with all the stakeholders during the period of performance before the review. Everybody's comments and wants can be incorporated into the concept. After the review, when zero RIDs are received, the issue is whether it is because a good job has been done or because nobody cared.

A better metric is based on the amount of rework to be performed following the review or the amount of work that has to be scrapped and replaced (as a percentage of the whole). Measuring the number of RIDs does provide a metric for the degree of customer involvement in the process, but as explained, these kinds of metrics can be manipulated by skilled project managers.

7 SOFTWARE QUALITY CHARACTERISTICS

It is useful to consider the considerable body of knowledge on software quality. ISO 9126 (1991) identifies the following six software quality characteristics:

- *Functionality*: Covers the functions that the software product provides to satisfy user needs.
- *Reliability*: Relates to the capability of the software to maintain its level of performance.
- *Usability*: Relates to the effort needed to use the software.
- *Efficiency*: Relates to the physical resources used when the software is run.
- *Maintainability*: Relates to the effort needed to make changes to the software.
- *Portability*: Relates to the ability of the software to be transferred to a different environment.

The applicable attributes and quality characteristics that apply to the software must be noted as requirements and the test program for the software must verify that all stated requirements have been met.

At all times, it is also necessary to ensure no new requirements have crept in without being allowed for or that any no-longer-needed requirements are still being worked upon.

8 CONFIGURATION CONTROL

All software should be placed under configuration control using a change management process. Changes should be approved before being implemented. The actual change control process will vary depending on the situation but the key elements are constant. These are:

- No changes are made without prior approval by an authorized body.
- Estimates of the effort and schedule time needed must be made before the change is implemented.
- Changes are to be made in an orderly and recorded manner.

Two types of changes occur:

- planned
- unplanned.

These can each be allocated into one of three degrees of urgency:

- stop the software from working: change now;
- can live with it: change soon;
- would be nice to have this addition: change whenever.

A serious problem with software changes is that due to the high degree of interdependence of all software instructions, there is a distinct risk that a change not only fixes known defects but can also add new features that are usually unwanted. Each change has to be subject to a regression analysis to reveal the impact of the intended change. The effort needed to carry this out can be major. Sound design partitions the modules to lessen the degree of interaction and makes it easier to investigate effects of changes.

1 INTRODUCTION TO SMART SENSING SYSTEMS

Today, users want sensors that are easy to select, install, and use on the 'fit and forget' basis.

Basic measurement sensor systems, however, have many potential failure modes that can degrade the metrological performance – the key performance characteristic of a sensor. Users also seek easy-to-install systems that can be used without the need to appreciate the theory and detailed practice of their operation in order to set them up and maintain them.

To make a basic sensor 'smart' has been a need for a long time. Numerous things can go wrong with a sensor; and it is often the key to sound overall systems success. A much more robust sensor unit is required.

Producing smart sensors is a matter of designing and making a sophisticated system in its own right. What was not so long ago a vision has now become widespread reality. Today, they are either designed as additional boards in the system's computer or in microcircuit form – the so-called microsmart sensor that can allow packaging with the sensor element.

Combination of sensor experience and research, advanced microelectronic technology and sophisticated signal processing (Tränkler and Kanoun, 2001) has led to many reliable sensors now being used routinely that can be truly defined as suited to fit and forget use. They are found in many places – automobiles, process control, aviation, health, manufacturing, agriculture, and more. The application of smart sensors in robotics has been discussed (Siegel, 2001).

So what is it that makes a simple dumb sensor become a 'smart' one?

A high-level system engineering definition of a smart measuring sensor would be:

> A sensor is smart when it detects, corrects or warns about any mechanism that will, is, or is about to degrade the metrological integrity of the sensor system during operation, this being with respect to both its capability and suitability regimes.

A word of caution: the name 'smart' is sometimes used in association with sensors without reasonable justification, one instance having only the smart feature of possessing a stabilized power supply!

A sound appreciation of smart sensor systems is needed in:

- creation of smart sensors
- appreciating the features of given systems

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

- critiquing operating systems
- maintenance
- making a sensor system more competitive.

Being relatively new, the literature on smart systems is still found much in the primary journals, or on manufacture's releases, where schemes and ideas are reported. Several books that survey aspects of the smart sensor field include Frank (2000), Gardner, Varadan and Awadelkarim (2001), Howell and Hamilton (1992), Inaudi (2002), Kirianaki *et al*. (2002), Pallás-Areny and Webster (2000), Zobrist and Ho (2000).

This article provides an appreciation of the basic issues of smart sensors. To this end, it first discusses the requirements of its two main regimes – capability and suitability. It then looks at the architectures of the basic sensor and how it changes to become smart. An overview of mechanisms that may need automation shows how the smart features rapidly make a simple sensor a complex system. Presets and balances are covered before the issue of autocalibration is dealt with. Implementation of smart systems and their pros and cons are discussed before finishing with operational aspects.

2 THE CAPABILITY ASPECT

In the engineering of systems, the completed design has to provide the user with the desired capability – *see* **Article 63, Outline of Systems Thinking, Volume 2**. A sensor then has to sense a measurand, satisfactory with respect to its metrological task – *see* **Article 57, Static Considerations of General Instrumentation, Volume 1** and **Article 58, Description of Accuracy, Linearity, and Drift, Volume 1** for explanations of the many features of a measurement determination.

The necessary capability aspects of any sensor are that it is:

- **Calibrated**

At any time of use to determine a measure, it must provide the required measurement functions of discrimination, precision, and accuracy. These are each different characteristics needing ongoing testing and possibly automatic correction to data. A word of caution is needed here; autocalibration is a misunderstood, and sometimes misrepresented feature of many smart systems – see Section 5.

- **Linear in operation**

Many sensors are not linear in their operation. Linearity is desired as the signal moves over its valid dynamic range. (The actual function may be of other laws such as exponential.) Linearity is vital to correct application and it is not covered as such in a sensor calibration that is usually only being performed for one or two spot values. Linearity needs periodic automatic determination of several points over its dynamic range so that correct ongoing signal linearization correction can be provided.

- **Giving adequately precise values**

A sensor signal needs to possess sufficient short-term grouping for repeated measurements of a given value (called *repeatability*), and also for its long-term reproducibility. Automation can speed up initial commissioning and long-term verification of these parameters.

3 THE SUITABILITY ASPECT

As well as the above-mentioned features needed for success, many others need to be correct for a sensor to be deemed fully capable. They are concerned with the suitability of the sensor at providing that capability over its working life. This aspect is its suitability for use in a specified task.

In general, the reasons for failure under operation are that parameters of the sensor system go too far over, or under, the design limits in which the sensor will give faithful metrological performance.

The main areas in which this can happen are

- set up conditions of the sensor system elements
- connections
- measurement range selection
- amplifier gain settings
- automatic data processing settings
- fault conditions.

Fault conditions provide numerous risk situations many of which can be given automated attention for their detection and possible correction within a smart sensor system. It is not only a case of total failure taking place but also the measurement being sufficiently corrupted from its correct value by a small amount such that it is not producing faithful metrological data.

Check lists of likely sources that might need to be considered follow.

External conditions

- excessive influence by an external parameter such as humidity, pressure, temperature, vibration, lightning, and so on causing severe degradation;
- external influence parameter altering working levels of key voltages, currents, and so on;
- power excesses overheating key components, causing metrological degradation;
- protective packaging failures;

- incorrect connection being made, such as DC power lines reversed or wrong connections inserted;
- connection to other systems needing selection of parameters, as in autoranging wireless links;
- leakage of electric currents, fluids, gases into the system.

Internal conditions

- stoppage of cooling fan;
- failure of drive motors or actuators;
- degradation of resistors, capacitors, inductors, and integrated circuits over time;
- rising of hot spots from dust, preventing cooling;
- occlusion in optical systems from dust and insect webs;
- chemical growth.

Detection and correction of numerous features could be included in a smart sensor. Obviously, the more that are needed, the higher will be the cost in terms of money and space.

Those features easily provided in the electronic domain have become routine. Their size of manufacturing scale and development tool availability has made them inexpensive to offer. However, addition of special needs outside an electronic-only solution can be very costly.

4 ARCHITECTURES OF SMART SYSTEMS

Designing a well-developed smart sensor with many features can be a major systems development task requiring application of the systems engineering process and detailed design, all coupled with a sound appreciation of the metrological aspects. The latter aspect is not always so well appreciated; implementation will usually be by persons not that familiar with sound measuring systems theory and practice. Overall, their design can be particularly difficult, for the system has to operate correctly within small measurement limits at all times.

The usually encountered basic architecture of a sensor unit that provides a processed signal ready for transmission or display is given in Figure 1. A sensor will need either, or both, auxiliary excitation and an offset bias.

For this classical structure, the sensor will need adjustment for linearity; the offsets and balances of the initial analog blocks will need adjustment. Gains will need setting. To make this structure handle automatic operation of such issues needs, in addition, several kinds of support subsystems in a systemic and systematic manner.

Figure 2, a simple schematic, shows how some basic smart features are added to the basic system to allow for sensor calibration in the short and long term; offset gain and zero adjustment; and linearization.

To effect a particular smart operation, as will be discussed in the following sections, additions will require extra circuitry and/or suitable physical devices that are coupled into nodal points, or are placed in series with signal lines. While the basic system of Figure 1 has already become quite complex, the extras shown are only a few of the additions that need to be added into a really smart sensor. The main difference shown here is that switches, test points, and a calibrator have been added under processor control to carry out the smart functions.

Software is used to sequence the various activities. Some need the sensor output to be held at a suitable value while they are implemented. Corrective actions, such as voltage regulation, can be continuous and be operating at all times. The order in which the functions are switched in can be critical, as is discussed in Section 6.

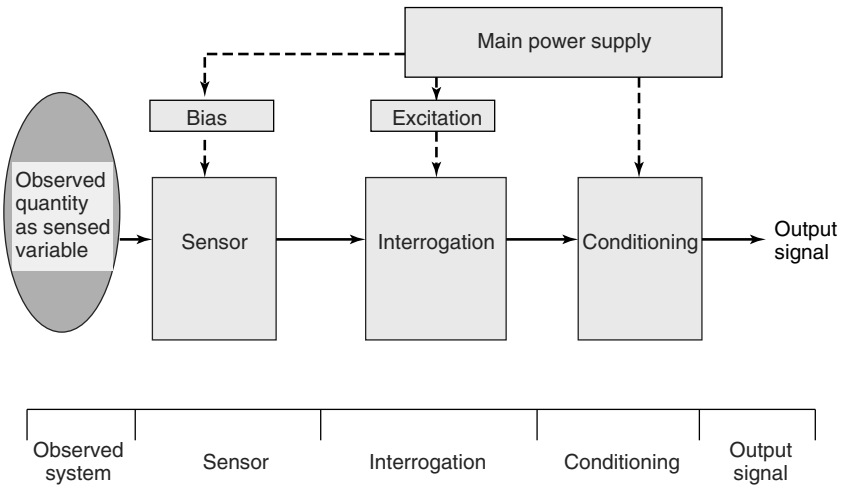

Figure 1. Architecture of basic 'dumb' sensor system.

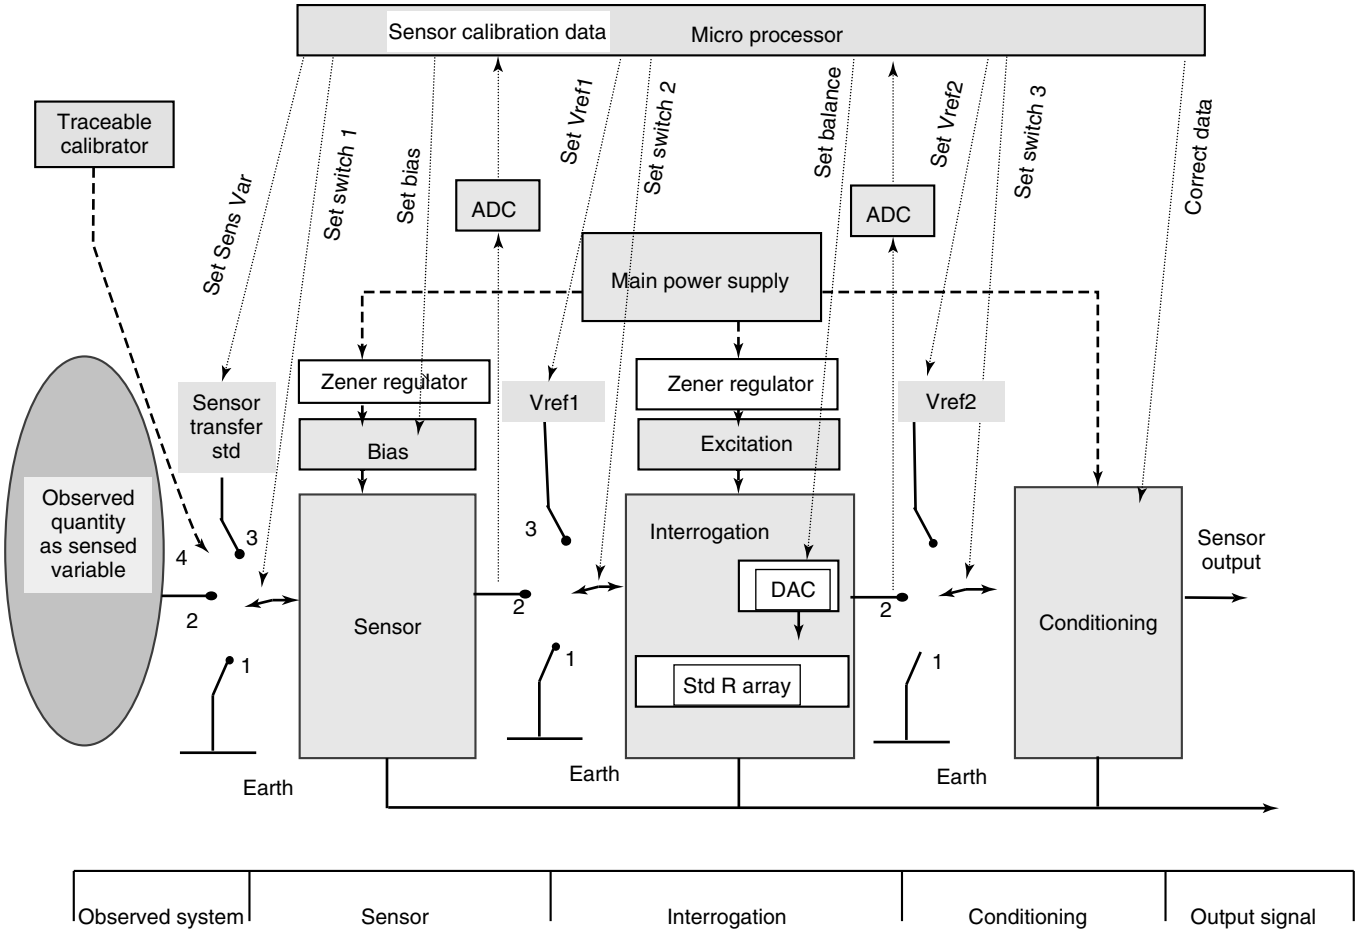

Figure 2. Smarts added to basic sensor system.

Some smart functions are best achieved in the early analog stage of the sensor signal chain. Others are a case of mathematical correction of the data stream. It is important to consider where they are best done to keep sensor performance high.

Advanced smart systems will also log sensor performance data for use in trend calculations that can be employed to make near to real-time corrections and for future design reference.

The rapid uptake of miniature wireless communication systems has called for smart sensors that can operate in the 'plug and play' mode.

5 METHODS FOR AUTOMATING SMART FEATURES

A collection of smart effects and their implementation is now outlined. Offsets, zero settings, and balances are covered in Section 6. Autocalibration is left for discussion in Section 7. The main features are now discussed.

- **Use of common-mode rejection of unwanted signals**

It is common practice in sensitive measuring systems to use a second similar unit, connected in opposition, to balance out unwanted effects. This is done routinely in the Wheatstone bridge – *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2** and **Article 127, Unbalanced DC Bridges, Volume 2**, in capacitance sensing – *see* **Article 204, Capacitance and Inductance Measurement, Volume 3**, in strain gauges – *see* **Article 192, Strain Sensors, Volume 3**, and in instrumentation amplifiers – *see* **Article 122, Operational Amplifiers, Volume 2**. This is the first issue to smarten, as there is need to reduce unwanted effects caused by not exactly matching elements.

- **Compensation by feedback from in-built auxiliary sensor**

Where a common-mode operation is not practical to implement, an auxiliary sensor can be used to sense the level of the unwanted effect and be used to produce a compensating signal.

An example of this is an auxiliary temperature sensor being used to correct strain gauges for the influence effects of temperature; the strain gauge unit is fitted with a metal film or semiconductor-sensing element.

Another instance arises in use of precision amplifiers; a solid-state temperature sensor is often used to measure the silicon substrate temperature in order to compensate for thermal errors.

- **Amplifier gain**

Circuitry is set up temporarily to create the network conditions needed to make error calculations or system component adjustments. Detail is given in Offsets and Balances – see Section 6. In array systems, such as photo detectors stages and amplifiers, this is usually performed in sequence of each gain stage as this allows use of the same test transfer standard for each channel test.

- **Incorrect voltage effecting metrological aspects**

Whereas the stability of the main power supply voltage is not that critical, it is vital that voltage applied as excitation to common-mode circuits, such as bridges, is sufficiently stable.

Not always appreciated is that common-mode arrangement such as the DC bridge configuration, only balance out unwanted effects when in the balanced null state. As unbalance increases, the compensation effect reduces. Thus, an unbalanced bridge will 'see' some effect from an unstable excitation, depending on the extent of unbalance and the voltage stability factor of its excitation source. This need also applies to amplifier power supplies for preamp stages, reference bias voltages, and when dealing with the measurement of critical currents.

The smart mechanism here is to test the stability of the voltage by comparing it with a sufficiently stable voltage reference source. Zener diodes set up with low power loss, that is, low through currents, to give more stability are often used. They have a wide plateau range wherein voltage across the diode is reasonably constant for a range of through currents. A more superior method is to use the reference Zener to control an amplifier, thus further reducing the through current in the Zener diode. Two Zener diodes used in piggyback connection can give superbly stable transfer reference voltage sources. These units are available in integrated form as standard voltage reference sources over a wide range of voltages.

Having detected an error voltage, closed loop digital methods are used to change the used voltage source until agreement is reached with the reference source.

- **Out-of-range detection in bridge and sensor outputs**

Fault conditions for specific sensor systems can be identified from a critical analysis of the system and the mechanisms set up to sense their presence.

For example, a Wheatstone bridge will have a normal output swing for inputs – such as when used to interrogate a strain gauge or resistance temperature sensor – that only swings over some $\pm 10\%$ of the magnitude of the excitation voltage. A common error state is for one arm of the bridge to go open circuit owing to resistance element failure. This state causes the output to swing to the maximum excitation voltage. A test for this magnitude is a sure sign of bridge failure and could be used to bring up an alarm. Auto replacement of failed components is done sometimes by replacement with a set of redundant components using a suitable switching arrangement.

- **Model-based operation**

All the above-mentioned methods make use of knowledge of the correct state of the sensing system by reference to some known factor. The idea can be extended by forming an executable model of the critical sensing parts of the sensor in the processing computer. If the model is white, that is, its detail models the interior of the system, then its nodal values at any given overall state can be used as a reference source for correct operation. Development of models can take time to develop – *see* **Article 71, Modeling Methodology, Volume 2** – but with manufacturing volume, or in supercritical applications, the expense can be justified.

These models can take the form of formal mathematical descriptions or be AI based using Knowledge-based Systems, KBS methods – *see* **Article 128, Nature and Scope of AI Techniques, Volume 2**.

6 PRESETS AND BALANCES

The main elements of a sensor – its sensing element, interrogation stage, excitation source, and preamplifier, usually, cannot be manufactured precisely enough not to need adjustment of such parameters as common-mode balances, gain, and presets adjustments.

- **Bridges**

These need the resistance of one or more of the arms to be trimmed to obtain an adequately zero output. If not balanced, the null point will be a minimum, having a value never equal to zero. A computer-controlled resistor network is switched into the bridge circuit using detection of the balance point to select the correct resistance value.

A trick here is to trim the bridge by adding parallel resistors, not by putting resistance in series. Their resistance will then need to be large, making the required resistance of the connecting switch more easily accommodated.

- **Instrument amplifier**

The gain of an electronic amplifier varies with ambient temperature and time. As the output of a sensor is decided by the gain factor of the processing chain, it is necessary to adjust the gain when first commissioned, and henceforth periodically.

Gain is usually adjusted by digitally altering a stable resistance network added to the circuitry, this often being incorporated into the amplifier chip. A similar setup as is shown in Figure 2 shows how this can be done in practice.

To detect a gain error, the amplifier input is first clamped to zero, using a suitably low resistance switch placed from the input to earth. The zero offset of the chip is then adjusted electronically to zero and that adjustment value held.

The next step is to replace the amplifier input with a suitable known voltage. The output of the amplifier is measured automatically and stored in the computer's memory. Gain is then calculated as the output/input ratio. Gain is then adjusted on the chip. Not setting the offset first can lead to a second order error in the above procedure.

To obtain linearity figures, the process is repeated at several positions across the working range. These values are then used to correct, in close to real time, the sensor.

7 AUTOCALIBRATION AND SELFTEST

It is common practice for measuring systems, when started up, to run through a suite of tasks that test for many fault conditions. This is called selftest. This process identifies areas where a system is already out of specification or, perhaps, trending toward it. The general principles and practices of selftest and auto correction are described above.

Special mention is needed about autocalibration. While many systems claim they provide automatic calibration, it needs to be understood as to what level and traceability the claims are valid.

Like selftest, autocalibration is a matter of comparing the present value of a parameter important to correct operation with one that is held to be sufficiently correct from direct calibration.

First let us clarify what calibration is? It is finding out how far a measured value lies from the value that is defined as being the true one by a method that is traceable to an accepted standard. This means the method used to declare true autocalibration has to have a traceable link used at a calibration interval – *see* **Article 46, Calibration Interval, Volume 1** suited to the application.

It is only possible to conduct calibrations without reference to the agreed standard in two situations:

- where the sensor itself is inherently calibrated in a traceable manner;
- where the sensor can, from past experience, refer to a replacement transfer standard for a sufficient time of operation before external calibration is needed again.

It is a fact that there is only one measuring apparatus that is inherently calibrated. The frequency-stabilized laser interferometer, if operating within design limits, has been declared to be a traceable length standard to stated limits.

The semiconductor diode/transistor has been described as also being self-calibrating and not needing reference to the Practical Temperature Scale. This is because it can be shown that its temperature current is related to only Boltzmann's constant, the charge of the electron and its temperature in K, thus being independent of geometry or specific manufacturing details.

Thus, at first sight, this appears to be able to provide a standard temperature reference source of high precision and accuracy. Analysis, however, of its practical use shows that the temperature variation needed to be measured is in the $\mu V K^{-1}$ range, yet the standing voltage for room temperature is nominally 600 mv. To gain adequate sensitivity, it requires the nominal value to be compared with a standard voltage source in a voltage comparator. The measurement then is not traceable to the metric System of Units for the standard voltage source needed is not inherently traceable.

This means all self-calibration sensors must periodically be compared to an external reference to be traceably calibrated. This situation is often overlooked.

Autocalibration in sensor systems needs the availability of a cheap and small enough reference source. A list of likely transfer standard sources used with measuring sensors is as follows:

- voltage (Zener diode, and the older Weston cells)
- radiation (Black body held at controlled temperature)
- chemicals (Standard Reference Materials)
- temperature (Standard Temperature Points, such as ice and boiling point and limited use of the semiconductor diode/transistor temperature sensing effect)
- length (Gauge blocks, interferometers)
- resistance (Calibrated stable resistor network with adequately low resistance connections).

Many other calibrators can be designed to order; careful analysis is always needed to determine that their accuracy and long-term repeatability are sufficiently stable.

For example, a standard pressure can be produced by the known sweep of a piston containing a fluid, or a relative humidity sensor can be calibrated in a suitable

chamber into which water is injected. In both cases, the physics of the chamber conditions needs to be well understood. Many special calibrators will, however, usually be too large to be practical in microsensor autocalibration use.

When conducting an autocalibration, a choice of calibration test signal and profile will need to be considered.

The input calibration signal format needs to match the practical situation. Where there exists considerable inertia in the object under test, such as when attempting to move mechanical systems, the ramp test signal is more realistic than trying to produce a step movement. Use of an impulse or sine wave can sometimes be used with domain Fourier transformation to obtain the needed response coefficients.

Some sensors will need special waveforms to be generated such as a heartbeat monitor signal. In cases where the signal arises in the electrical domain, the smart system digital processor can generate the test signals.

Some tests need noise sources. Again the digital processor can generate the type needed, be it white, grey, pink, or some other specific distribution.

8 IMPLEMENTATION OF SMART SENSOR SYSTEMS

Today, the list of suppliers of smart sensors is ever growing, IRN (2004). Growth of the smart sensor market has attracted the preparation of reports, Frost & Sullivan (2003).

Their design is often supported by excellent database libraries. These, coupled with application of best practice systems engineering, makes the creation of sophisticated sensor systems more routine by the specialist sensor makers, Tränkler and Kanoun (2001).

There are also available specialized computer-based tool kits for building the microsmart sensors. The *NI Plug & Play*® kit facilitates the integration of a smart design into a virtual instrument formed in the LabView tool system – *see* **Article 105, Modeling with LabVIEW™, Volume 2** and **Article 106, Virtual Instrumentation in Physics, Volume 2**. It allows rapid integration of the design of IEEE P1451.4 smart analog sensors into computer-based data acquisition applications. It also assists conversion into embedded computer chips. This tool kit works with a broad range of sensors, including accelerometers, temperature sensors, load cells, pressure sensors, displacement sensors, and others.

Judgment will be needed as to how much is automated, for special features can be expensive to design and make.

A microprocessor is used to pace and control most of the features explained above, although some will be done continuously with special circuitry. Processors often provide features that support smart operation. They need some nonvolatile memory to retain the settings in the case of a power down.

The first smart sensors used additional circuitry boards to carry the extra components. Progression into cheaper, better systems has taken much of supply into the integrated chip form wherein the sensor and its basic signal conditioning and additional smart features are all integrated into one unit. Some are still built in printed circuit and hybrid forms, being necessary for special cases with low volume demand.

During selftest and autocalibration operations, it is usually necessary to hold the output of the sensor to the most recent value, for during these operations the output can run to extremes, causing glitches in the output.

Analog signal correction loops can be replaced with digital Expert System methods, for example, a simple rule set might be:

If Voltage V exceeds 10.0 V (a limit of safe operation, for example),
Then reduce V by 0.1 V
Repeat until V is equal to 6 V

A wide range of smart sensors are now on offer, so it is wise to consider already available products before launching into a new design.

9 PROS AND CONS OF SMART SYSTEMS

The main advantage of smart sensors is that they can provide fit and forget operation, thereby reducing maintenance costs and risks of total or gradual failure.

One very common problem seen with basic sensor systems is that they often make erroneous indications. For example, they can indicate states in equipment that cause unnecessary shutdowns. Smart systems should be more reliable in operation, for a good design exercise is needed to thoroughly analyze the sensor systems for its various fault conditions and set up corrections for many.

On the other hand, a smart sensor can be very complex and that condition can involve poor reliability unless very well designed and tested. The smart sensor can be much more expensive than its basic unit, but the extra cost should be easy to justify in terms of cost avoidance.

The increased facility for taking a basic sensor to the smart state carries penalties:

- need for more access connection and test points in the sensor system;

- need for additional auxiliary components and subsystems;
- more system administration and control processing power and its supporting software is needed;
- additional complexity exists compared to the simple basic sensor;
- can be more difficult to maintain – need training and special test sets.

Assessing their capability and suitability, however, is a costly issue. This can be validated by three strategies:

- where sufficient detail is available, using assessment of the design features and the design execution (called *verification*);
- from experience with a given design, this being usually from another's use (validation);
- by submitting the sensor system for an instrument evaluation exercise – *see* **Article 217, Instrument Evaluation, Volume 3** (Full evaluation and maybe accreditation).

All take time and cost to perform and thus there can be the tendency to accept claims of a manufacturer without question. Instrument evaluation experience – **Article 217, Instrument Evaluation, Volume 3** – has repeatedly shown, over several decades, that instrument performance claims are often not all met. Smart sensor systems are little different to many complex instrument systems so it is reasonable to assume that they might also sometimes fall short of their stated specifications. Any area of difficulty will usually lie in their metrological performance. Caution is needed in their selection.

10 OPERATIONAL ASPECTS OF SMART SENSOR SYSTEMS

The sequence in which the initial set up, and then in-service calibration, is performed is most important.

As a general guide the order of tests for a start-up situation is as follows:

1. Ascertain that the nonautomatic settings needed are correctly set.
2. Check if system alarm states are all within the 'OK to go' state.
3. Check if power supply availability is within range and with sufficient endurance.
4. Ensure that environmental conditions are within acceptable bounds.
5. Generally, test for 'out of normal range' operation of internal operations, such as wildly incorrect open and short circuit input states; and out of range values for bridges and sensors.
6. Determine and adjust any zero states that need to be balanced at their device source.
7. Determine and set offsets to correct value.
8. Calibrate the internal electronic subsystems with standard electrical components, holding the raw sensor input first to zero and then at the 100% range value by switching in suitable shunts and sources.
9. Calibrate the sensor against a suitable transfer calibrator, using the now set up electronic amplification. It is usually not possible to sense the low-level sensor output signals without this gain being added.
10. Calibrate the correction table for linearity over the range from a suitable set of test points.
11. Record all values that have later use, such as trends, maintenance needs, and audit of performance. These help to build up confidence in the system.

Not doing these steps in this order can result in an apparently correctly set system. However, there are some traps for learners here. For instance, balancing out the offset in common-mode rejection systems at the post-block stage can be used with signal processing, but it could leave one of the two compared variables at an extreme of the range, thus, offering little working range before saturation is reached.

Overall the reliability of well-tried varieties of smart sensors, as are used in industrial control and process plants, is such that they get close to being a 'fit and forget' application. Smart sensors are not a fad but an essential part of sound measuring practice.

1 CHOOSING METHODS FROM THE KBS RANGE

In Information societies, people desire free access to information any where, any time, and on demand with every device. This ensures success within a knowledge-based society (KBS). The dividing lines between professional and private life are shrinking.

Knowledge-based systems (KBS) or, in short, knowledge systems comprise knowledge servers; multiuse ontologies, knowledge bases and knowledge system modules; computational environments for modeling structure, behavior, and functionality of technical (physical) devices; compositional modeling; architectures for adaptive intelligent systems; and knowledge-based systems for science, engineering, and defense applications (http://www-ksl.stanford.edu).

Ontologies are definitions of terms and their relationships to other terms with the aim of building semantic webs (http://ftp.ksl.stanford.edu/pub/KSL_Reports/KSL-01-07.doc).

Intelligent measurement is an experimental process for acquiring new knowledge about a product with the help of measurement devices, computers, and specialized software.

Ambient intelligence and ubiquitous computing holds a high potential of applications for micro system technology (MST), micro electromechanical systems (MEMS), and micro-opto–electromechanical systems (MOEMS) (http://www.mstnews.de/download_0202.htm).

These paradigms are due to become available in all kinds of products and services; within their software, hardware, and processed material and processes (see ISO 9000:2000, point 3.4.2) (http://www.iso.ch).

Many products comprise elements belonging to different generic product categories. Whether the product is then called a service, software, hardware, or processed material depends on the dominant element.

Process is a set of interrelated or interacting activities that transform inputs into outputs (see ISO 9000 : 2000, point 3.4.1) (http://www.iso.ch). Inputs to a process are generally outputs to other processes.

Knowledge-based or intelligent measuring instruments or measuring equipments are known as virtual instruments or VIs (Figure 1) (http://www.ni.com)

2 SETTING UP THE SENSOR SIGNALS AND PROCESSING

Virtual instrumentation systems (VIS) have developed with improving sophistication in measurement resolution and frequency bandwidth. In some five years, virtual instrumentation systems have improved in measurement performance

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

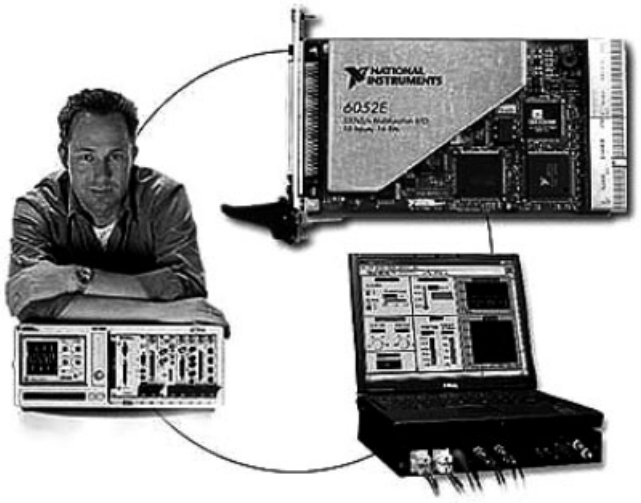

Figure 1. Knowledge-based intelligent measurement systems (http://www.sine.ni.com/apps/we/nioc.vp?cid=1036&lang=us).

to meet, and sometimes exceed, the capabilities of traditional analog instruments. With the introduction of the FlexDMM and RF signal analyzer, virtual instrumentation systems have taken an order of magnitude leap in performance.

The key to the innovative improvements in virtual instrumentation is the leverage they derive from standard PCs; and off-the-shelf analog-to-digital (ADC) and digital-to-analog (DAC) converter technologies – *see* **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**; **Article 133, Amplifiers and Filters for DAS, Volume 3**; **Article 134, Analog Multiplexers, Volume 3**; **Article 135, Sample-hold Circuits, Volume 3**; **Article 136, Quantizing Theory Relevant to DAS, Volume 3**; **Article 137, Coding for Data Converters, Volume 3**; **Article 138, Sampling Theory Relevant to DAS, Volume 3**; **Article 139, Analog-to-Digital (A/D) Converters, Volume 3**; **Article 140, Integrating Type A/D Converters, Volume 3**; and **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**. In contrast, stand-alone instruments often use custom ADCs and proprietary computing architectures. Several years ago, these proprietary architectures offered superior performance to their mainstream counterparts. However, advances in semiconductor technologies and the explosive demand in the last decade for computing and telecommunications capabilities have created an abundance of high-performance, commercial ADCs. Consequently, gaps between virtual instrumentation only appear at the extremes of frequency and resolution (Figure 2) (http://digital.ni.com/worldwide/bwcontent.nsf/web/all/721E2E2BB3AD847B86256C25005890BC)

3 EXAMPLE FOR MEASUREMENT SIGNAL PROCESSING SITUATIONS

The ever-increasing processing power of PCs, combined with the advanced analysis tools available in software packages like LabVIEW – *see* **Article 105, Modeling with LabVIEW™, Volume 2**, provide a more recent example of the progress of virtual instrumentation. For example, new Lock-In Amplifier start-up kit for LabVIEW, offers a FREE downloadable VI that brings the functionality of a lock-in amplifier – *see* **Article 184, Photon Counting, Volume 3**, to virtual instrumentation (Figure 3).

The LabVIEW Lock-In Amplifier start-up kit provides for precise measurement of AC signals that are partially or completely buried in noise. An example of this includes

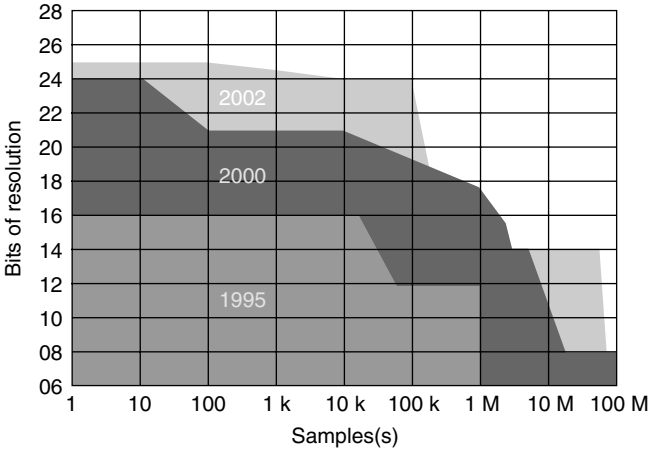

Figure 2. Performance development of digital measuring instruments (http://digital.ni.com/express.nsf/bycode/nsi2401?opendocument&lang=en&node=seminar_US).

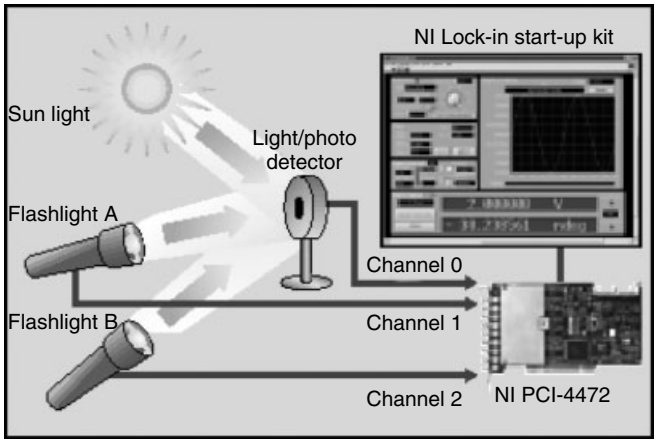

Figure 3. Knowledge-based intelligent measurement of noise-buried measuring signals (http://www.ni.com/pdf/newsletters/us/inl_q4_2002.pdf).

extracting a 50-μV sine wave from a white noise signal with 5-V amplitude.

The lock-in amplifier removes the noise by performing a Fast Fourier Transform (FFT) on the input signal at the frequency and phase the reference signal carries – *see* **Article 143, DFT and FFTs, Volume 3**.

In Figure 3, a flashlight A modulated at 10 kHz is pointing to a photodetector. Sunlight acts as unwanted noise in the system. The opto sensor converts incoming light from the sun and flashlight A into an electrical signal. The electrical signal from the sensor is connected to channel 0. The reference signal coming from the on/off switch of flashlight A is connected to channel 1. The Personal Computer Instrument PCI-4472 digitizes the data and the Lock-In Amplifier start-up kit processes it. The flashlight A signal is extracted from the sunlight noise. Flashlight B is modulated at 1 kHz and connected to channel 2. Both signals can be measured with the same opto sensor (photodetector) (http://www.ni.com/pdf/newsletters/us/inl_q4_2002.pdf) page 12.

4 MEASURING INSTRUMENTS IN KNOWLEDGE-BASED SOCIETY

Owing to the triumphal development of microelectronics and microcomputing in the last 30 years, increasing measurement processes are designed and accomplished with electrical and electronic instruments (Figure 4). Typical examples are

1. time measurement with electrical watches;
2. temperature measurement with electrical thermometers;
3. weighing with electrical balances;
4. energy measurement with electrical Watt meters;
5. health care with electrical pacemakers;
6. security supervision with digital cameras;
7. pattern recognition with electrical microphones;
8. channel hopping with electrical remote control;
9. automatic light switching with opto sensors;
10. computer games with electrical joy sticks;
11. wireless cooking with microwave oven;
12. wireless communication with cell phones.

Figure 4. Measuring instruments in knowledge-based society.

Modern algorithms for pattern recognition – another kind of measurement – distinguish automatically between normal and dangerous situations (Figure 4).

Components of modern embedded technologies are

1. Personal Computer Instrumentation (PCI) (http://www.ni.com)
2. Pocket Personal Computers (PPC) (http://www.pocket.at)
3. MS Windows Operation Systems (http://www.microsoft.com)
4. Local Networking with Ethernet (http://www.gigabit-ethernet.org)
5. Global Networking with Internet (http://www.internet.com)
6. Wireless Communication with Bluetooth (http://www.bluetooth.com).

Modern embedded technologies have turned the character of conventional measurements to intelligent or knowledge-based measurements with hardware and software having equal rights. Microelectronics and microcomputing bring low-cost measurement tools to scientists and engineers. Global remote access to knowledge (http://www.kmbook.com) and especially measurement knowledge via Internet is state of the art (http://www.messweb.de and http://www.globalspec.com).

The main information and knowledge source for measurements is the Internet. From 1996 till now, the Web archive has collected 100 Terabyte data on more than 10 billion Web pages (http://web.archive.org).

The availability of highly accurate, reliable, and robust measurement technologies is very important to research and development, manufacturing quality control, and marketplace exchange. Measurements of electrical quantities are particularly important.

Electrical quantities are the common currency of measurements; that is, many non-electrical quantities are converted into electrical quantities to facilitate measurement by electronic instrumentation. Further, the foundational International System of Units (SI), and all research based on it,

rely on a time-invariant, internationally consistent realization of the electrical units

(http://www.eeel.nist.gov/811/nat-elec-stds.html).

5 KNOWLEDGE-BASED SIMPLE AND COMPLEX MEASUREMENTS

Simple (plain) measurement is defined as the direct or indirect comparison of a measurement object with a known metrological measurement standard (reference standard) (Figure 5) and a known measurement method. In practice, it is a standardized measurement.

Metrological standards based on the International System of Units (SI) are, for example, etalons for m, kg, s, A, K, mol, cd (http://www.bipm.fr).

Complex measurement (Figure 6) is defined as direct or indirect comparison of a measurement object with different measurement standards (reference standards) like

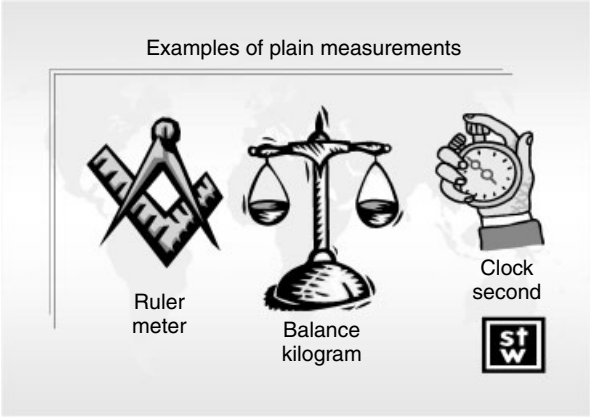

Figure 5. Simple (plain) measurements clipart (see http://www.google.de).

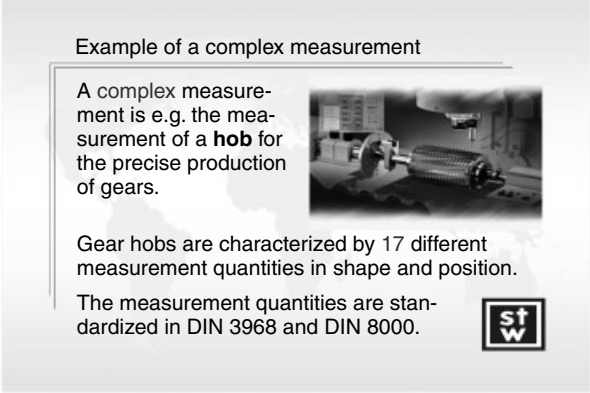

Figure 6. Complex measurement Hob (see http://www.okm-jena.de).

- metrological (etalons)
- particular (material pattern, master tools, gauges)
- virtual objective (simulation programs)
- virtual subjective (experience)

measurement standards and appropriate measurement methods.

Complex measurements are not yet standardized, or cannot readily be standardized.

Complex measurements are now accomplished as knowledge-based measurements in the framework of Internet Metrology – *see also* **Article 47, Internet Calibration, Volume 1**.

A *particular* measurement standard (Figure 7) is an objective material pattern intended to

- define,
- represent material,
- conserve, and
- reproduce

the identification marks of an object or an event in order to transmit it to other measuring objects by comparison.

A *virtual objective* measurement standard (Figure 8) is a nonmaterial pattern, for example, a numerical, textual or graphical one like a software program or a database intended to

- define,
- represent nonmaterial,
- conserve, and
- reproduce

the definition signs of an object or an event in order to transmit it to other measuring objects by comparison.

The application of virtual objective measurement standards (reference standards) is increasing in Net-environments due to the fact that they are more

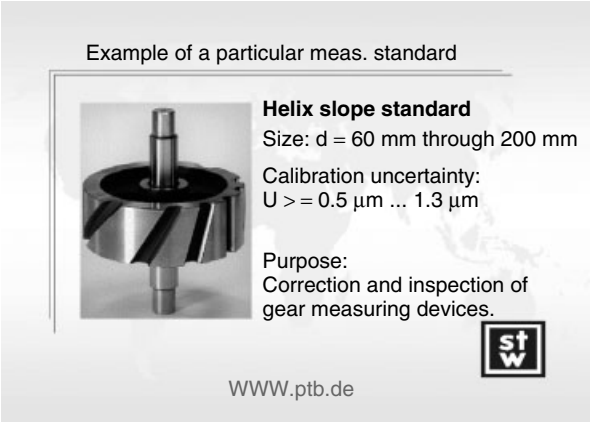

Figure 7. Particular measurement standard Helix slope standard (see http://www.ptb.de).

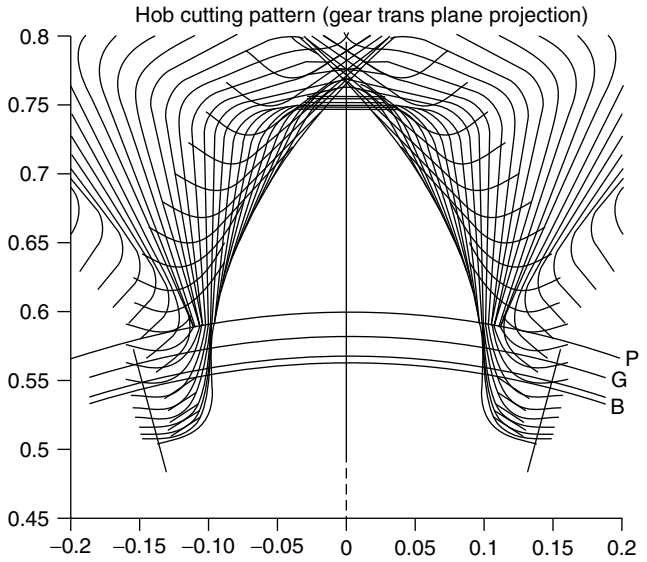

Figure 8. Virtual objective measurement standard hob cutting pattern (see http://www.uts.com/gear/411ex1.html).

- individually appropriate,
- functionally powerful, and
- financially affordable

in comparison with material patterns.

The knowledge about *virtual subjective* measurement standards is not yet adequately introduced and accepted in the body of knowledge on metrology. Nevertheless, a huge number of measurements are daily supported by the individual experience of the user. People are able to 'measure' mechanical, electrical, optical, and thermal quantities by using their individual sensual apparatus with many millions of natural sensors (receptors), nerve strings, and brain. (Figure 9) (http://www.berlin.ptb.de/8/_indexe.html).

6 KNOWLEDGE-BASED LEGAL METROLOGY

The electrical current I is a base measurement quantity of the metrical International System of Units SI (http://www.bipm.fr). The base unit of the electrical current is the Ampere A.

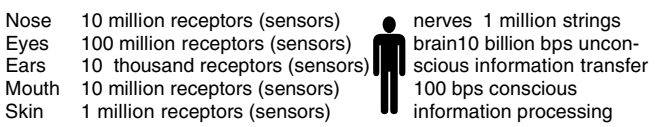

Figure 9. Information acquisition and processing capabilities of man.

The formal definition is

*The **Ampere** is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to* 2×10^{-7} *Newton per meter of length.*

From the standpoint of a knowledge-based metrology, it is critical that the terms 'infinite', 'negligible', and 'would' in the definition of Ampere make its practical realization from a technological standpoint impossible. Therefore, the Ampere, since 1994, is realized by indirect measurements (http://www.ptb.de). Voltages and resistances are therefore used in the practical realization of governmental etalons in the institutions of legal metrology since January 1, 1990. Bases used are Ohm's law and the von Klitzing constant.

The electrical voltage U, current I, and resistance R relationship follow, after George Simon Ohm's (1787–1854) work, the characteristic interrelation given in Ohm's law (Figure 10):

$$U = I \times R \tag{1}$$

The National Physical Laboratory NPL, for example, adopted on January 1, 1990 (http://www.npl.co.uk/npl/cem/dclf/publications/booklet/resistancelc.html) a new value for its reference value of the ohm based on the new SI value of the von Klitzing constant

$$R_{\mathrm{K}-90} = 25\,812.807\,\Omega \pm 0.2\,\mathrm{ppm} \tag{2}$$

Measurements of resistance are referred to the quantum Hall effect using the conventional value $R_{\mathrm{K}-90} = 25\,812.807\,\Omega$ exactly (Figure 11). The uncertainty of this value in the International System of Units SI is not included in the uncertainty assessments.

The first step in the calibration chain of resistance measurements is to relate a room temperature wire-wound resistor to R_{K}. This is done, for example, at NPL using an automated cryogenic current comparator bridge (CCC) to measure a 100-ohm resistor against a quantized Hall resistance (QHR) sample.

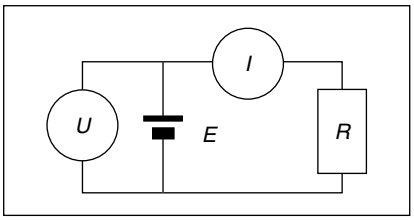

Figure 10. Fundamental electrical circuit with E energy source; U voltage meter (Volt V); I current meter (ampere A); R resistance (Ω); $R_{\mathrm{Ui}} = \infty$; $R_{\mathrm{Ii}} = 0$; $_{\mathrm{i}}$ = internal.

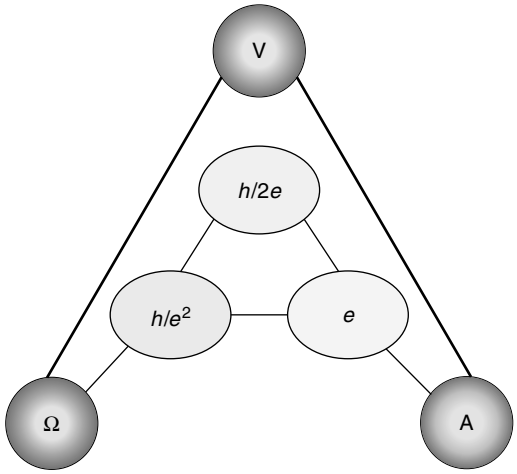

Figure 11. Interrelation between electrical units and natural constants (http://www.ptb.de Bildstelle) with V Volt voltage U; A Ampere current I; Ω Ohm resistance R; h Planck's constant; $h = 6.626\,068\,76 \bullet 10^{-34}$ J•s; e elementary charge of the electron; $e = 1.602\,176\,462 \bullet 10^{-19}$ C; R_K von Klitzing constant; $R_K = h/e^2$, R_H Hall resistance; $R_H = 1/i\,R_K$ with $i = 1, 2, 3, \ldots$; K_J Josephson constant; $K_J = h/2e$ $U = n K_J f$ with $n = 1, 2, 3, \ldots$; $i = nef$ with $n = 1, 2, 3, \ldots$; f, frequency of the irradiated microwave; J joule = W•s = V•A•s; C Coulomb = A•s; W Watt = V•A; s Second.

The high ratio accuracy of a CCC overcomes the difficulty of comparing the awkward value of the QHR with a decade value of resistance. Turns ratios of 4130 : 32 and 4130 : 64 on the CCC are used to measure the 100-ohm resistor against the i = 2 and i = 4 plateaux respectively. The measurements are estimated to have an accuracy of 0.01 ppm at the 1 sigma uncertainty level.

For the physical reproduction of Volt and Ohm measurement standards, microelectronic devices are used (Figure 12).

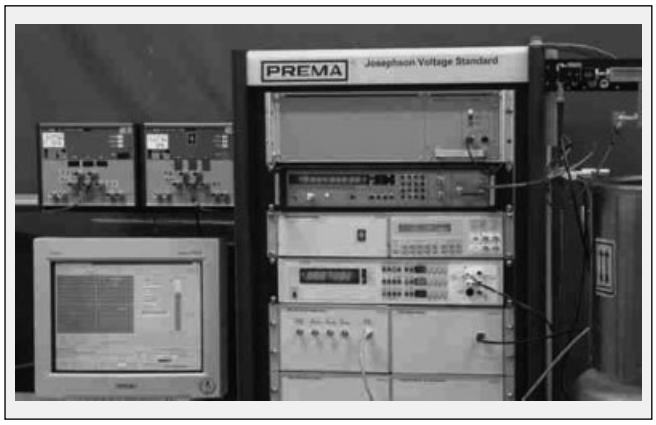

Figure 13. Josephson voltage standard rack with drive frequencies in the 70 GHz range (http://www.ipht-jena.de/BEREICH_1/abt13_cryo_electronics/cryo_start_b1.htm) and (http://www.prema.com/D/JVSe.htm).

Paradoxically, the small dimensions of the central tools of the voltage and resistance standards, contrast sharply with the very large cost of the instrumental apparatus, laboratory, and operation that is needed to make determinations. (Figure 13).

7 KNOWLEDGE-BASED INDUSTRIAL METROLOGY

Under the influence of modern technologies with standardized affordable microelectronic components for analog, digital, and mixed signal processing, the paradigm of instrument designers and manufacturers for electrical instrumentation is changing. The functionality and artificial intelligence of new instruments is high. The price of offering this extension to capability is low.

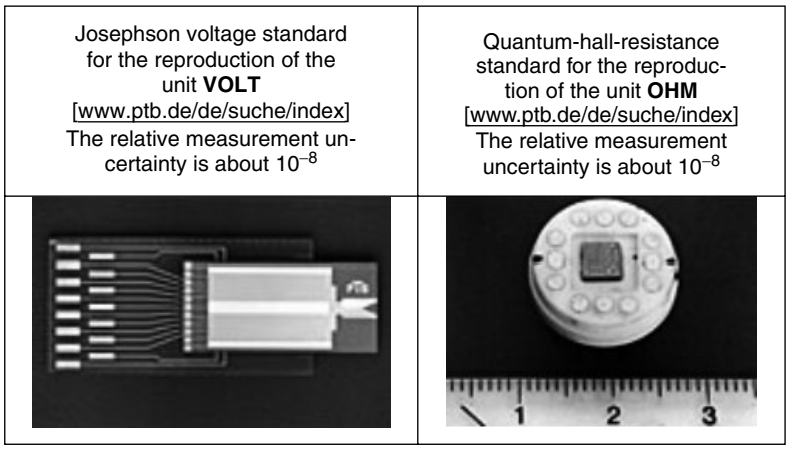

Figure 12. Microtechnological electronic standards for the units volt and ohm (http://www.ptb.de/de/suche/index).

The number of different instrument makers in the market place is decreasing. The qualification of people who use the instruments might be lower than before and individual repair of the instruments is usually not economic.

A standard statement on modern electrical and electronic instruments is

Do not attempt to disassemble your product. The product does not contain consumer serviceable components.

Owing to their high technological reliability, electrical measurement devices are less likely to age in their functionality than do their esteem and modernity factors. Users are less interested in *what* to do, than in *how to* do, in real time, in easy and affordable ways. Enlightened firms follow this thinking.

All-in-one (AIO) intelligent electrical instruments for knowledge-based industrial measurements are seen, for example on (http://www.fluke.com/about_fluke/corporation.asp?AGID=11&SID=0):

Electrical AIO instruments for industrial service and maintenance

- digital multimeters,
- electrical power controls and accessories,
- integrated ScopeMeter hand-held test tools.

Electrical AIO instruments for measurement of electrical and thermal quantities

- power harmonics meters,
- electrical testers,
- digital multimeters (DMMs) and accessories,
- clamp meters,
- ScopeMeter test tools,
- current clamps,
- digital thermometers.

Electrical AIO instruments for precision measurements

- calibrators,
- standards,
- waveform generators,
- calibration software products.

Electrical AIO instruments for process measurements

- test tools for field calibration and maintenance,
- simple loop calibrators,

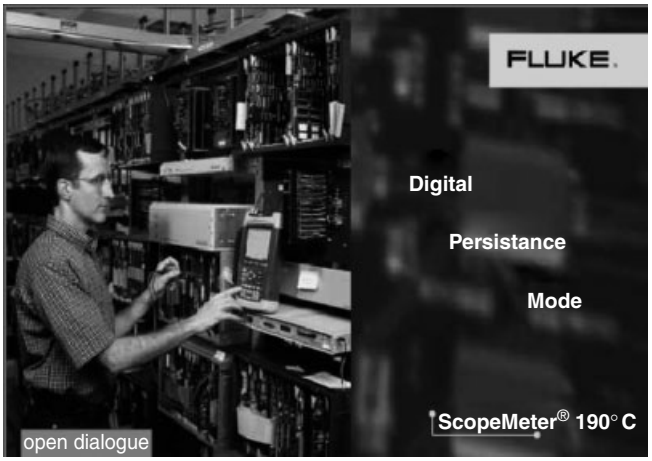

Figure 14. Multimedia sequences of ScopeMeter tests (http://www.fluke.com/products/home.asp?SID=0&AGID=0&PID=31768).

- sophisticated documenting process calibrators for current, voltage, resistance and frequency, temperature and pressure.

In addition, many intelligent instruments offer computer connectivity and documentation software to help report and analyze data results for rigorous maintenance documentation.

Market leaders provide exacting standards for companies and government organizations who rely on tightly calibrated instruments for their quality and standards programs as well as to meet strict international quality requirements.

The full functionalities of, for example, ScopeMeters are shown in multimedia sequences (Figure 14) at (http://www.fluke.com/products/home.asp?SID=0&AGID=0&PID=31768).

REFERENCES

At present there appear to be no titles available in KBS measuring systems.

Primary papers can be searched in sources such as the *KBS Journal*. However, the content of papers is often, despite the article titles, not that closely associated with KBS methods. Only a few papers will address use of KBS in measurements.

1 DEFINITION OF MEMS

MEMS is an acronym for Microelectro Mechanical Systems, it defines mechanical structures fabricated with IC processing on (most often) silicon wafers. In Europe, MEMS is labeled Microsystems and in Japan it is labeled Micromachines.

The term MEMS evolved in the United States in the 1990s. Prior to that period the technology was labeled *silicon micromachining*.

MEMS defines the technology; not specific products. This technology encompasses a collection of a variety of processes enabling three-dimensional shaping of wafers or stacks of wafers. While most of the applications use silicon wafers, many other materials have been used, including glass and quartz wafers.

As a result of batch manufacturing technology (fabrication of multiple devices photolithographically defined on the wafer, Figure 1), the cost of single device depends on its size; wafer processing cost is fixed for a given process. The cost difference between a 1×1 mm device and a 10×10 mm device is 100 times, as the first device would yield about 16 000 devices on a 6-in diameter wafer, and the larger device would yield only about 160 devices on the same wafer.

The beginning of MEMS technology dates back to the discovery of semiconductors at Bell Laboratories in the early 1950s. Many consider their 1954 paper, announcing the discovery of piezoresistive effect in silicon and germanium, as the birth date of MEMS.

A related acronym MOEMS stands for Micro Opto Electro Mechanical Systems and defines a subset of MEMS, that is, devices performing optical functions.

2 WHY A HIGH LEVEL OF INTEREST IN MEMS?

A high level of interest in MEMS technology results from both business and technical factors.

Factors on the business side are given below:

- Multiple emerging markets for MEMS devices promise large financial gains. The cumulative venture capital industry investments into MEMS-based companies is estimated at over $1 billion as of 2003.
- In 1999, Business Week selected MEMS as one of the three technologies expected to fuel the growth of the economy in the twenty-first century. (The other two were information technology and biotechnology.)
- The IC industry created a solid technology infrastructure immediately available for MEMS.

On the technical side, some of the multiple factors that contributed to making MEMS attractive are as follows:

- Potential for integration of devices with IC circuitry, to create integrated systems on a chip.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

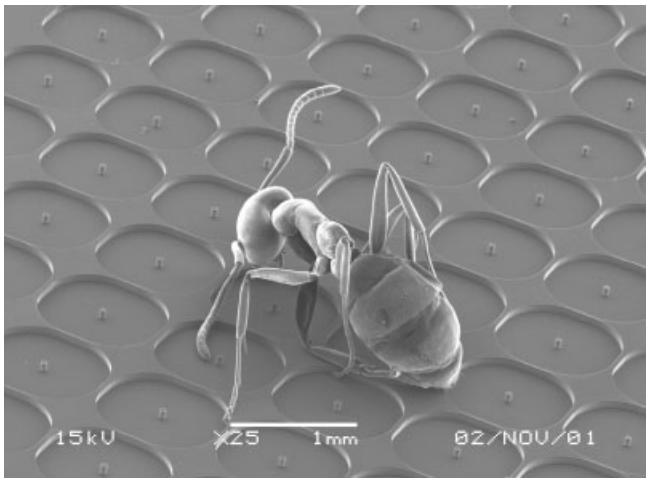

Figure 1. Scanning electron microscope (SEM) close-up of a wafer showing photolithographically defined and etched pattern forming part of the mirror array (1 mm each), contrasted in size with that of an ant. (Copyright © Transparent Networks, Inc.)

- Excellent mechanical properties resulting from the extremely pure crystalline structure with a silicon content of 99.999% or better, resulted in no material fatigue or mechanical hysteresis. This makes silicon almost a perfect material for sensors. The mechanical properties are comparable to steel, see Table 1.
- Batch wafer processing technology, enabling low-cost, high-volume production.
- Excellent lateral dimension control to submicron level.
- Available cutting edge IC processing equipment, offering easy transition to volume production.
- Available ultrapure (no mechanical fatigue) low-cost materials.
- Available sophisticated diagnostic and test equipment.
- Available design and simulation tools (software).
- Available high-volume IC packaging technologies.
- Available pool of educated silicon processing technologists.

Another aspect of MEMS that adds to its attractiveness is its synergy with nanotechnology, which receives a high level of government funding worldwide. In many cases, MEMS can be used as a packaging vehicle for nano devices.

Table 1. Mechanical properties of steel and silicon.

	Steel	Silicon	Units
Yield strength	<4.2	7.0	$1010\,\mathrm{dyn\,cm^{-2}}$
Young's modulus	2.1	1.9	$1012\,\mathrm{dyn\,cm^{-2}}$
Density	7.9	2.3	$\mathrm{g\,cm^{-3}}$
Thermal conductivity	0.97	1.57	$\mathrm{W\,cm^{-1}\,^{\circ}C}$
Mechanical hysteresis	Yes	No	
Sensitivity to stress	Low	High	
Fabrication resolution	10	0.1	μm
Fatigue failures	Yes	No	

3 PROBLEMS WITH MEMS COMMERCIALIZATION

While MEMS technology has been very promising, commercialization efforts encountered multiple stumbling blocks thereby significantly delaying the availability of commercial devices as summarized below:

- IC industry has not provided many process modules required to process mechanical devices, such as wafer-deep etching of wafers, double sided wafer alignment, multiple wafer bonding, and so on. Development of such unique processes was long and expensive, as they were usually funded by a small company with limited funding and a pool of technologists dedicated to a particular process.
- Mechanical properties of many IC materials are unknown and vary with the process selection.
- Structure thickness control was underdeveloped by the IC industry, which typically was satisfied with ±10% accuracy for ICs; but often required better control for mechanical structures.
- Mechanical and electrical stability of structures were considered black magic for a long time, as scientists did not understand its origin for a long time.
- Hermetic wafer lamination technologies critical to many devices had to be developed entirely by the MEMS industry.
- High-volume, low-cost MEMS dedicated testing, especially with the application of a mechanical stimulant (such as pressure) had to be developed entirely by the MEMS industry.
- Compatibility with the real world, such as fluids, was a major task to be developed by the MEMS industry.

As a result of these problems, volume implementations of initial devices was slow, as shown in Table 2.

These incubation periods may seem long, but are similar to the incubation times of other emerging technologies, including VCRs, cell phones, and satellite television.

4 MEMS PROCESSES

Many processes for fabricating mechanical structures were developed over time. Three major categories of such processes are as follows:

Table 2. Development of MEMS.

Product	First prototype	Cum volume 1 M	Incubation (years)
Pressure sensor	1961	1984	23
Acceleration sensor	1970 piezoresistive	1995	25
	1977 capacitive	1995	18
Ink jet printers	1977	1996	19
Displays (DLP)	1979	2001	22

- bulk micromachining of silicon
- surface micromachining
- deep reactive ion etching.

4.1 Isotropic etching

Bulk micromachining makes use of the entire wafer thickness, which typically may range from 500 to 1000 μm.

The first bulk micromachining process made use of the anisotropic wet etch developed for pressure sensors in 1970 by Kulite, New Jersey. This etch could remove silicon in all directions, independently, according to the crystallographic orientation of the substrate. The shape was defined by a masking process, Figure 2. The accuracy of the structure definition was not very good, as it depended on many factors, such as time, temperature, and etchant concentration. No good etch-stop technology enabling termination of the etch at a predefined depth was developed.

4.2 Anisotropic etching

A major improvement in accuracy of etching was achieved with the development of anisotropic wet etching, which relied on crystallographic orientation. This was first demonstrated by Kulite, in New Jersey, in 1976 for pressure sensors. Different crystallographic directions of silicon exhibited different etch rates for selected etchants, such as KOH. The etched rates could differ by 2 orders of magnitudes (depending on the direction); thus, the mask was defining the shape of the etched cavity, with the only variable being the depth. This depth still depended on temperature and concentration and could be controlled to about ±10% of etched depth in the best cases. If the starting wafer thickness was 600 μm and etch depth was 500 μm, this meant the variation of thickness of unetched silicon would be 100 ± 100 μm, or 0 to 200 μm. This was not good enough for the first application, that is, in pressure sensors, as pressure sensitivity varies as the square (for piezoresistive sensors) or cube (for capacitive sensors) of the diaphragm thickness.

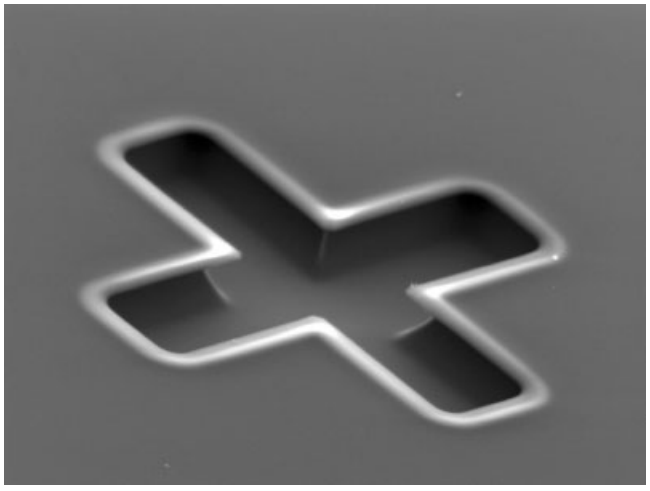

Figure 2. Example of isotropic etching of silicon through a cross-shaped mask and with nonetched surface layer of silicon oxide. (Copyright © Transparent Networks, Inc.)

Several techniques for stopping the etch on this layer were later developed. One of them took the advantage of the high differential etch rate as a function of the silicon-doping level: for high doping, the etch rate was significantly slower as compared to the low doping level. Using diffusion or ion implantation, a thin (submicron to tens of microns) highly doped (carrier concentration $>10^{19}\,\mathrm{cm}^{-3}$) surface layer could be formed, which would terminate the etch. The depth accuracy of such a layer was still about ±10%, but the tolerance of the intended feature was not dependent on the etched thickness. If 5-μm thickness was programmed, it would have ±0.5-μm tolerance, which was not achievable without the etch stop. This type of etch stop was deployed (among others) in General Motors pressure sensors, Figure 3.

Another etch-stop technique was based on the p-n junction, biased by the voltage. During the initial etch, the p-n junction was blocking the flow of the current. As soon as one of the layers (p or n) was etched, the current flow caused oxidation of the exposed area, stopping the etch. This type of etch stop was deployed (among others) by NovaSensor, California.

4.3 Sacrificial etching

Surface micromachining focused on using the few micron thick surface layer of the wafer, to simplify cointegration

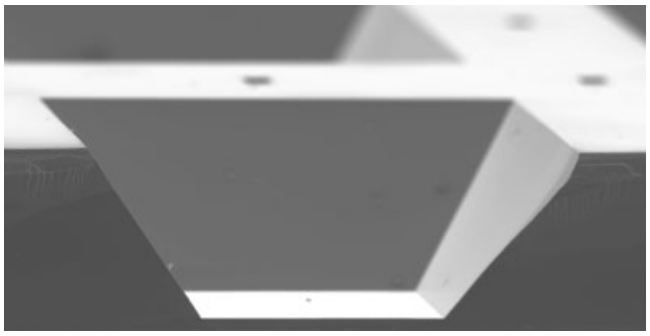

Figure 3. Anisotropic etching of silicon follows crystallographic planes, enabling precision control of the rectangular patterns and formation of thin membranes. With etch stop, the thickness of the thin membrane (on the bottom of the chip) could be controlled to less than 10%. (Copyright © Transparent Networks, Inc.)

with electronics. The process emerged through the 1980s, with major progress in its development at the UC Berkeley and Sandia National Laboratories (2004).

The principle of sacrificial etching is based on silicon oxide etchants that do not etch polysilicon. The structures are formed by patterning a layer of oxide into the required shape by photolithography, covering it with patterned layers of polysilicon, and then etching away (sacrificing) the oxide through small holes etched in polysilicon.

The thickness of structures fabricated with surface micromachining is typically under 4 μm, due to limitations in polysilicon deposition. One of the highest volume products based on this technology is the family acceleration sensor from Analog Devices, Massachusetts.

A well-advanced process is Summit V, developed at Sandia National Labs, enabling five layers of polysilicon to be independently shaped to create complex mechanical systems in the chip, such as gears, pumps, and mirrors – see Figure 4.

4.4 Deep reactive ion etching (DRIE)

None of the deep wet etch technologies are friendly to the processing of integrated circuits. Furthermore, sloping silicon in an anisotropic etch unproductively consumes the chip area, thus, increasing its cost.

Development of plasma-based deep etching was a dream tool for the MEMS industry. This tool emerged in the 1990s, with major progress contributed by Bosch. Their process was based on alternating two cycles: plasma etching and vertical polymer wall coating to prevent lateral etching.

Initial etch speed was about 1 $\mu m\,min^{-1}$. As of 2004, the fastest machines can deliver up to 10 $\mu m\,min^{-1}$ rough etch (dimensions are not very well controlled).

While this deep reactive ion etching (DRIE) etches silicon, its etch rate of silicon oxide is 100 to 1000 times slower

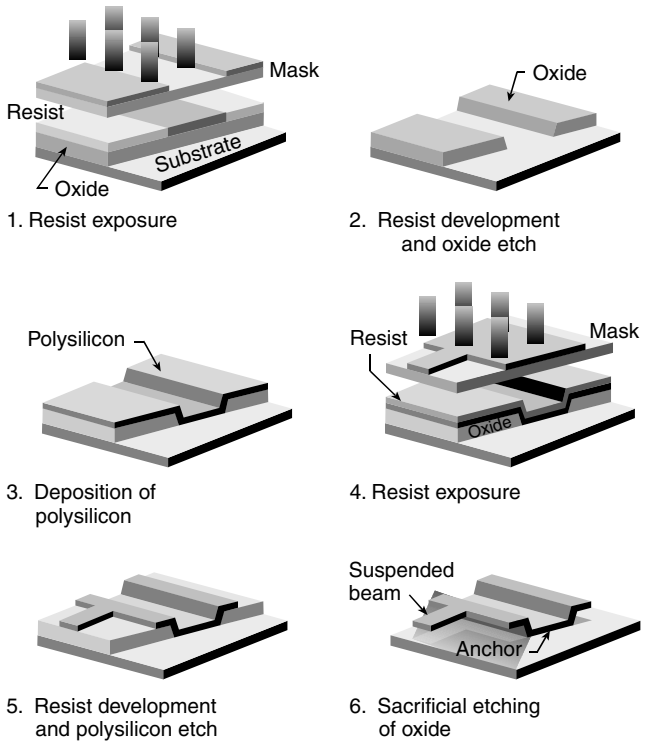

Figure 4. Foundation for surface micromachining is sacrificial etching of silicon oxide underneath of polysilicon, to create suspended mechanical structures. (Copyright © Nadim Maluf, New Focus.)

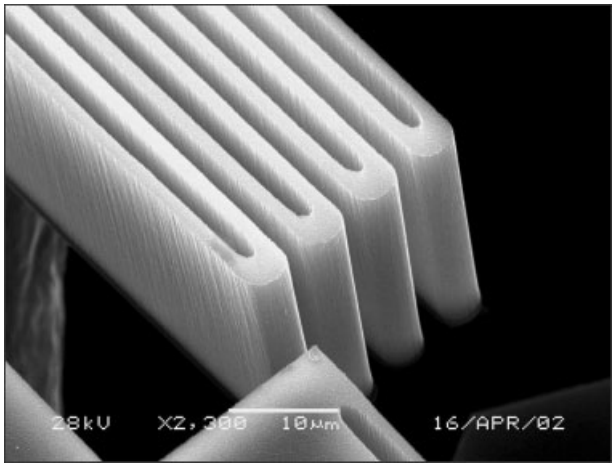
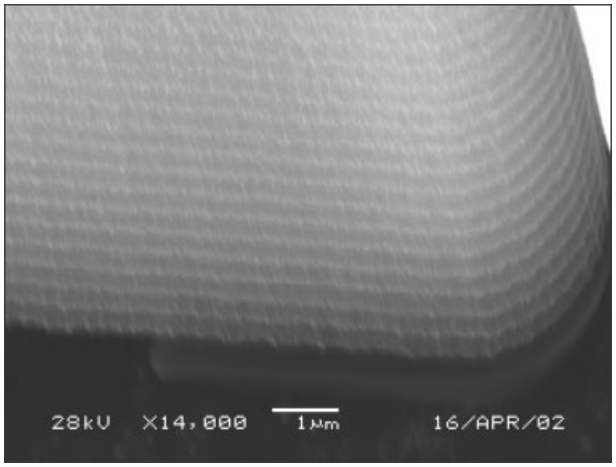


(depending on settings), enabling creation of the etch stop on the oxide. One of the easiest approaches is the use of silicon on insulator (SOI) wafers, containing an embedded layer of oxide.

While the etch speed for DRIE is now comparable to anisotropic etch, the throughput is not. DRIE equipment can etch only one wafer at a time, while wet etching can simultaneously process a large number of wafers (e.g. 100), limited only by inexpensive tooling.



If the design needs several DRIE etches with a cumulative depth of 800 μm (typical for many sensors), and the effective (accuracy limited) etch speed of 4 $\mu m\,min^{-1}$, each wafer will use an etcher for 200 min. This allows etching of only 7 wafers per day using three shifts, or about 1800 wafers per year, in a 5-day week. This makes DRIE a significantly more expensive process than wet etching. Examples are shown in Figure 5.

5 ROLE OF MEMS IN MEASUREMENT SYSTEMS

MEMS-based devices play a valuable and instrumental role in the sensor world, in their application in the measurement of physical variables. Key MEMS sensors include the following:

(a)

(b)

Figure 5. Deep reactive ion etching (DRIE) enables high aspect ratio vertical etching of silicon. (a) SEM picture shows 1-μm wide, 30-μm deep silicon springs with 1-μm spacing between springs. (b) Close-up of the vertical wall, showing the surface scalloping resulting from the alternative etching and polymer deposition during the DRIE process. As shown, each cycle etches approximately 0.3 μm of silicon, resulting in highly vertical etch. (Copyright © Transparent Networks, Inc.)

- *Pressure*: with MEMS sensors representing over 90% of units and 50% of revenues.
- *Acceleration*: with MEMS sensors representing over 95% of units and 25% of revenues.
- *Rate*: with MEMS sensors representing about 95% of units and 75% of revenues.
- *Force*: with MEMS sensors representing about 20% of units and 5% of revenues.

Pressure sensors were the first devices based on silicon technology introduced to the market in the 1960s, for military and aerospace applications. In the year 2003, the volume of pressure sensors produced approached 200 million units, with automotive (most models of advanced cars use over 10 pressure sensors) and medical (primarily disposable blood pressure sensors) markets dominating the unit volume.

Acceleration and gyro MEMS-based sensors were developed for military and aerospace market in the 1970s. In the year 2003, over 100 million units were produced and it was dominated by the automotive airbag applications.

MEMS rate sensors were developed in the 1990s, first for military, and then for automotive applications. In 2003, their unit volume was about 2 million units. The largest volume markets are automotive (stability control and GPS) and consumer (camera shake stabilization and cell phone GPS), with the potential for 10 million rate sensors by 2010.

The major market for silicon force sensors are home scales, absorbing millions of devices.

The emerging MEMS sensing applications include the following:

- infrared
- flow
- chemical
- biological.

6 KEY PRINCIPLES USED FOR MEMS SENSORS

Major sensing technologies that can be applied in the MEMS form include the following:

- piezoresistive
- capacitive
- resonant
- thermoelectric.

The piezoresistive effect (Smith, 1954) in silicon produces resistance change that is approximately 2 orders of magnitude larger when compared to the change that would result from a dimension change under applied stress (typical for metals). For example, if the material is elongated 0.1% by stretching, typical metallic resistors used for strain gauges would change by about 0.2%, but the resistance of silicon would change by about 10%. Piezoresistive sensors dominate pressure, acceleration, and force applications. Typically, four piezoresistors are connected into a Wheatstone bridge configuration to reduce temperature errors. Figure 6 is a simple example of a piezoresistance sensor.

Capacitive sensors have at least one electrode moving under the input variable, which typically would be pressure, acceleration, or rate. While the simplest configuration is two flat electrode capacitors, the interdigitated silicon fingers (Figure 7), gained wide acceptance as an inertial sensor, as it allows for larger sensing capacitance.

Resonant sensors are based on resonating beams or diaphragms. Applied strain changes the resonant frequency

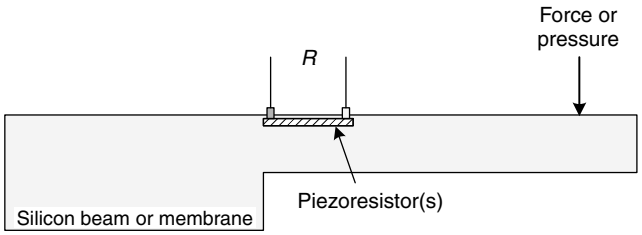


Figure 6. Sensing piezoresistor schematic.

(similar to a guitar string), enabling measurement of input variables such as pressure, acceleration, rate, and temperature. Resonant frequency pickup may use any of the sensing technologies.

MEMS thermoelectric sensors are based on a large number of tiny thermocouples connected in series. These are primarily used to measure IR radiation. One end of the thermocouple is located over a thermally isolated region of the chip, the other end over conducting silicon. In response to radiation, the thermally isolated end of the thermocouple gets warmer, enabling measurement of IR power.

The emerging approach for both chemical and biological MEMS sensors is based on carbon nanotube technology, demonstrated by Silicon Valley companies; it has great potential for creating new markets for yet more MEMS sensors – *see* **Article 163, Uses and Benefits of MEMS, Volume 3** and **Article 164, Principles of MEMS Actuators, Volume 3**.

1 INTRODUCTION

MEMS (Microelectro Mechanical Systems) products, limited in their first decades to pressure and acceleration sensors, significantly lagged in making an impact on international economy and wealth. In the 1980s and 1990s, many governments heavily funded the development of MEMS technology, with the United States, Japan, and Germany giving the highest investment levels.

As a result, a large number of MEMS devices were demonstrated and some were commercially deployed in high volumes.

A general introduction to the principles of MEMS devices is given in **Article 162, Principles of MEMS, Volume 3** and their use in actuators is covered in **Article 164, Principles of MEMS Actuators, Volume 3**. This article discusses their application in products.

During the period from 1998 to 2001 ('optical bubble'), over US $1 billion was invested into MEMS-based companies by the venture capital industry, with the main focus on optical networking. This greatly helped accelerate the development of MEMS products, and the design and manufacturing infrastructure for their fabrication.

Automotive pressure and acceleration sensor markets were the first to become a multibillion-industry sector, with high-end value cars using up to 14 pressure and 11 inertial (acceleration and rate) sensors on the 2003 model cars.

Several other killer applications based on MEMS also emerged. The most visible examples of these new billion-dollar markets include ink-jet printers and projector displays. Several more applications are getting ready to create other major areas, including multiple biotech, medical, RF, aerospace, and consumer applications, each capable of creating their own billion dollar market.

As a spin-out of MEMS, nanotechnology started to receive significant attention, culminating in over US $3.6 billion of funding in 2004 from the US Government. While most of the nanotechnology applications are still decades away from commercialization, selected developments promise high volume applications.

2 BENEFITS OF USING MEMS DEVICES

MEMS is labeled an enabling technology: it enables development of products that would not otherwise be possible.

In some cases, it could provide a feature that is not possible with other technology, such as a single chip optical display with two million tiny mirrors enabling wall-size projection of movies with high definition.

It could provide a breakthrough in cost reduction, such as disposable blood pressure sensors.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

It could also be a combination of multiple factors similar to the benefits seen by the introduction of integrated circuits, such as:

- low cost of manufacture per item due to batch replication manufacturing of multiple wafers, each with a large number of devices per wafer, as compared to one device at a time in the classical manufacturing technology;
- improved mechanical performance due to the excellent mechanical properties of silicon in its pure state;
- capability to deliver very large volume of products, the result of adopting IC processing technology;
- significant reduction in size and weight of the structures, often enabling new applications in which fast response and small size are needed;
- improved reliability because of the use of an integrated structure with a small number of external connection points;
- possibility to cointegrate the MEMS structure with that of the processing electronics, thus enabling new system architectures to be made that were not possible with discrete electronics; and,
- feasibility of building single chip complex electro-mechano-optico multisystems.

As the MEMS technology has entered a high volume production phase for only several applications out of the demonstrated several hundred, it is to be expected that many new benefits will be discovered along the way.

3 MEMS MARKET OVERVIEW

In the 1990s, MEMS programs were established at all major universities around the world. Several hundred MEMS fabrication facilities (MEMS foundries) have been funded, as of 2004, in the academic and commercial environment. Hundreds of MEMS applications have been demonstrated during the last two decades. Only selected applications, however, reached volume production, this not being unusual for any new technology.

One of the problems with a widespread introduction of manufacturable MEMS technology has been its multidisciplinary nature: the integrated circuits designed primarily by electrical engineers who also required a deep background in other disciplines, such as mechanical engineering, material science, optics, biotechnology, and measuring systems.

The largest applications for MEMS technology in the near future (Mancef, 2002) are characterized in Table 1.

Some of these applications are characterized below.

Table 1. Forecast applications for MEMS, Mancef (2002).

Application	2005 (US $ in billion)	2015 (US $ in billion)
Pressure sensors	3.0	6.0
In-vitro diagnostics	0.01	5.0
Read/write heads for hard disks	2.0	4.0
Ink-jet print heads	2.0	3.5
Optical displays	1.0	3.0
Gyroscopes	0.1	2.0
Lab-on-a-chip	0.01	2.0
Drug delivery systems	0.0	1.5
Inertial sensors	0.2	1.5
Chemical sensors	0.1	1.0
Optical switches	0.1	1.0
RF devices	1.0	0.1
Microspectrometers	0.02	0.4

4 PRESSURE SENSORS

The first MEMS-based pressure sensors were developed in the early 1960s in the form of silicon strain gages bonded to metal diaphragms. In the 1970s, silicon strain gages were integrated into silicon diaphragms, and in the 1980s, signal-conditioning electronics had been cointegrated.

Applications for silicon pressure sensors were initially in aerospace and military markets because of their low weight and small size. The first high accuracy silicon pressure sensors were used on commercial DC-9 airplanes in 1967 for airspeed and altitude measurement.

The next market to adopt MEMS pressure sensors was the process control market. Honeywell introduced its Class 41 pressure transmitters in this market in 1970.

As soon as prices started to move toward the US $100 mark, and below, industrial applications started to reach the market in 1970s. Currently, thousands of products use pressure sensors, including compressors, paint sprayers, air conditioning systems and hydraulic controllers.

The medical market adopted MEMS pressure sensors in the 1980s. The world's first disposable blood pressure sensor (developed by the author) reached the market in 1982, with the volume in 2004 being about 20 million units per year. Other medical applications include infusion pumps, catheter tip pressure measurement, and intrauterine pressure measurement during the delivery of babies that was able to prevent unnecessary cesarean sections. An example of a blood pressure sensor system is shown in Figure 1.

Automotive applications for pressure sensors received a major boost from the US government. In 1974, the United States created its Corporate Average Fuel Economy (CAFE) standard in response to the energy and pollution crisis. This targeted an increase of fuel economy from 12 mpg (miles per US gallon) in 1974 to 27.5 mpg in

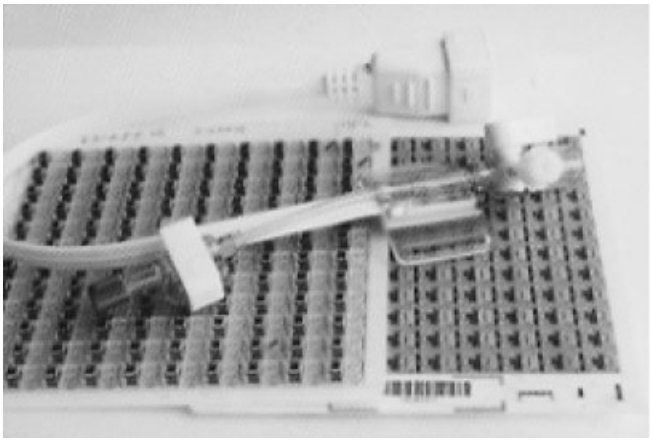

Figure 1. Disposable blood pressure sensor based on MEMS chip bonded to ceramic substrate with laser trimmed calibrating resistors. (Copyright © NovaSensor/Abbott.)

1997 also with a dramatic reduction in exhaust pollution. The goal was achieved by a closed loop gasoline combustion control using a pressure sensor enabling stoichiometric air-to-fuel ratio control, independently of altitude and barometric pressure. The world followed this development with some delay.

In 2003, high-end value cars used up to 15 pressure sensors, including fuel injection, barometric pressure measurement, suspension pressure control, electrohydraulic brake actuation, tire pressure sensing, air-conditioning compressor control, exhaust gas recirculation control, side air bags actuation, oil pressure measurement and many other measurements. In 2004, the total usage of pressure sensors exceeded 100 million units, with a potential for 500 million pressure sensors by 2015.

5 ACCELERATION SENSORS

The acceleration sensor was the second MEMS device to reach the market in large numbers. It was initially developed for the military and aerospace market, with piezoresistive devices being the first to reach the market in 1970s. The first capacitive sensors reached the market in 1980s.

In the 1990s, the US government mandated implementation of air bags in cars. Initially air bag sensors were based on mechanical sensing of a crash using a metal ball moving inside of a sleeve, forming an acceleration activated switch. While such a device was sufficient for the first air bags, typically five of such sensors had to be wired and mounted in the front of the car.

To lower the cost, an improved acceleration sensor was required that would open up multiple options for air bag system design. These include

- Production line reprogrammability that would reflect the car configuration affecting crash response (e.g. engine weight and geometry).
- Elimination of sensor wiring cost; the sensor could be mounted inside of the cabin or engine compartment, and need not be in the bumper unit.
- Reduction of number of required sensors, as the car crash pattern signature, in frequency domain, could be stored in the memory through use of the fast Fourier transform of acceleration.

In the early 1990s, a massive effort was initiated throughout the world to develop a low-cost silicon acceleration sensor. NovaSensor (Silicon Valley) started shipments of advanced sensors in 1992, but exited in 1995 due to dropping prices. Another Silicon Valley startup, ICSensors, started shipments in 1993, but exited in 1998 when it failed to introduce a lower cost device. Sensonor in Norway started shipments of a simple but cheap sensor in 1993, becoming the industry leader in 1997. Failure to introduce a low cost, more advanced model almost destroyed the Company in late 1990s.

Analog Devices, USA, started shipments of the industry's first, surface micromachined, sensors integrated with its signal conditioning electronics in 1994, after a rumored US $200 million investment into the program. It shipped an estimated 50 million units in 2003, becoming one of the key players in this market.

Bosch, Germany, unsuccessfully tried to buy NovaSensor technology in 1990. It introduced its own version, see Figure 2, in 1997 shipping about 50 million units in 2003, primarily to captive applications.

Nippon Denso, Japan, developed a sensor for captive applications in 1995 and shipped an estimated 30 million units in 2003.

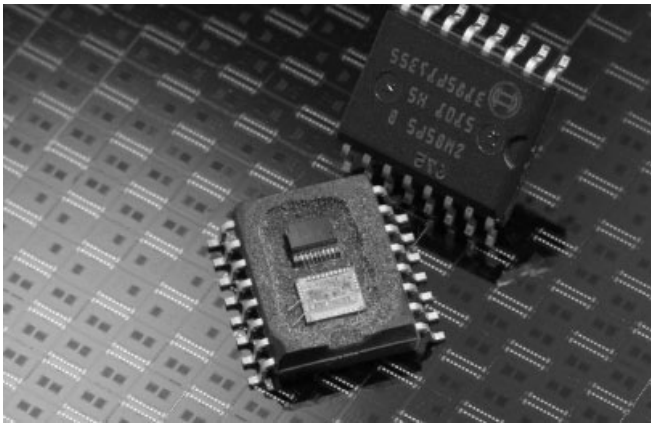

Figure 2. Air bag acceleration sensor built as a two-chip configuration: hermetically sealed sensor chip (upper part of picture) wirebonded to sensor signal processing IC (bottom) are molded in a plastic package for low cost. (Courtesy of Bosch.)

Finally, Motorola, USA, introduced an integrated sensor in 1997 and shipped an estimated 20 million units in 2003.

Clearly, the market for MEMS devices is major and is still in its infancy.

6 DISPLAYS

Developments of MEMS light modulators started at IBM in late 1970s (Petersen, 1977). Texas Instruments, TI, started development of MEMS optical scanners in 1977 and in 1987, demonstrated the digital micromirror. In 1994, a prototype of the digital light projector (DLP), based on digital mirror display chip (DMD) was shown (Figure 3).

The first DMD chip consisted of one small ($17 \times 17\,\mu m$) mirror per display pixel. For their initial 800×600 pixel displays, the chip had 480 000 mirrors. Each mirror could direct the light either to the screen, or the light absorber by tilting $\pm 10^{\circ}$ on one axis. For forthcoming HDTV2 displays, the DMD chip will have about two million mirrors.

Projection was based on time division multiplexing, when each mirror was sequentially controlled to pass light to the screen or to the absorber. One cycle consisted of 256 intensity levels for three colors. If during the cycle the color light was directed towards the screen all the time, it represented the brightest pixel for this color, and if light was directed during the entire cycle to light absorber, it was the darkest pixel.

In a single DMD chip, the color switching (RGB) was accomplished using a rotating color wheel.

DLP™ technology-enabled projectors for very high image quality or high brightness applications such as cinema and large home-theater displays use a three-DMD-chip configuration to produce stunning images, whether moving or still.

In a three-chip system, the white light generated by the lamp passes through a prism that divides it into red, green, and blue. Each DMD chip is dedicated to one of these three colors; the colored light that the micromirrors reflect is then combined and passed through the projection lens to form an image.

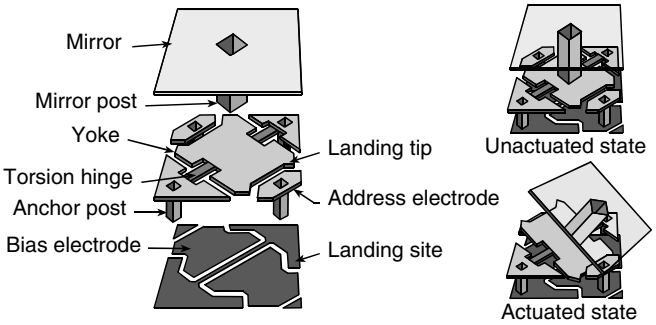

Figure 3. Mirror light switch is electrostatically driven to tilt mirror by about 10° in approximately $10\,\mu s$. (Courtesy of TI. (2004) Texas Instruments DLPs, http://www.dlp.com/dlp_technology/dlp_technology_overview.asp.)

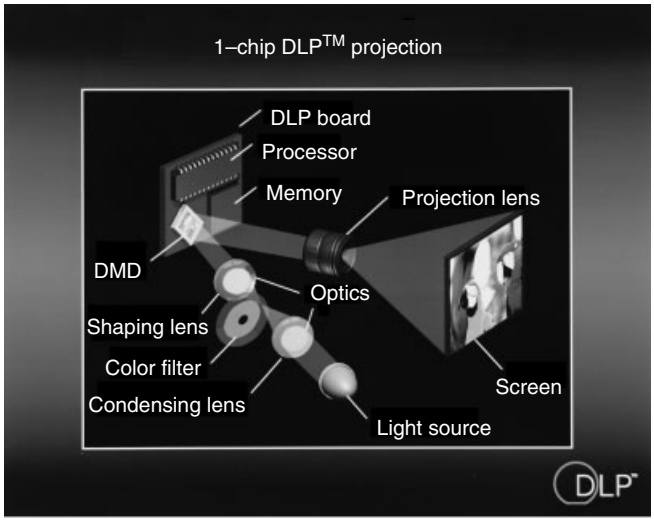

Figure 4. Single-chip DLP Projection system uses rotating color filter to sequentially modulate color on a display, relying on human eye to integrate the resulting picture. (Copyright © Texas Instruments.)

The first projector based on the DLP technology, diagrammatic view shown in Figure 4, was shipped in 1996 following US $1 billion cumulative of funding by Texas Instruments. The first cumulative million units of the DLP™ subsystem were shipped in 2001, the second million in August 2003, and the third million in April 2004, TI (2004).

A promising, emerging application of this digital mirror technology is the pixilated headlight for cars, Figure 5. The left headlight is a xenon type that blinds oncoming traffic. The right one, also energized, includes a unit with 477 000 MEMS mirrors, which individually direct the light to prevent the blinding effect and improve road lighting.

Figure 5. Pixilated headlight for cars using digital mirrors. (Copyright © BMW.)

7 INK-JET PRINTERS

Ink-jet printers emerged in the 1990s, creating one of the largest volume MEMS applications. The first companies to develop this technology were Xerox and Hewlett Packard.

While several different approaches for ink-jet printers are used, one of the more popular printers (the bubble jet form) is based on the formation of tiny bubbles through the on-chip heater and ejection of the bubble through a nozzle. As of 2004, consumer ink-jet printers reached the lower size of 1.5-pL (10^{-12}) droplets and print density 5760 × 1440 dots per inch having 180 nozzles on the chip (for the Epson Stylus Photo R800), delivering professional picture quality for home printers.

The printer application became the largest volume MEMS device in production, with hundreds of millions of printer cartridges being shipped yearly (see Figure 6).

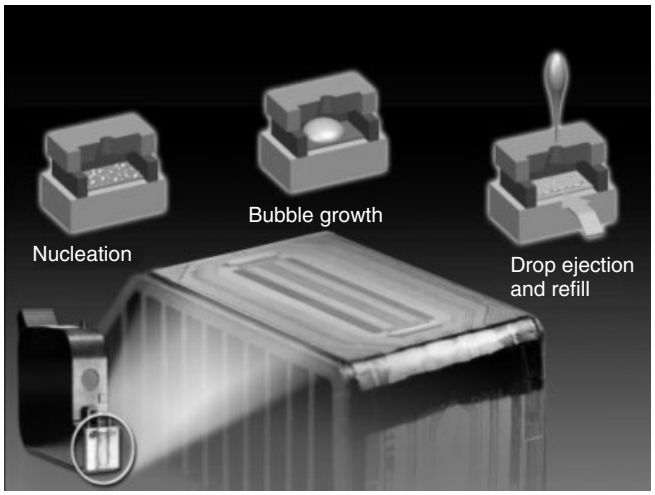

Figure 6. Print head of ink-jet print cartridge includes MEMS chip enabling nucleation of the droplet, bubble growth and drop ejection with micron precision to deliver high resolution photo quality prints. (Copyright © ST Microelectronics.)

8 LAB ON THE CHIP

The most promising and potentially the largest MEMS applications are foreshadowed to be in the biotechnology and medical markets. Single chip integration of a variety of sensors and actuators on the single chip makes possible development of systems replacing entire laboratories. This offers multiple benefits:

- spectacular reduction of size and weight, enabling the laboratory to be taken to the site (i.e. a patient);
- dramatic reduction of cost making the laboratory disposable, if needed;
- stunning reduction of sample volume needed from milliliters to nano- and picoliters;
- major reduction of test time from hours or days to minutes.

The functionality that can be provided on-chip can integrate pumps, channels, fluid mixers, and separators, and optical, biological, and chemical detectors (Figure 7).

The idea of a microminiature, mass replicated, chromatograph-style analyzer is not new and its various parts

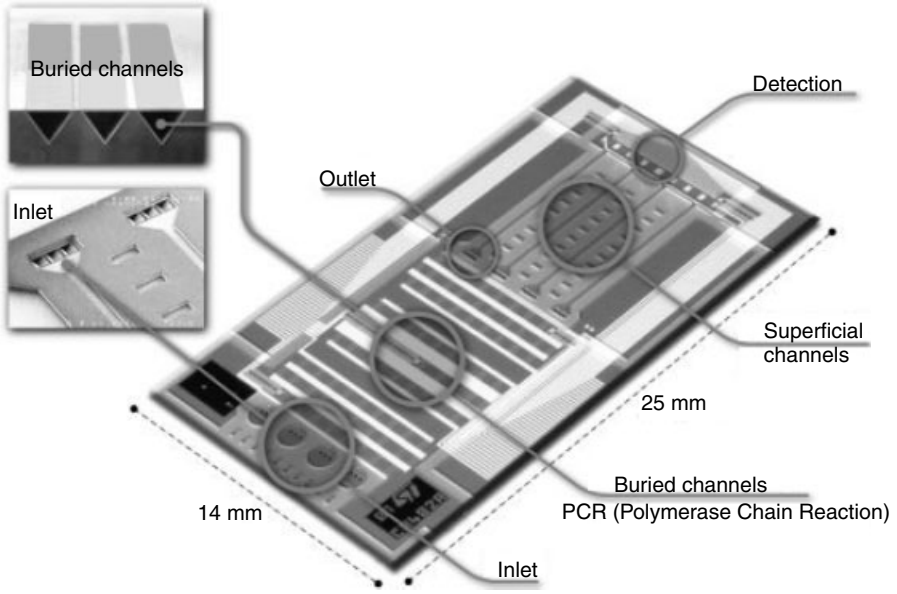

Figure 7. Lab-on-chip example includes micromachined inlets for sample introduction, buried channels for polymerase chain reaction processing DNA and detectors. (Copyright © ST Microelectronics.)

have been demonstrated. This is clearly another area of sensing that will take on many a new application once these microminiature forms are available at low price with satisfactory performance.

1 DEFINITION OF AN MEMS ACTUATOR

An actuator converts one of many forms of energy into a motion or force. MEMS actuators are microminiature integrated devices, for example, converting electrical energy into a deflection.

Actuators find use in measuring systems as devices that can balance a known force against an unknown force, thus enabling a measurement to be obtained from the input force voltage or current – *see* **Article 113, Force-feedback Sensors, Volume 2**. They also are found as driver mechanisms in printer heads, plotters, and printers. This article describes the microminiature forms used in MEMS devices; *see also* **Article 162, Principles of MEMS, Volume 3**; and **Article 163, Uses and Benefits of MEMS, Volume 3**.

Five basic control actuators have been developed for MEMS devices:

1. Electrostatic
2. Magnetic
3. Piezoelectric
4. Thermal
5. Optical

These are discussed in turn.

2 ELECTROSTATIC ACTUATION

These are formed in the archetype version as two electrically conducting plates held apart with insulating supports. Voltage is applied across the plates. It is essentially a capacitor.

The forces of electric fields are inversely proportional to the square of the distance between the plates forming the capacitor. As the device is made smaller, this force becomes significant enough to provide displacement. Electrostatic actuators, however, still provide very low drive energy; they became a dominant approach for MEMS actuation as they involve electric fields. Such drives require a relatively high drive voltage (20 to 500 V) to be effective. Predominately, electrostatic actuators are implemented in two types: parallel plate and comb drive.

2.1 Parallel-plate electrostatic drive

The parallel-plate actuator uses parallel electrodes to form the capacitor structure. At least one electrode is suspended on a spring support such that it can change position in response to the applied voltage differential connected across the insulated plates.

Figure 1 illustrates this concept. The electrode with voltage $V1$ is suspended on a spring allowing its rotation. Stationary electrodes with voltages $V2$ and $V3$ create differential forces F_{1-2} and F_{1-3} that try to rotate the upper

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

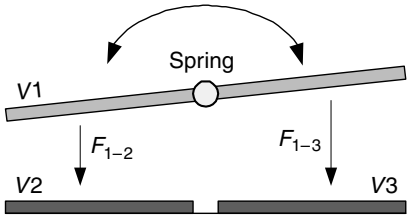

Figure 1. Concept of parallel-plate electrostatic actuator.

electrode. As electrostatic force is only positive, the rotation will be in a direction of the larger of the $V2, V3$ voltages.

The equilibrium of a simple system can be found by equating the electrostatic force F_e with the restoring force F_r provided by the spring constant of the system:

$$F_e = \frac{\varepsilon V^2 A}{2d^2} = F_r \tag{1}$$

where

- ε is the dielectric constant for the substance between the electrodes,
- A is the area of the plates,
- d is the gap height between the electrodes at the zero position, and
- V is the difference voltage applied to the electrode set.

The electrostatic force F_e varies as the voltage squared and the inverse of the gap squared.

However, the restoring force F_r of the spring varies linearly with the change in gap. Because the electrostatic force increases much faster than the restoring force, it can be shown that this system is unstable in the open-loop control mode at less than one-third of the gap height. After that point, the parallel-plate actuator will pull in, or snap down to the electrode.

Parallel-plate actuators have the advantage of being simple to fabricate. They require only an electrode (typically metal) and the conductive actuator. Many applications of electrostatic actuators have been demonstrated including microgrippers, microrelays, micromotors, cantilevers, optical shutters, variable optical attenuators (VOAs), and micromirrors (Figure 2).

2.2 Comb drive

Comb drives were developed to reduce the drive voltage, improve drive linearity to voltage and eliminate the snap-down effect in plate actuators.

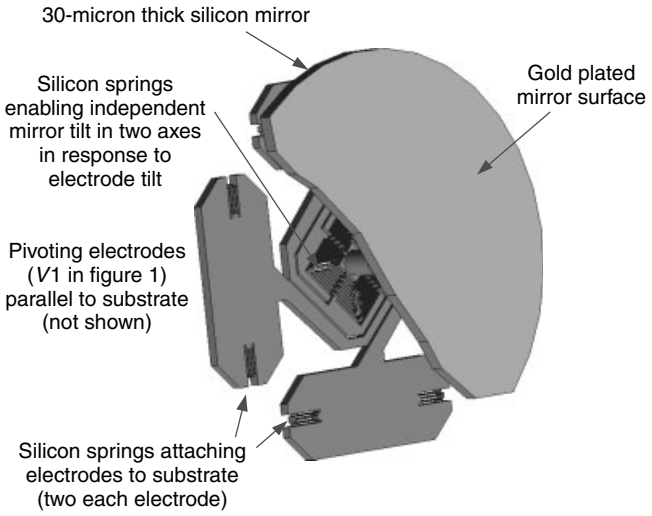

Figure 2. Integrated micromirror with parallel-plate electrostatic actuator. (*Source*: Transparent Networks, Milpitas, CA.)

The force F_x generated by applying a voltage across a comb structure can be expressed as

$$F_x = \frac{\varepsilon V^2 h}{2g} \tag{2}$$

where

- ε is the dielectric constant for the substance between the electrodes pairs,
- h is the height of the comb,
- g is the gap between fingers, and
- V is the applied voltage.

Unlike the parallel-plate capacitor, the gap between comb fingers does not change as the combs slide together. The force generated is solely a function of the fabricated geometry and the applied voltage, not the position of the combs. This simplifies the actuator response and control.

Interdigitated finger or comb drives were first introduced as lateral comb drives in surface micromachined polysilicon. The comb drive pictured in Figure 3 was produced at Sandia National Labs and is now available through the standard SUMMiT™ V process. Comb drives have also been made in bulk silicon by deep reactive ion etching (DRIE).

A second variation on the comb drive design is vertically asymmetric combs where differences in height and lateral restriction cause the comb structures to move vertically rather than laterally. This is less common because it is much more difficult to fabricate.

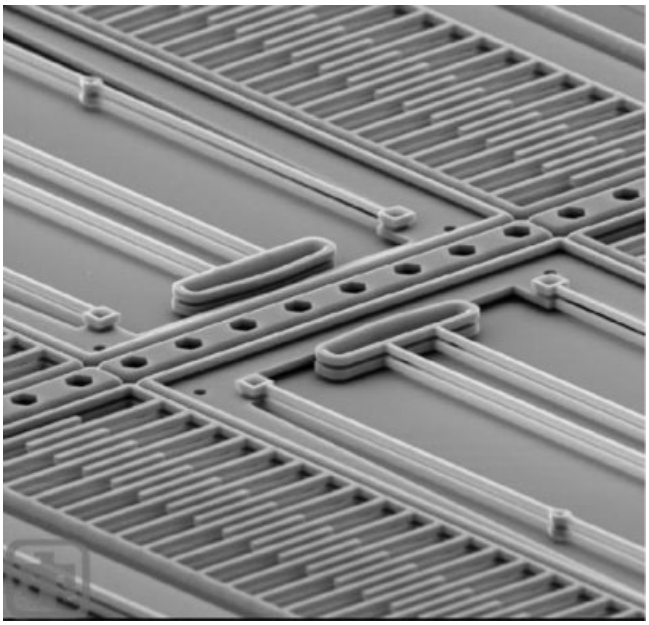

Figure 3. Shown is the lateral comb drives of a three-layer polysilicon microengine. The springs in the center provide the restoring force. (Courtesy Sandia National Laboratories, SUMMiT™ Technologies, www.mems.sandia.gov.)

3 ELECTROMAGNETIC ACTUATION

In the electromagnetic form of actuator, an electromagnetic field generates force that causes motion. This is done by passing current through a conductor to generate a magnetic field.

These can be formed in many styles in traditional designs but they are more challenging to implement in the MEMS form, as very few MEMS foundries offers a suitable fabrication process. A typical implementation involves a blanket magnetic field across an entire MEMS device with a patterned loop-generating field locally. Unlike electrostatic devices, electromagnetic devices typically require a constant power dissipation to hold a position.

For a current carrying coil in a uniform magnetic field, two important aspects of the electromagnetic form of actuator exist.

The first is that the torque of a rotational form is linear with input control coil current and decreases as the dipole from the coil and the magnetic field move into alignment (Figure 4). Consequently, unlike the capacitor form, there is no instability point in controlling the rotation of a magnetic actuator.

There is, however, zero net force in a homogeneous magnetic field. Producing a net force on the actuator requires more complex engineering of both the mechanics of the actuator and the gradients of the field.

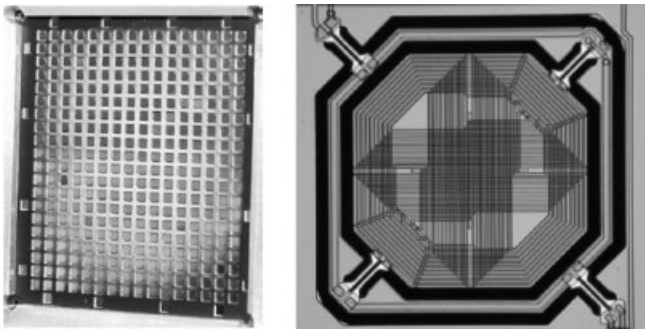

Figure 4. 320-mirror array and patterned control coils under each mirror. (Copyright Corning.)

4 PIEZOELECTRIC ACTUATION

Piezoelectric actuators rely on the piezoelectric transducer (PZT) effect whereby the application of an electric field causes a material to exert a force along the axis of the electric field (Figure 5).

Displacements obtained from piezoelectric materials are typically very small. Changes in dimension range from 10^{-10} to 10^{-7} cm/V and several hundred volts are usually required to achieve adequate displacement. They are often used as part of bimorphs or other leveraging structures to increase the effective travel.

The force generated by applying a voltage across a piezoelectric material can be derived from

$$F = \frac{V\varepsilon_0\varepsilon_r A}{\ell d} \tag{3}$$

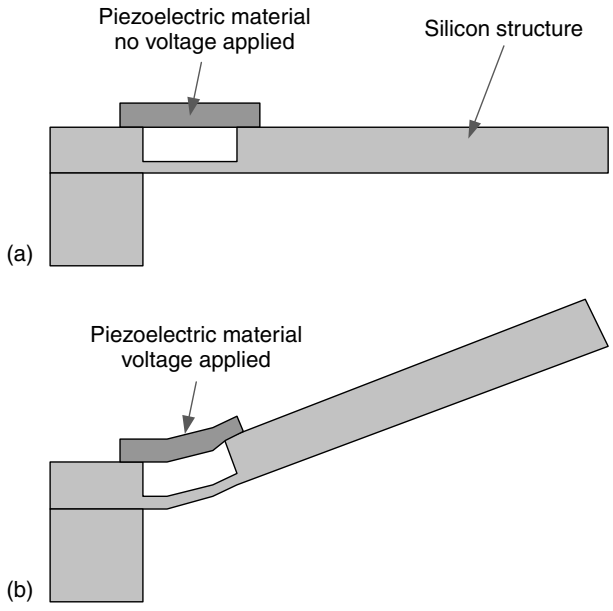

Figure 5. Principle of piezoelectric actuator.

where V is the applied voltage,

ε_0 is the permittivity of free space,
ε_r is relative permittivity for the substance between the electrodes,
A is the area of the electrodes formed on the PZT material,
ℓ is the length of the material (along the axis of the field), and
d is the piezoelectric constant.

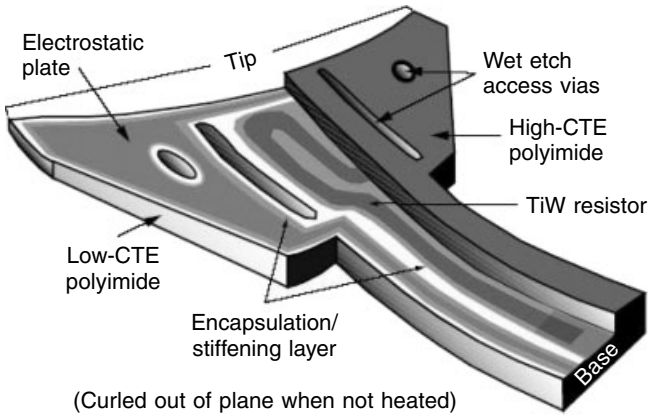
The piezoelectric constant d, and hence the amount of force generated, is dependent upon the crystalline axis of the material. To give an idea of the size of parameters involved, for the commonly used lead zirconate titanate PZT material, d in one crystal direction of cut is 370 pC/N. For more detail on PZT materials and their application, *see* **Article 118, Ultrasonic Sensors, Volume 2**; and **Article 119, Ultrasonic Instrumentation Principles, Volume 2**.

One application where piezoelectric microactuators have been used extensively is for precise positioning of hard disk drive heads (Evans, Griesbach and Messner, 1999).

While the small displacement makes them difficult to use for some applications, the precision achievable is ideally suited for positioning within tracks, especially as hard disk drives reach for submicron track width. Typically, piezoelectric actuators are the second stage of a multistage head where the gross positioning is done with a voice coil actuator. The control requirements for this application are very demanding and extensive research has been done in this area (Oboe, Beghi and Murari, 1999).

One of the newest areas for piezoelectric actuators is energy scavenging for wireless sensors. With a proper design, vibration can be on-chip converted into voltage with a power on the level of single μ W to mW, depending on the chip size.

5 THERMAL ACTUATION



Thermal actuators take advantage of material expansion in a material due to heating, generating the force for actuation. While it would be possible to use this simply, a more effective use of thermal actuation involves pairing two materials of dissimilar coefficient of thermal expansion (CTE) into a thermal bimorph. As the structure is heated, the CTE mismatch causes strain between the layers, which if unconstrained along an axis, will cause motion. The force exerted by a temperature change in a material can be quite considerable for the small displacements generated.

An example of this implementation is the ciliary array produced by Suh *et al*. (1999) (Figure 6). A TiW heater was sandwiched between two layers of polyimide selected to have severe CTE's mismatch (50 and 2 ppm/C respectively). The chip achieved a 95-μm vertical displacement, generating 23 μN of force. In addition to the thermal actuator, each cilia element had a plate that was used for an electrostatic hold down.

Thermal actuators have the disadvantage of high static power dissipation. They also typically exhibit relatively slow time constants.

6 OPTICAL ACTUATION

Optical actuation is a relatively new approach. One of the first approaches was presented by Zook *et al*. (1995), wherein optical energy was used to power the resonant beam with a very high Q (Figure 7). The beam located on a diaphragm was stressed by pressure, generating a high accuracy conversion of pressure to frequency.

1 COMPUTER-BASED INSTRUMENTATION

Instrumentation using machine information processing improves the versatility of the equipment so that it enhances the abilities of humans to perform information-handling operations.

Although all instrumentation involves some processing of information by machine, intelligent instrumentation involves some machine functions beyond basic information processing. Hence, processing operations such as interpretation of complex data, reasoning, learning, inference, or any operation associated with Artificial Intelligence or Knowledge Expertise must be included before instruments may be termed *intelligent – see also* **Article 160, Smart Sensor System Features, Volume 3**.

Computerized measurement systems (Lang, 1987; Lang, 1991) do not differ essentially from other measuring instruments. Using special instrument interfaces for communicating with a computer is the main difference (Iotech Inc., 1991; Maine, 1986; Senbon and Hanabuchi, 1987). The task of the computer is to schedule and command the instruments and then to perform any further processing of the measurement data. As a computer has a large processing capacity, several instruments can be connected to the computer simultaneously using different connection structures (*see* **Article 166, Instrument Interconnection, Volume 3**). In the same way as inside a computer or microprocessor, a bus structure is used to reduce the wiring and the number of interface circuits. These buses also use asynchronous or synchronous transfer protocols (*see* **Article 167, Asynchronous and Synchronous Interface Protocols, Volume 3**). The instruments are all connected to the bus in parallel. To transport the data in an orderly fashion, each instrument is equipped with a more or less intelligent interface.

Communication of data is an essential enabling component of all measurement systems. It provides the essential core of technology, which permits both local and remote distribution of information. It is only possible to give a general background of this topic, as it is relevant to measurement systems.

2 DATA COMMUNICATION STANDARDS

In the application of computers to measurement, the measurement system must quickly convert input data to processed output results. Hence, a high priority is placed upon real-time processing. Progress in microprocessors, as well as the technologies applied to them, has advanced the intelligence and decentralization of measurement systems. These advances are responsible for the increased importance in measurement of data communication technologies (Duck, Bishop and Read, 1996; Marshall, 1980)

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

that allows high-fidelity communication of the required data in real time.

Data communication can be described as the linking of equipment such as measuring instruments and control devices by means of communication lines, through which digital data is mutually transferred with good efficiency and with fidelity according to certain predefined procedures. To send correct data to the destination system, the communication circuits in both the data source and the data sink systems require the same methods and specifications. These include the types of communication cables and connectors, the electrical characteristics of the signal, the signal delivery procedure and the method of expressing the data. Simplification of the overall aims of the interconnection is achieved by the following standardized methods and specifications for hardware, software, signal definitions and communication protocols.

One of the most frequently applied approaches is the generalized set of standards known as the *open systems interconnection*, or OSI, basic reference model (Iotech Inc., 1991; Duck, Bishop and Read, 1996) created by the International Organization for Standardization, or ISO. As shown in Table 1, the OSI model classifies all the functions that are indispensable for data communications into seven layers, ranging from the physically implemented hardware layer, which includes the function of converting data to an electrical signal for the transmission line, to the software implemented application layer. This layer includes application-oriented functions such as methods of expressing messages and file transfer procedures. In addition, the functions of each layer are defined and serve as guidelines for standardization. Nevertheless, the boundaries between these layers are sometimes not clear. A system that implements all of these layers is called a *high-level interface*. Many other interface definitions omit many layers.

Table 1. OSI reference model.

Layers	Label	Function
Layer 7	Application	Provides all services directly comprehensible to application programs
Layer 6	Presentation	Restructures data to/from standardized format used within the network
Layer 5	Session	Synchronizes and manages data
Layer 4	Transport	Provides transparent, reliable data transfer from end node to end node
Layer 3	Network	Performs packet routing for data transfer between nodes
Layer 2	Data link	Improves error rate for frames moved between adjacent nodes
Layer 1	Physical	Encodes and physically transfers bits between adjacent nodes
Physical medium		Transmission line

There are several defined standards relating to both serial and parallel transmission. Serial signal transmission, which can be used for much more distant communication than parallel transmission, is very commonly applied in telemetry systems. Factors to be taken into account are

1. data rate
2. transmission distance
3. immunity to interference and noise and
4. the number of multiplexed signals over one link.

Well-known serial communication specifications are

1. EIA/TIA 232 E, also known as RS 232, RS 449, RS 422 and RS 423 (Axelson, 1996; Campbell, 1989; Iotech Inc., 1991; Lang, 1987; Maine, 1986; Seyer, 1991), *see* **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**;
2. 4–20 mA current loop (Jordan, 1995; Lang, 1987; Michalski *et al*., 2001), *see* **Article 169, Voltage and Current Loop Transmission, Volume 3**;
3. CCITT Consultative Council on Information Technology Transfer (Europe) V24;
4. Fieldbus (Burton, 1995; ISA, 1997; Verhappen and Pereira 2002) and its automation version PROFIBUS (Bender, 1993).

Equally well-known parallel communication specifications are

1. IEEE-488 (Caristi, 1989; Colloms, 1983; IEEE, 1987; Iotech Inc., 1991; Lang, 1987; Senbon and Hanabuchi, 1991)
2. VMEbus/VXIbus (Heath, 1994)
3. SCSI, IDE and ATAPI. (Schmidt, 1998).

The RS 232 serial communication standard is considered in **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**. The IEEE-488 standard is described in **Article 170, IEEE-488 Instrumentation Bus, Volume 3**. Voltage and current loop transmission is described in **Article 169, Voltage and Current Loop Transmission, Volume 3**.

On the other hand, there are also many widely used communication networks and protocols, which do not entirely conform to international standards. One such example is the Systems Network Architecture, or SNA, which has been the

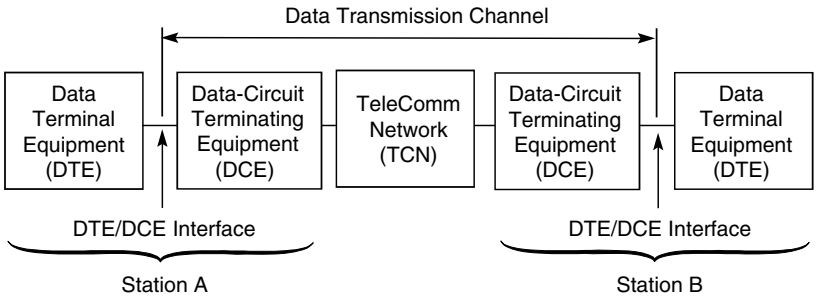

Figure 1. A data transmission channel showing the various subsystem blocks.

IBM Corporation standard network since 1974. It is also used worldwide.

There are many examples of practical optical communications systems. This is another area in which standardization is proceeding slowly. In any case, when the use of nonstandard protocols is unavoidable, it is necessary to make detailed preparations and carefully design for stability and reliability.

3 DATA COMMUNICATION EQUIPMENT

Figure 1 illustrates the various parts of a channel for data transmission. There are three main elements of such a channel. Data terminal equipment, or DTE, includes terminals or computers. Data circuit terminating equipment, or DCE, interfaces between the DTE and the telecommunications network, or TCN. DCE includes modems, packet switched networks, connection pads, and statistical multiplexers among others. The TCN may be circuit switched, packet switched, or private leased line. Circuit switched networks route connections through fixed paths selected by switches. In packet switched networks, each data message is subdivided into a number of separate blocks, or packets, of data.

Some terminology associated with data communications requires explanation. When data can only be transmitted or received, the exchange of data is called *simplex* operation. *Half duplex* is an extension of the simplex method, which allows both transmission and reception but not simultaneously. When the data transmission channel can transmit and receive simultaneously, it is said to be operating in *full duplex*.

The *modem* (Duck, Bishop and Read, 1996) is a hardware unit that can modulate and demodulate signals. It is often used as a simple and convenient way to make a fixed connection between two, probably remote, devices. Introducing a modem between devices equipped with the RS 232 interface, described in **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**, allows extension of the transmission distance. There are different types of modems. The telephone protocol of the modem is governed by the following special signals:

1. REQUEST TO SEND, or RTS, and CLEAR TO SEND, or CTS, are used in *half-duplex* telephone lines. In this operating mode, traffic can be bidirectional, but the telephone line can only send in one direction at a time. When the computer is ready to transmit a character, it signals the modem with RTS. Transmission will be achieved only when the computer receives a CTS signal coming from the modem.
2. The CTS and RTS lines are held at a constant voltage in *full-duplex operation.* In this mode, transmit and receive functions can be performed simultaneously on independent wires.
3. DATA SET READY, or DSR, indicates that the modem is operational.
4. DATA TERMINAL READY, or DTR, indicates that the equipment on the opposite end, such as a computer or terminal, is operational.
5. CARRIER DETECT and RING INDICATOR are related to the telephone network functions. CARRIER DETECT indicates that the remote connection is normally active.

4 DATA COMMUNICATION METHODS

Representing the many data communication methods, in terms of communication distance versus communication speed results in Figure 2 (Senbon and Hanabuchi, 1991). Although the grouping looks clearly defined in the diagram, it is much looser. Nevertheless, the following rough classes, or categories, can be distinguished:

1. communication between devices in close proximity;
2. communication between devices at intermediate distances;
3. communication between devices at large distances.

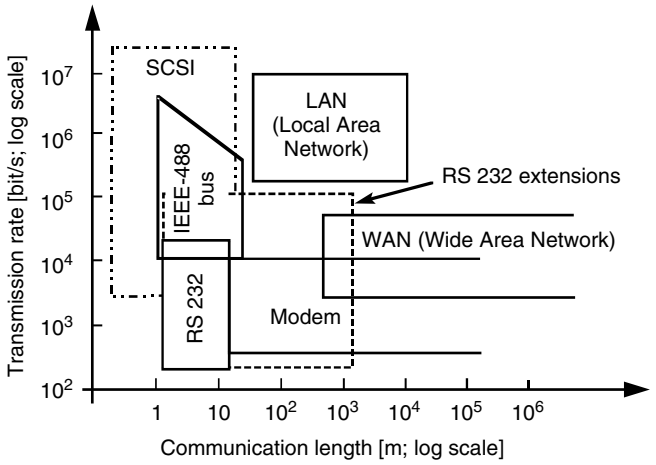

Figure 2. Performance ranges of different instrument interfaces.

It is not possible to give precisely defined divisions between the three classes given above. However, it can be seen that the SCSI, RS 232, and IEE-488 interfaces can be regarded as in close proximity over distances up to about 50 m. Distances from 50 m up to about 10 km, which normally use local area networks (Anderson and Minasi, 1999; Hodson, 2001; Thompson, 2000) and extensions to RS 232, can be considered as intermediate distance communication systems. Wide area networks, whose lower distance range lies within the upper limit of the intermediate distance range, are generally considered as most suitable for distances between about 800 m and more than 1000 km.

5 COMMUNICATION AT CLOSE PROXIMITY

Within testing laboratories and other closely integrated locations, automatic measurement and data processing is often carried out with various measuring instruments connected to a computer. The IEEE-488 parallel instrument bus, specified by the Institute of Electrical and Electronics Engineers (USA), is widely used for such purposes. It is compatible with the specification for the IEC-625 bus, specified by the International Electrotechnical Commission, or IEC. IEEE-488 allows easy reconfiguration of the system for various experiments because instruments can be easily connected to and disconnected from the system. The Computer Automated Measurement and Control Equipment, or CAMAC standard, which is used for roughly the same purposes as IEEE-488 and IEC-625, has been established in the atomic power field.

Another possibility is to use the VERSAModule Eurocard, or VMEbus, which was originally specified by Motorola as the VERSAbus. Later, extensions to the VMEbus were incorporated in the 1987 specification for VXIbus, which is an acronym for "VMEbus eXtensions for Instrumentation". Although VXIbus expands on VMEbus, it has an open architecture, including features of IEEE-488. It is useful for automated test systems and data collection. The issue of electromagnetic radiation is part of the VXIbus specification.

Small computer system interface, or *SCSI*: This interface contains specific design features to permit communication between small computer systems and their peripherals. It was first standardized by the American National Standards Institute, or ANSI, in 1986, although it was originally developed by Shugart as Shugart Associates System Interface, or SASI. It has now reached the third revised version.

All IBM compatible personal computers possess what is commonly called the *AT-Attachment*, or ATA interface. It is also widely known as the *Integrated Disk Electronics*, or IDE interface.

Its development, which began in 1984 with the support of Compaq, grew out of the desire to embed the hard disk controller of IBM AT compatibles on the hard disk itself. By 1988, ANSI began its involvement, which led to the approval of a standard. This resulted in the IDE interface being renamed as the ATA in 1994. Subsequent developments resulted in ATA-2 in 1995. The ATA Packet Interface, ATAPI standard, which was developed to allow components other than hard disks to operate under the IDE interface, was developed in parallel with ATA-2. Although it will be well known to many users of CD-ROM technology, it may also be used for other peripherals. It is a combination of SCSI and IDE. Lately, ATA-3 has evolved to offer new commands as part of the ATA interface. It is intended that ATA-4 and ATAPI will be integrated.

SCSI, IDE, and ATAPI will not be considered further.

EIA/TIA 232 E, or *RS232*: This very widely used serial interface, which was originally supervised by the Electronic Industries Association, or EIA, later was supervised jointly by EIA and Telecommunication Industries Association, or TIA, in the United States. Since 1997, EIA changed its name to Electronic Industries Alliance, an alliance of five trade associations representing the most dynamic and fastest-growing industry in the world. It is commonly used for connection of computers to terminal equipment such as CRT (cathode ray tube) terminals and printers, connection of various types of measurement instruments and automation machinery such as robots and numerically controlled or NC, machines. To overcome the limitations of the RS 232, it is now common practice to use the RS 422, RS 423 and RS 485 standards as an extension of the RS 232 for longer distance communication at higher data rates. These

RS 232 extensions are described in **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**.

6 INTERMEDIATE DISTANCE COMMUNICATION

In the field of measurement and control, local area networks (Anderson and Minasi, 1999; Duck, Bishop and Read, 1996; Hodson, 2001; Thompson, 2000), or LANs, are the most important method for data exchange. PROWAY, or Process Data-way, is a widely used standard, specified by the IEC. It is a means of highly reliable, high-speed data exchange between the operator console and multiple dispersed field measurement and control units. In a distributed control system, these may be computers, control devices, terminals and other distributed equipment at distances up to 10 km.

Recently, the demand for total network integration of production information systems, at both the line and corporate enterprise levels, has become high. For this reason, the Manufacturing Automation Protocol, or MAP, which is a factory LAN, is being used increasingly by many enterprises in the United States, Europe, and Japan. MAP, which also conforms to OSI, is under the primary leadership of the General Motors Corporation. MAP and PROWAY are both receiving wide attention as a means of integrating dispersed equipment in various environments such as offices, research centers, and factories.

7 LARGE DISTANCE COMMUNICATIONS

When instruments are to be connected over large distances through commercial communication systems, the network is frequently referred to as a *wide area network* or WAN (Duck, Bishop and Read, 1996). Data is transmitted over the communication lines in the form of data blocks called *packets*. Information on the destination and packet sequence number are included in the packet. Thus, the communication circuit utilization efficiency is very high because many users can share a circuit. This method can be used for on-line transmission of orders, production plans, and other information from the head office to distant factories.

1 GENERAL ISSUES OF INSTRUMENT INTERCONNECTION

Main forms of interfacing allow serial or parallel information distribution. A typical minimum configuration set for computerized instrumentation is shown in Figure 1. These systems consist of components, boards, and peripherals. Components within the computer have direct access to the processor bus of the system. Extension boards, which are located within the computer housing, have access to the back plane or system bus of the computer. Bus extension means that an external box may also be connected to the PC by only one slot. Bus length is usually limited to a maximum of 2 m.

Versatility is achieved by three main kinds of communicating boards. General Purpose Input/Output (GPIO) boards acquire signals of diverse types such as status, alarm, control, analog, and set points. The IEC bus (International Electrotechnical Commission), also known as IEEE-488 or General Purpose Interface Bus (GPIB), is a peripheral bus system. It allows up to 15 devices to operate together at distances not exceeding about 20 m. It is highly suitable for laboratory automation. Serial connections allow operation over a wider distance. Hence, it is suitable for single buildings or factory floors. It is also versatile in data communications for Local Area Networks, or LANs, and Wide Area Networks, or WANs. Front-end subsystems are flexible, versatile, and economical for measurement systems.

2 PARALLEL AND SERIAL TRANSFER

Instruments may be connected for either parallel transfer of data or serial transfer of data (Maine, 1986). These two possibilities are illustrated in Figure 2. Serial data is passed between devices by using either asynchronous data transfer method or the synchronous data transfer method – *see*

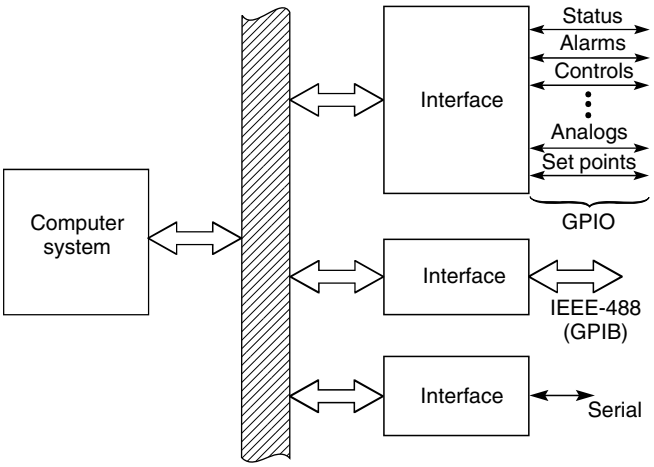

Figure 1. Microcomputer with a minimum equipment of interfaces for intelligent measurements. (GPIO: General Purpose Input/Output; GPIB: General Purpose Interface Bus, identical with IEEE-488).

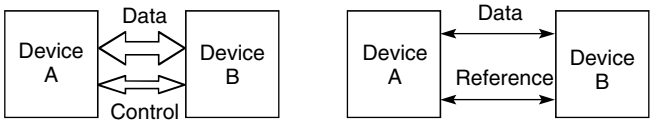

Figure 2. Parallel and serial instrument interconnection.

Article 167, Asynchronous and Synchronous Interface Protocols, Volume 3.

3 BUS AND LOOP CONFIGURED INSTRUMENT INTERFACES

When more than two instruments are interconnected, the configuration may be either a bus connection or a loop connection as in Figure 3. The data transfer is usually bit parallel byte serial in the bus system, where the limiting factor is the signal path length. Each device has equal access to the data. In the loop structure, where the data transfer is normally serial, the limiting factor is the loop transmit time. Information passes from device to device. The system is low power, with a higher reliability, as there are normally only two wires.

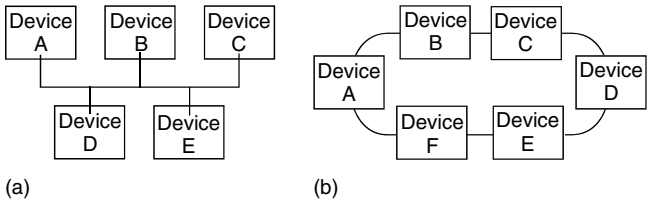

Figure 3. Instrument configuration: (a) bus structure and (b) loop structure.

Some systems employ analog voltage or current loop systems for communication. These have been in use for decades and are still good choices in some circumstances. The life of these is being extended by gradual take-up of digital communication methods. They are covered in **Article 169, Voltage and Current Loop Transmission, Volume 3**.

Designers of communicating links usually simply specify proprietary circuits boards for this. In use, they need setting with some hardware toggles and within the operation software.

1 ASYNCHRONOUS PROTOCOLS

A protocol is a mutually agreed arrangement for initiating and maintaining a connection in a communication network (Duck, Bishop and Read, 1996; Marshall, 1980). There are asynchronous protocols or synchronous protocols. The asynchronous protocol is mainly used in serial communication systems. Three hardware connections commonly used in serial communication (**Article 165, Introduction to Networked Instrumentation, Volume 3**) are

- EIA/TIA 232 E, previously known as RS 232 and still widely referred to as such, with its extension possibilities embodied in the RS 422 A, the RS 423 A, and the RS 449 – *see* **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**;
- 4–20 mA current loop – *see* **Article 169, Voltage and Current Loop Transmission, Volume 3**;
- CCITT V24, which is more common in Europe;
- Fieldbus.

The Recommended Standard, or RS, which refers to the published standards of the Electronic Industries Alliance, or EIA, of the United States, can use asynchronous signals with the general timing for the character structure illustrated in Figure 1(a). In this figure, the idle state is assumed to be in a high state or '1'. Data is handled in units of one character, which may have 6, 7, or 8 bits.

A character is delimited with an appended starting '0' level bit, followed by 8 data bits, then followed by one and a half or two successive '1' bits. Note that data are always transmitted with the least significant bit first. One of the 8 data bits is a simple error-checking bit, termed the *parity bit*. It is used to make the total number of '1' bits in the character always odd or even, depending on whether odd parity or even parity is required. The bit interval is defined with a fixed period controlled by a local clock in the transmitter and receiver.

The receiving device recognizes the beginning of the character by detecting the start bit. From that time it reads each bit making up the character at fixed time intervals, determined by the transmission speed.

2 AMERICAN STANDARD CODE FOR INFORMATION INTERCHANGE (ASCII)

The seven character bits in Figure 1 are assigned according to the American Standard Code for Information Interchange, or ASCII system, which is also known as *American National Standards Institute*, or ANSI, standard X3.4-1977.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

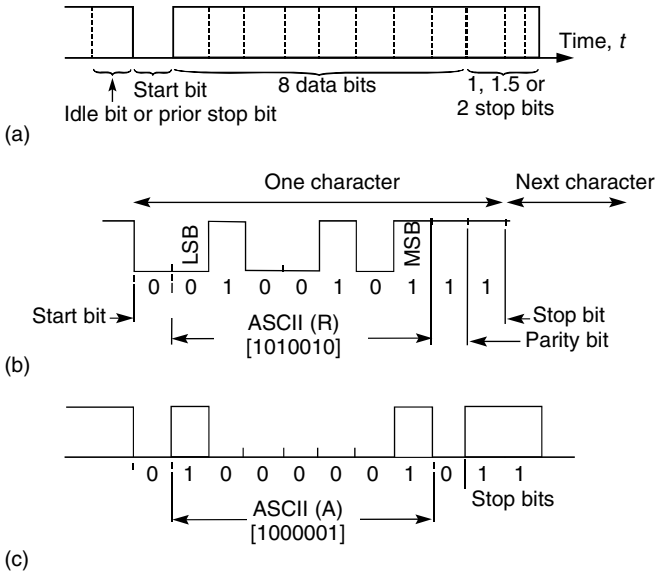

Figure 1. Asynchronous data: (a) character structure showing location of 'idle', start, data, and stop bits; (b) representation of letter 'R' in ASCII; and (c) representation of letter 'A' in ASCII.

This code, which uses 7 bits/characters, covers a range of 128 characters. Thus, the code represents all of the upper and lower case letters, the numerals 0 to 9, punctuation marks, and 32 nonprintable, or control, characters. Another encoding scheme applies to information other than text. For example, the IBM PC extends the ASCII character set from 128 to 256 characters using the binary encoding scheme. This allows representation of non-English alphabets and special graphic characters.

The ASCII code for the letters R and A are shown for illustrative purposes in Figure 1(b) and (c) respectively. Note that the time patterns are written with the least significant bit, or LSB, first in both cases. The *start* and *stop* bits, which identify the beginning and the end of each data character, also allow the receiver to synchronize a local clock to every character. Signaling frequencies can be 300 Hz, 1200 Hz up to 19.2 kHz.

3 SYNCHRONOUS INTERFACE PROTOCOLS

Synchronous protocols, which are intended to allow communication at very high speed, are characterized by the presence of a synchronous clock designed to control character-to-character timing within a stream of characters. Thus, they present numerous advantages over the asynchronous standards. As start and stop bits are eliminated, the bandwidth for data transmission is widened. Data are made up of a number of characters into units of character

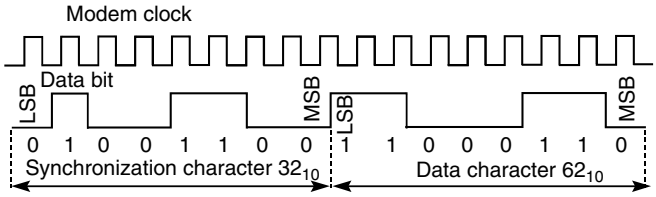

Figure 2. Synchronous data character structure.

strings. As shown in Figure 2, no start bits or stop bits are added as is done when the transfer unit is one character. Bit position is detected by synchronization with a special clock signal. Characters are distinguished by detecting a special synchronization character at the head or in the middle of the character string. Bits are then counted as the data is received.

Communications can be achieved at higher bit rates over longer distance than in the asynchronous protocol described above. Asynchronous links run at a maximum speed of 19.2 kHz, while a synchronous link can easily run at about 500 kHz or higher. However, proper electrical connections are required to attain very high data rates. For instance, the use of a double-ended transmitter/receiver such as an RS 422 interface is recommended.

Block-oriented synchronous protocols allow the inclusion of control and redundancy information in the communication link. The receiver locks onto the frequency of the received data through a phase-locked loop located at the input of the synchronous I/O port. This extracts the received clock from the received data stream. The receiver is synchronized to the beginning of a character by an additional logic, which may be different from protocol to protocol.

After character synchronization, the receiver then divides data bits into 8-bit characters, with character-to-character synchronization established in the same time with block-to-block synchronization. The interface consists of shift registers and buffer registers to achieve conversion between parallel and serial data. Typical synchronous interfaces use three registers in a queue known as a *first-in-first-out*, or FIFO, structure.

The three widely used protocols are the Binary Synchronous Communications Protocol, or BSC, the Digital Data Communication Message Protocol, or DDCMP, and the High-Level Data Link Control, or HDLC (Duck, Bishop and Read, 1996).

Only the BSC protocol (Senbon and Hanabuchi, 1991) and the HDLC protocol (Duck, Bishop and Read, 1996; Senbon and Hanabuchi, 1991) will be considered here because they are easily realizable.

4 BINARY SYNCHRONOUS COMMUNICATIONS PROTOCOL

This protocol, which has been primarily used in IBM equipment since 1960, operates in half-duplex transmission. In this protocol, one or two successive synchronizing characters are used to identify character and block synchronization. Character synchronization is achieved by a special pattern providing three operating modes with respect to character synchronization. These are external synchronizing mode, one-synchronizing character mode, and two-synchronizing character mode.

5 HIGH-LEVEL DATA LINK CONTROL PROTOCOL

A synchronous transfer method called the *High-Level Data Link Control Protocol*, or HDLC, has been standardized. This protocol, which was initially proposed by IBM, operates in full duplex. HDLC protocols are frequently used for point-to-point links. It is also used in wide area networks for connecting computers, where successive throws of transmissions may be interspersed by idle periods. As their serial bandwidth is high enough, it is possible to connect several synchronous devices together on one line in order to share the bandwidth.

The method uses frames of variable bit length as the data transmission unit rather than single characters or character strings. Character synchronization is maintained by a unique pattern at the beginning of a block.

The typical structure of the HDLC protocol, which appears in Figure 3, indicates that the *flag sequence*, or synchronizing pattern, 01111110, is placed at the beginning and end of the frame. These flags are used to detect the frame and the bit positions. Address and control information follows the opening flag. In the figure, the address represents the address of the secondary station corresponding to the main station, while the control information specifies the data frame type.

Initial flag	Address	Control	Information field	Frame check	Ending flag
01111110	1 byte	1 or 2 bytes		2 bytes	01111110

Figure 3. Typical structure of the data frame of the HDLC protocol.

When the data sequence contains many successive '1's, it is important to distinguish the *data sequence* from the *synchronizing sequence*. Hence, whenever the transmitter has sent five successive '1's, it inserts a false '0'. The receiver then has to remove the '0' located after the sequence of five '1's. The address and control information, consisting of 8 or 16 bits, generally contains a source and destination address and a sequence number.

After the address and control information, the next block can use the ending flag as its initial flag. The information block may have variable length. It is followed by a 2 bytes check, which has to determine if any errors have occurred in the previous transmission. When the transmitter runs out of data, an abort code, consisting of a sequence of eight '1's, is used.

When the transmission line is long, or in factory environments where there is much electrical interference, noise errors may be generated in the transmitted data. Thus, a means of detecting and correcting these errors is needed to allow transmission of correct data. In asynchronous transfer, a parity bit is added to each character unit of data. In the synchronous method, a check code that has a high error-detection power is appended to the end of each data unit. Using these features, the receiving side can detect whether there is an error in the data. If an error is detected, the receiving side issues a request to the transmitting side for retransmission. Coding, as this is, is covered in **Article 33, Coding Theory and its Application to Measurement, Volume 1**.

1 INTRODUCTION TO THE SERIAL DATA INTERFACE

Serial communication is the simplest, cheapest, and probably the most widespread type of communication method used between computers and other measuring instruments. Unfortunately, it is also the slowest because data are transmitted using one data line in a serial form.

This uses either an asynchronous protocol, or one of the synchronous protocols described in **Article 167, Asynchronous and Synchronous Interface Protocols, Volume 3**. Since computers handle their internal data in parallel, it is necessary to include some means of transforming any parallel data into serial form for subsequent serial transmission. It may also be necessary for any measurement instrument to reconvert the received serial data back to a parallel format.

A widely used serial data communications protocol is the *recommended standard*, or RS interfaces, which are specified by the Electronic Industries Alliance, or EIA, of the United States. The EIA was known as the *Electrical Industries Association* until 1997, when it joined with five other organizations to form the Electrical Industries Alliance.

The RS 232 standard was originally used for data communications on telephone lines with interfacing through a modem. Since the original development of this standard more than 30 years ago, the EIA has published three modifications. Initially, it provided a means for connecting remote systems together by the use of a telephone line as a transmission channel. In 1987, the EIA 232 D, also widely referred to as the RS 232 D, was issued as a revision of the 1969 specification for RS 232 C.

A little later, in 1991, the EIA collaborated with the Telecommunications Industry Association, or the TIA, in issuing a new version of the standard called EIA/TIA 232 E. Besides changing the name, some signal lines were renamed and various new ones were defined, including a shield conductor. In spite of the name change, it is still widely referred to simply as RS 232. It now broadly conforms to CCITT V24, V28, and ISO.

Nowadays, it is widely used in both terminal and computer systems. It may be used at distances up to about 15 m with data rates up to 9600 baud, or 20 000 bps. Terminals can be connected directly to computers through EIA/TIA 232 E ports. For remote connections, modems must be used through a telecommunications network similar in structure to that in Figure 1 of **Article 165, Introduction to Networked Instrumentation, Volume 3**.

Electrical conventions for RS 232, RS 422, RS 423, and RS 485 circuits, which are given in Table 1, show that the voltage levels are largely different from TTL and CMOS voltage levels. The RS 422 A, RS 423 A and RS 485 interfaces, which are extensions of the RS 232, are considered in more detail later in this article. For example, voltages in the RS 232 standard, which use negative, bipolar logic devices,

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Table 1. Typical electric specifications of RS 232, RS 422, RS 423, and RS 485.

Driver configuration	RS 232	RS 422	RS 423	RS 485
Connection mode	1 : 1	1 : 10	1 : 1	*n : n*
Txd–Rxd circuits				
Transmitter	Single ended	Differential	Single ended	Differential
Receiver	Single ended	Differential	Differential	Differential
Txd signal	±5 to ±15 V	±2 to ±6 V	±4 to ±6 V	±1.5 to ±6 V
Rxd signal threshold	±3 V	±200 mV	±200 mV	±400 mV
Transmission distance	15 m	1.2 km (100 kbps or less) (0.2 mm^2 twisted pair)	1.2 km (6 kbps or less) (0.2 mm^2 twisted pair)	1.2 km (10 mbps) (special cable)

are symmetrical with respect to ground. In this logic, a negative voltage signal represents logic '1', and a positive voltage represents logic '0'. This use of negative logic can be traced to the use of teletype machines in the 1950s, where a flowing current represented logic '1'. It should be noted that this negative logic used in RS 232, is different from the modern digital circuit convention. The standard also uses the terms 'Mark' and 'Space' to replace logic '1' and logic '0' respectively. Table 1 indicates 3 V for a logic '0' (or Space) and −3 V for logic '1' (or Mark). Practically, the voltage levels are ±15 V and ±5 V (TTL). It is necessary to use translator circuits for changing the voltage levels. More details appear later. These circuits must be able to accept TTL input level (logic '1' > 2 V, logic '0' < 0.8 V) and to produce RS 232 output levels. They are located in the transmitter output. Similar circuits also exist in the receiver input to transform RS 232 input levels into TTL output level.

2 RS 232 INTERFACE AND MODEMS

The word modem is an abbreviation for modulator–demodulator. These devices are used to extend the distance for remote communication routes. They perform different functions at the sending and receiving ends. Specialized modems for on-site communication lines are used to extend the distance between connected devices within a facility. Public communication line modems and private communication line modems can connect devices that are far apart on a one-to-one basis through lines provided by commercial communications enterprises. At the sending end, a serial digital signal is used to modulate an analog signal, using frequency modulation, for example, which is sent out on the communication circuit. The analog signal is detected and demodulated at the receiving end to reconstruct the original serial digital signal. Modems for connection to private or public communication lines must be authorized, approved, and must conform to standard frequency band and transmission power specifications. They must also be designed to transmit signals while avoiding external interference from adjacent communication lines. Modulation is covered in **Article 34, Modulation Theory, Volume 1**.

The interface between the modem and the devices it is connected to is standardized in terms of connectors, signal lines, electrical specifications, data exchange method, and timing. One such standard is the RS 232 interface.

The RS 232 interface can also be used for direct connection of devices within 15 m of each other, as well as for the widely used standard modem connection. For these reasons, it is standard equipment on many computers and control devices. As a substitute for the RS 232 interface for transmission without using a modem at relatively longer distances of the order of several hundred meters, depending on the cable diameter, the RS 422, differential type, the RS 423, single-ended type, and the RS 485, differential multidrop type, interfaces have been standardized, and their use is spreading. The electrical specifications of these interfaces are given in Table 1.

3 SPECIFICATIONS IN RS 232

RS 232 only defines specific characteristics of an interface between the DTE (Data Terminal Equipment), such as a computer or VDU (Visual Display Unit), and some sort of DCE (Data Circuit Terminating Equipment), such as a modem, packet switched network pad, statistical multiplexer, and so on. All of the different aspects of the standard are covered in four parts describing

- electrical signal characteristics,
- mechanical interface specifications,
- functional description of interchange circuits,
- standard interfaces for selected communication system configurations.

Electrical specification: The signal definitions of RS 232, illustrating pass and fail types of signal, are shown in Figure 1. These important characteristics mainly concern the signal levels, impedances, and rates of change, which are also covered in CCITT V28. RS 232 signals are characterized by their very large voltage swings, which are required for noise immunity on the transmission wire. For the maximum recommended cable length of about 15 m and

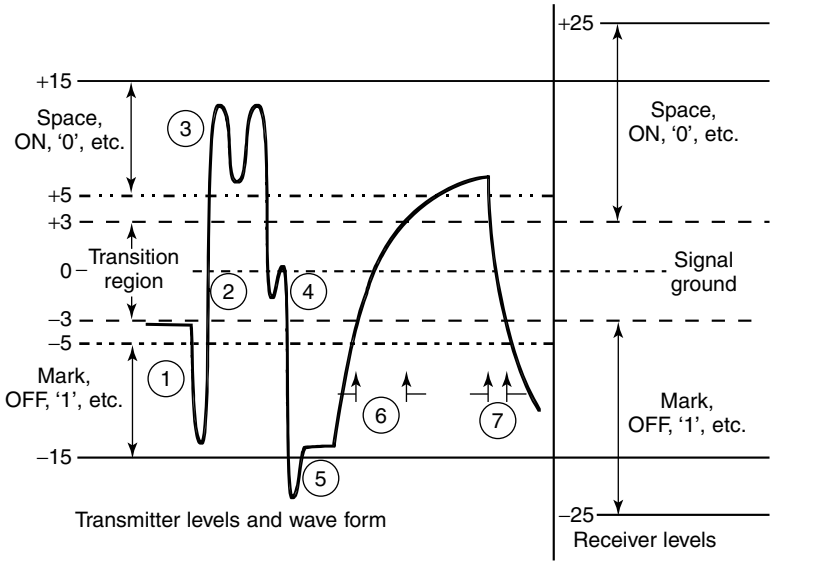

Figure 1. Signal definitions for RS 232 interface.

for these voltages, the standard is able to cover signaling rates up to 20 kHz.

Essentially, any voltage above +3 V is treated by a receiver as a logic '0', a space condition or an ON condition. A signal below −3 V is treated as a logic '1', a mark or an OFF condition. The band between −3 V and +3 V is an undefined transition region.

The generator, or driver, must provide a minimum of +5 V for logic '0', or a maximum of −5 V for a logic '1' at the interface point. Any level between these two, such as at point 1, is a 'fail' because the steady state is out of range. During a pass through the transition region, the dV/dt must not exceed 30 V μs^{-1}, otherwise, the condition, similar to point 2, is a 'fail'. Provided the level of interference, such as power supply hum in point 3, does not cause the signal to go outside the permitted steady state band, the interference level is acceptable.

An unacceptable level of interference is shown at point 5, where a voltage spike drives the signal outside its steady state band. In less than a certain time, the slope must not reverse during the transition as it does in the illustration at point 4, otherwise the transition is a 'fail'. This situation could arise if the duration of a transmitted bit is too short.

Other 'fail' and 'pass' conditions are shown at points 6 and 7 respectively. At point 6, the transition occurs too slowly, while at point 7 the transition, although slow, is still within the accepted tolerance on dV/dt.

Mechanical interface specifications: The specified connector in RS 232 is defined as a 25-way 'D' connector, with dimensions specified in the standard. The DTE connector shall have Male pin contacts and a Female shell, and the DCE shall have Female socket contacts and a Male shell as shown in Figure 2(a) and (b). The signal functions, which enable a fully interlocked handshake exchange of data between equipment at opposite ends of a communications channel, are also covered in CCITT V24. However, V24 defines many more signal functions than RS 232. Those that are common are compatible. Designated functions are associated with 22 of the 25 connector pins, although few, if any, practical implementations use all of them. A detailed discussion of all these signals is beyond the scope of this summary.

The most commonly used signals with the connector pin number in parenthesis, corresponding to Figure 2(c), are as follows:

- *Signal Ground* (7) – interface ground reference.
- *Transmitted Data* (2) from the DTE to the DCE. Data must be transmitted only when the modem compatible signals *Request to Send*, or RTS, *Clear to Send*, or CTS, DCE ready, or DCR, and DTE ready, or DTR, are all in the ON state. A common reason *standard* RS 232 devices fail to work together is that one implements only some of these four handshake signals, but the other is expecting them all.

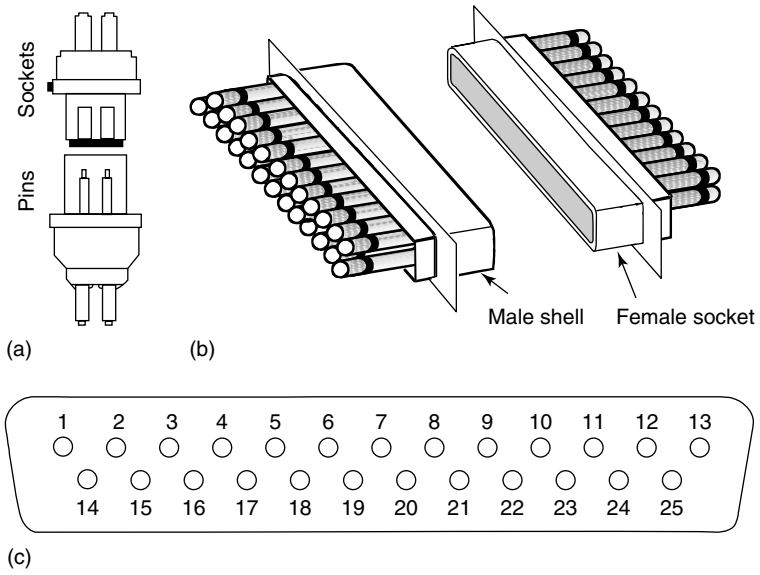

Figure 2. Mechanical specification for RS 232.

- *Received Data* (3) from the DCE to the DTE.
- *Request to Send, or RTS*, (4) – the DTE telling the DCE it wants to *transmit*. This is also used to control direction of communication in a half-duplex system.
- *Clear to Send, or CTS*, (5) – the DCE telling the DTE, in response to RTS and its own ready condition, that the DTE may transmit.
- *DCE Ready, or DCR* (6) – the DCE telling the DTE that it is connected to a communications channel and all dialing, talking, testing, and other operations are finished. This used to be Data Set Ready.
- *DTE Ready, or DTR* (20) – the DTE telling the DCE that it is ready to transmit or receive data.
- *Received Line Signal Detector* (8) – the DCE telling the DTE that it is receiving valid signals over the channel. Sometimes called *Carrier Detect*.
- *Ring Indicator* (22) – the DCE telling the DTE that a ringing signal is being received on the communication channel. Used in auto-answer systems. There are several other, less commonly used handshake functions, including lines to control synchronous communication timing.

All serial protocols operate on the basis that the receiver is ready to receive and identify transmitted data. The handshake timing must always ensure that the transmitter knows when the data set is ready to receive and also when successful reception has been completed. Serial communication uses asynchronous and synchronous protocols as in microcomputer buses.

Figure 3(a) shows that a minimal system only requires two lines for transmission and reception and one signal return line. In asynchronous communication, two lines are used for data transmission and reception, four for control

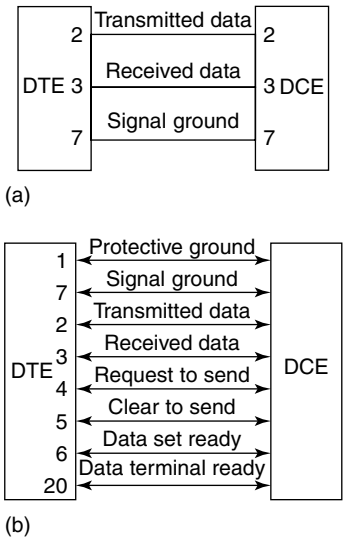

Figure 3. Connections for RS 232: (a) minimal and (b) typical.

signals and one for common return as shown in Figure 3(b). This communication interface is effective at rates of up to 20 kbps over short distances of up to 15 m.

4 WHAT RS 232 DOES NOT COVER

The RS 232 standard covers many aspects of serial communication. However, it should be emphasized that it is not primarily an interface between computers and printers, though it is often used as such.

Moreover, it is not a standard for asynchronous communication. In fact, it contains specific provisions for

synchronous communication if desired. The familiar asynchronous character structure of *one* start bit, eight *data* bits, *two stop bits* is widely used in conjunction with RS 232. However, this is just the most common application of the standard. As it does not appear in the specification of the standard, RS 232 is not a communication format standard.

There is no provision for tri-stating communication lines in the definition of RS 232. Hence, since it is not defined as a local area network, it cannot be used for multiple access to a single line without modification. Networking of multiple lines is covered in **Article 171, Local Area (LANs) and Wide Area Networks (WANs), Volume 3**.

5 EXTENSION OF RS 232 TO RS 422, RS 423 AND RS 485

The two most significant disadvantages of the RS 232 serial communications interface are the comparatively short transmission length of up to 15 m and the maximum transmission rate of 20 kbps. These limitations are mainly due to the fact that the transmission system is an economical space division multiplexed system for transmit and receive lines that share the same common signal. Consequently, they are susceptible to externally induced series mode interference. Moreover, the resistance/capacitance effects of the lines cause attenuation of voltage pulses.

Over longer distances, up to about 1.2 km, and for higher data transmission rates, up to 100 kbps, the RS 449 standard, which uses a 37-pin connector, is gradually replacing RS 232. RS 449 is the mechanical specification for the RS 422 and RS 423 electrical specifications of the extensions. RS 422, which is a balanced double-ended transmission specification, allows the higher data rate with the RS 232 compatible signal. Both this system and the RS 423 have higher transmission rates because they each may use twisted pair cables due to their possessing a unique signal return line. RS 423 is a single-ended unbalanced system. This allows connection to RS 232 and RS 422, but with the RS 449 mechanical specification.

The electrical characteristics of the RS 422 and the RS 423: These standards, which are specially designed for a high signaling rate bandwidth and greater immunity to electrical interference over long distances, of the order of 1.2 km, are now replacing the older RS 232. They have the electrical characteristics given in Table 1. Full duplex connections for both RS 422 and RS 423 are shown in Figure 4. A single-ended RS 423 standard, given in Figure 4(b), is intended to achieve compatibility with other standards. In particular, the RS 232 and RS 422 links can be connected through an RS 423 link, which is characterized by the electrical characteristics of unbalanced digital interface circuits.

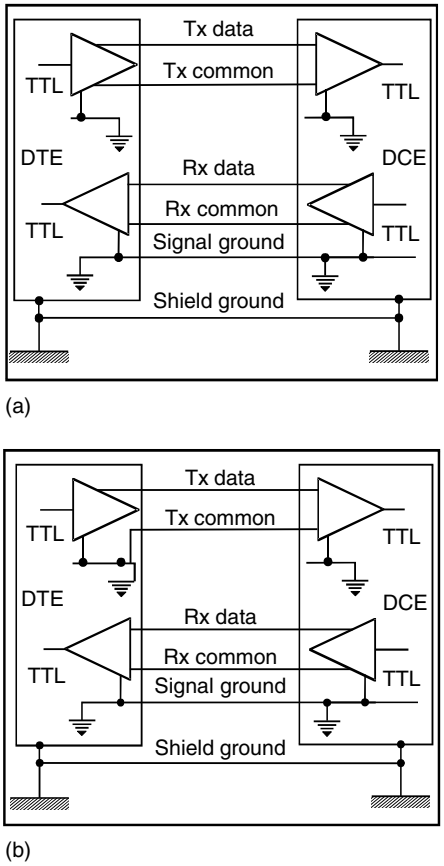

Figure 4. Full-duplex connections for extended RS 232: (a) RS 422 connection and (b) RS 423 connection.

Note that the electrical characteristics of RS 232 are nearly identical to those of the RS 423 standard. The principal objective of RS 422 and RS 423 is to move to higher speed communications.

RS 422 supports multipoint connections, whereas RS 423 supports only point-to-point connections. RS 422 defines a balanced electrical interface, while the RS 423 standard is characterized by its unbalanced interface. This is emphasized by the differential nature of RS 422, which is specified to have two lines of opposite polarity for data transmission. This pair of lines is such that one is positive, in the range 2 to 6 V, while the other is negative, within the range -2 to -6 V, for a logic '1'. Logic '0' corresponds to a reversal of the polarity of each of these lines. Compatibility between these different interfaces is achieved through adequate differential receivers. Proper precautions must be taken when an RS 423 interface is connected to RS 232 interfaces. For example, the SIGNAL GROUND of RS 232 must be tied to the SEND COMMON connection of RS 423. To go beyond 20 kHz, the double-ended signaling, defined by the RS 422 standard is recommended.

RS 485 standard: This is a specialized interface that would not be considered standard equipment on today's home PC but is very common in data acquisition. RS 485 will support 32 drivers and 32 receivers, which means it is a bidirectional, half duplex, multidrop communications interface over a single twisted pair cable or a dual twisted pair cable. An RS 485 network can be connected in a 2-wire or a 4-wire mode. Maximum cable length can be as much as 1.2 km because of the differential voltage transmission system used. The typical use for RS 485 is a single PC connected to several addressable devices that share the same cable. RS 485 can be viewed as a *party-lined* communications system in which the addressing is handled by the remote computer unit. RS 232 may be converted to RS 485 with a simple interface converter. This can have optical isolation and surge suppression.

When choosing a transmission line for RS 485, it is necessary to examine the required distance of the cable and the data rate of the system. Losses in a transmission line are a combination of AC losses, due to skin effect, DC conductor loss, leakage, and AC losses in the dielectric. In high quality cable, the conductor losses and the dielectric losses are of the same order of magnitude.

1 VOLTAGE LOOP TRANSMISSION SYSTEM

Communicating signals over cables requires means of accepting and delivering signals with accuracy. The simple electrical circuit loop can be used for this by varying the voltage or current in the loop. These two methods are discussed here, starting with the voltage option.

Consider the circuit shown in Figure 1. The voltage at the input of the receiving instrument, v_I, contains a component, v_{ISV}, due to the transmitted signal, v_s, given by

$$v_{ISV} = \frac{R_I}{R_I + R_s + R_w} v_s \tag{1}$$

Another component appearing at the input of the receiving instrument is due to the interfering signal, v_m. Interfering signals may be caused by coupling to nearby power lines or from cross talk in adjacent transmission channels. The interfering component at the input of the receiving instrument is

$$v_{ImV} = \frac{R_I}{R_I + R_s + R_w} v_s \tag{2}$$

Assuming that $R_s \ll R_w$ gives

$$v_{ISV} \approx \frac{R_I}{R_I + R_w} v_s \tag{3}$$

and

$$v_{ImV} \approx \frac{R_I}{R_I + R_w} v_m \tag{4}$$

Hence, if the voltage source is ideal, then only cabling attenuation due to R_w affects the received signals. Note that both the transmitted information bearing signal and the interfering signal are attenuated in the same proportion so the receiving end signal-to-noise ratio is unaffected by either the cabling or whether the source is ideal or not.

2 CURRENT TRANSMISSION SYSTEM

The current loop option is now explained.

Suppose the signal is a current, i_s, generated in a nonideal current source with an output resistance, R_g, as shown in Figure 2. In this case, the signal generated at the receiver by the current, i_s, is

$$v_{ISC} = \frac{R_g(R_I + R_w)}{R_g + R_I + R_w} \times \frac{R_I}{R_I + R_w} i_s \tag{5}$$

whilst

$$v_{ImC} = \frac{R_I}{R_g + R_I + R_w} v_m \tag{6}$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

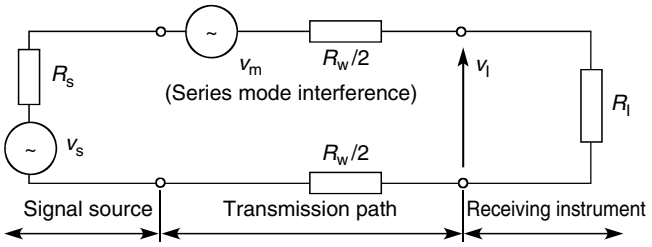

Figure 1. Voltage transmission with series mode interference.

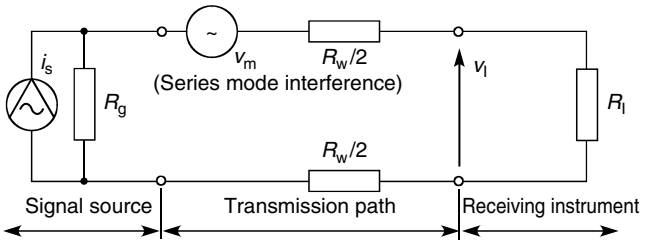

Figure 2. Current transmission with series mode interference.

Substituting for the relation between v_{ImV} and v_m gives

$$v_{ImC} = \frac{R_I + R_s + R_w}{R_g + R_I + R_w} v_{ImV} \ll v_{ImV} \tag{7}$$

Thus, the received voltage due to series mode interference in the current transmission system is very much less than the received voltage due to series mode interference when the information signal is transmitted as a voltage.

3 PRINCIPLES OF THE CURRENT LOOP

In harsh industrial and process system environments, even the RS 449 protocol is not impervious to severe series mode interference. Consequently, it cannot be used. A current-transmitting loop, which can be used for transmitting either analog or digital signals, has a limited digital rate of 4800 bits s^{-1}. When the signal is digital, the transmitter is switched between two distinctly different current levels that indicate the binary logic '11111' and '110011' levels. If the signals have to be transmitted/received between computers or other instruments, it is normal to include a converter to restore the loop current to a voltage signal compatible with RS 232 – *see* **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**. By using frequency modulation – *see* **Article 34, Modulation Theory, Volume 1** – it is possible to transmit high-fidelity current signals with low interference over longer distances. In the current control, a logic '1' is encoded by a current of 20 mA and a logic '0' by zero current.

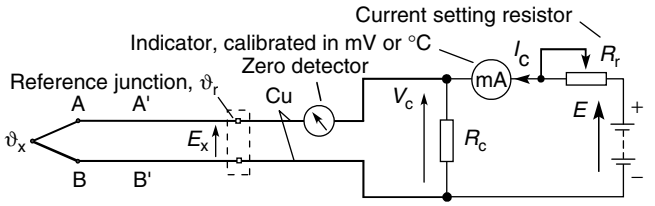

Figure 3. Basic circuit of a variable current potentiometer.

4 VARIABLE CURRENT POTENTIOMETERS

Process transmitters, similar to those based upon BS 5863, which still represent the most widely used forms, are usually based on the principle of variable current potentiometers. BS 5836 has two parts. Part 1 (1984), which replaces BS 3586, is equivalent to IEC 60381-1 for CENELEC HD 452.1 signals. Part 2 (1980) is equivalent to IEC 60381-2 for its specification of direct voltage signals. Variable current potentiometers have the basic circuit given in Figure 3, which uses a thermocouple sensor as a specific example. The temperature to be measured is ϑ_x, and ϑ_r is the temperature of the reference junction. The voltage to be measured, E_x, which may also be due to any other type of sensor, represents the thermoelectric emf. It is opposed by an adjustable voltage, V_c, which is generated as a voltage drop across a constant resistor, R_c. This voltage drop is adjusted by changing the compensating current I_c, using a slide wire resistor, R_r, to satisfy the condition

$$E_x = I_c R_c \tag{8}$$

The value of the current, I_c, is a measure of the unknown voltage, E_x to be determined. A zero-detector, which is used to indicate the null balance condition, may be a current indicating milliammeter actually measuring in mA, but calibrated in mV. The restricted accuracy of milliammeters is compensated for by the simplicity of the construction of the potentiometer. It is easy to assemble such a potentiometer from typical laboratory instruments. Their accuracy is about 0.2 to 0.5% of the measuring range. When they are configured as self-balancing potentiometers on the basis of an operational amplifier with feedback, they become what are now known as *current transmitters*. More detail is available on amplifiers for data acquisition systems (DAS) in **Article 133, Amplifiers and Filters for DAS, Volume 3**.

5 CURRENT LOOP TRANSMITTERS

Current transmitters, which may be configured as two-wire or four-wire transmitter units, are widely used. Figure 4

shows typical block diagrams for each, once again using a thermocouple as the sensor.

In the schematic diagram of a four-wire current transmitter, given in Figure 5(a), it can be seen that the output signal is proportional to the measured emf, E_x. The voltage drop across the resistor, R_c, caused by the current, I_c, compensates the measured emf, E_x, so that the input voltage, e, of the operational amplifier is

$$e = R_c I_c + E_x + V_{off} \tag{9}$$

where V_{off} is the input offset voltage of the amplifier.

Terms used in measurement are covered in **Article 41, Terminology and Classification of Measurement Systems, Volume 1**; and **Article 57, Static Considerations of General Instrumentation, Volume 1**.

Define the amplifier gain as $K = -I_c/e$. Inserting this into (8) and (9) gives

$$I_c = -\frac{K}{1 + K R_c}(E_x + V_{off}) \tag{10}$$

Assuming a high amplifier gain, K, (10) can be rewritten as

$$I_c \approx -\frac{E_x + V_{off}}{R_c} \tag{11}$$

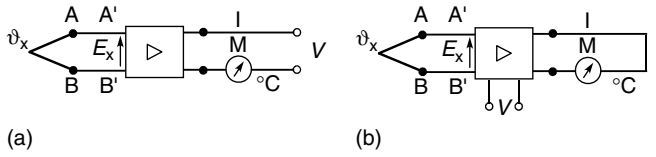

Figure 4. Current transmitter types: (a) two wire and (b) four wire.

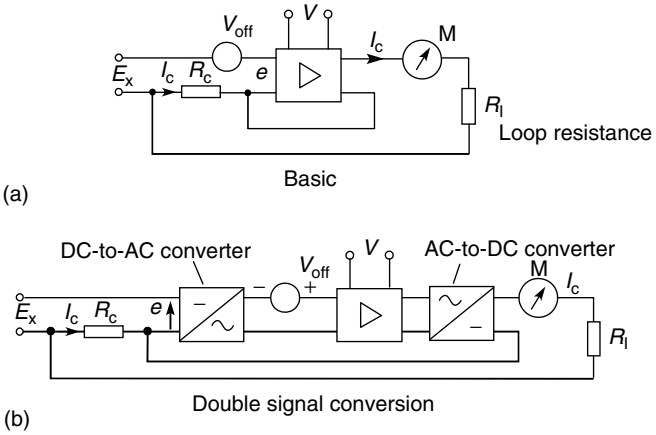

Figure 5. Four-wire thermocouple transmitters.

The compensating output current, I_c, is thus directly proportional to the measured emf, E_x. The effects of low frequency drift and offset in the amplifier are eliminated using double signal conversion transmitters, as shown in Figure 5(b). The two converters and the amplifier form one integrated circuit.

The two-wire transmitter, with the block diagram shown in Figure 6, is primarily intended for use with thermocouples. Amplification of the thermocouple signal in 6 (see Figure 6), is followed by conversion in 7 into an output current, proportional to the measured emf. The transmitter's measuring current, I_c, is composed of two components so that

$$I_c = I_o + I_m \tag{12}$$

The current, I_o, in most cases 4 mA in 4 to 20 mA systems, which is used to supply the necessary power to the transmitter of two-wire systems, is kept constant by a current stabilizer, 8. The component, I_m, is a function of the measured temperature. An advantage of 4 to 20 mA systems is that a transmitter failure, corresponding to the occurrence of zero output current, cannot be mistaken for a zero-measured temperature value. The reference junction corrector, 1, adjusted to match the thermocouple characteristic, simultaneously feeds the thermocouple break-safe circuit, 2. In the case of a thermocouple break, the output current either falls to zero or increases over the 20-mA high limit, to a value of 35 mA in most transmitters. The voltage stabilizer, 3, and the resistors of the circuit, 4, determine the minimum measuring range, whereas the circuit, 5, is used to set its maximum value. Both output current components flow through the diode, D, protecting it against any reversal of supply voltage, while protection for the transmitter against any voltage peaks is provided by the other Zener diode, 9.

A transmitter for resistance thermometers is shown in Figure 7. As for the thermoelectric emf in the thermocouple transmitter of Figure 6, the temperature-dependent resistance variations of the RTD (resistance temperature detector) are converted into an output current, linearized in current source, 1. The input signal is fed through the temperature range module 2 and the amplifier, 3, to the output current converter, 4. The current stabilizer, 5, sets a component of the current, I_o, smaller than 4 mA. Two-wire, three-wire, or four-wire connections are used for circuit completion between the RTD and the transmitter.

Although using a two-wire connection between the RTD and the transmitter is a convenient method of circuit completion for head mounted transmitters, it does not give precise measurements. It also imposes a limit upon the loop resistance variations. As a three-wire connection or a four-wire connection between the RTD and the transmitter

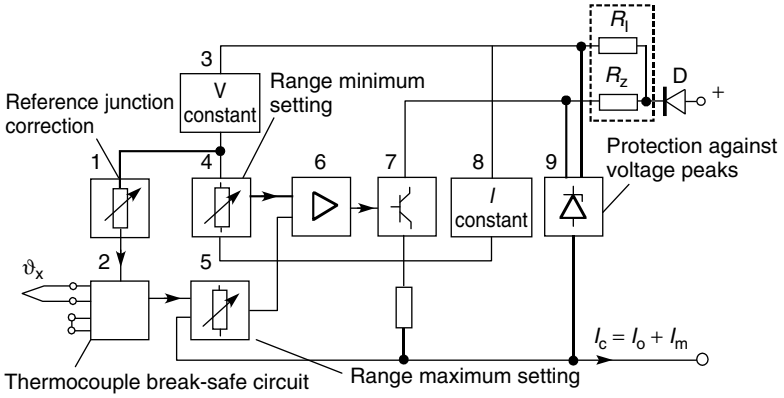

Figure 6. A two-wire transmitter.

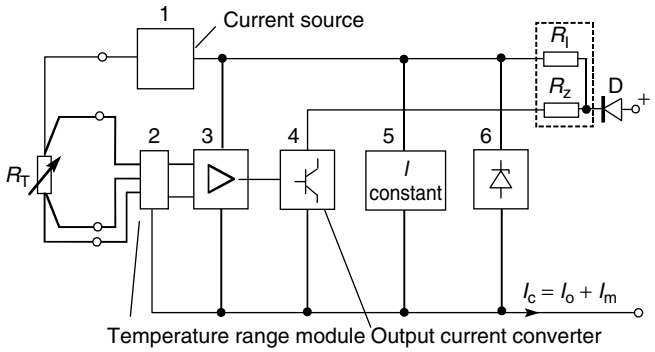

Figure 7. A two-wire transmitter for RTDs.

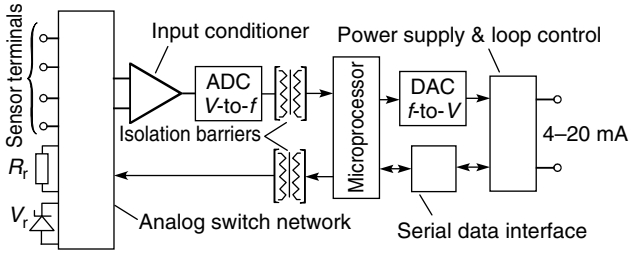

Figure 8. An intelligent current transmitter.

ensure the compensation of loop resistance variations, they are normally used in the case of larger distances between the sensor and the transmitter.

6 INTELLIGENT TRANSMITTERS

Further development of transmitters has led to this generic type. For example, the transmitter, shown in Figure 8, can accept inputs from a variety of temperature sensors such as Pt-RTD or different thermocouples without changing any modules or altering any links or switches. This microprocessor-based transmitter can be programmed by a remote transmitter interface, or RTI, which also enables the measuring ranges to be changed. The output signal can be linear or any other function of measured temperature. Galvanic isolation between input, output, and earth is an important feature of the transmitter. These transmitters usually have a high accuracy over their entire working range as well as high immunity to any airborne radio-frequency interference, or RFI, due to the included effective filtering. This last quality is very important in view of the increasing use of radio transceivers for on-plant personnel communication.

Selection of a sensor type causes the analog switch network in Figure 8 to gate the relevant sensor signal. The same network also gates the reference resistor, R_r, or the reference voltage, V_r, to the output circuit, which conditions the sensor signal. After conversion by a voltage/frequency converter, the frequency signal is passed through an isolating transformer to the microprocessor. Between samples from the sensor, the resistor, R_r, voltage, V_r, and short circuit are checked to calculate the circuit drift due to ambient temperature variations or aging of elements. The microprocessor, which then corrects these influences, also compensates for the influence of changing reference junction temperature, if a thermocouple is used. Either a digital or an analog 4 to 20 mA DC output signal is provided by the microprocessor. For computer interfacing, these transmitters can also communicate digitally over the 4 to 20 mA lines using an appropriate protocol.

Modern current transmitters are very reliable, reaching up to 12 000 working hours, which is about eight years.

It is to be expected that digitally based transmitters, where the current transmitted will be in digital form, will continually replace the 4 to 20 mA analog standard units as their performance deteriorates with age.

Further information on these still popular traditional analog loop transmission systems is found in the classical process control texts given in the bibliography and on the

web sites of major manufacturers by searching with 'current loop transmission'.

Intelligence in measuring systems is covered in **Article 160, Smart Sensor System Features, Volume 3**.

1 GENERAL DESCRIPTION OF IEEE-488 INSTRUMENTATION BUS

Several attempts to standardize similar bus systems that were suitable for interconnecting measurement instruments from the specifications of various manufacturers were made during the 1970s. The International Electrotechnical Commission, or IEC, and the Institute of Electrical and Electronics Engineers, or IEEE, have respectively succeeded in producing the IEC-625 bus and the IEEE-488 bus, which are the most widely adopted and generally compatible, if not identical, instrument bus standards.

The IEEE-488 bus or General Purpose Interface Bus (GPIB) is an internationally accepted specification, which defines the mechanical and electrical interface between all IEEE-488 compatible instruments. The mechanical, electrical, functional, and operational features are shown in Table 1. It defines a standard communication link for data and commands between instruments. This leads to significant simplification of the combined use of a variety of devices from different manufacturers. However, it should be noted that only the operational aspects of this bus depend upon the device or system. It does not define *device-dependent programming*, which is the way any instrument will respond to a given command. One analogy is the international telephone system, where the hardware and hookups are all compatible, but the language spoken over the system is not defined.

The bus, which is restricted to a maximum of 15 measuring instruments, can consist of up to 31 in certain circumstances. The IEEE-488 instrument bus is most often used to connect computers and personal computers to various kinds of laboratory testing and measuring instruments, such as multimeters, frequency counters and analyzers, and other peripheral devices such as plotters and signal generators among others. In this way, automatic measurement, analysis, data processing, and recording can be accomplished.

Controllers, *talkers*, and *listeners* are the three classes of functional devices that are connected to the bus. Each device must be capable of executing one of these three functions. An instrument that functions as a talker can only transmit messages to the bus. A listener can only receive messages from the bus. However, most instruments are designed for both transmitting and receiving messages,

Table 1. Some features of the IEEE-488 bus.

Mechanical	Electrical	Functional	Operational
Device or system independent specification			Device or system dependent specification

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

although not simultaneously. Examples could be for the control of the measurement range and for the transmission of the measured data. Only one instrument can talk at a time, although several instruments can function simultaneously as listeners.

To regulate the information stream along the bus, one of the connected instruments, usually a computer, acts as a controller, or supervisor. The controller determines which instrument is the talker and which is the listener. Each instrument has a unique address, which is set with a series of small switches, usually located on the back plane of the instrument. Only the instrument with the address that corresponds to the address transmitted by the computer receives the message. It is even possible to let two instruments communicate without the intervention of the computer.

The controller performs management functions such as releasing a connection or specifying the talker and listener. Whereas a talker loads data onto the bus, a listener downloads data from the bus. Computers are usually equipped with all three functions, while measurement instruments are talkers, and plotters and other such devices are listeners. As an example of a simple system, a computer performs the required controller functions, specifies an instrument as a talker and itself as the listener after which it then receives the measurement data. After completion of data transmission, the designations for both talker and listener are released. When data analysis is complete, the computer specifies itself as the talker and a plotter as the listener before sending the analysis data to the plotter for recording.

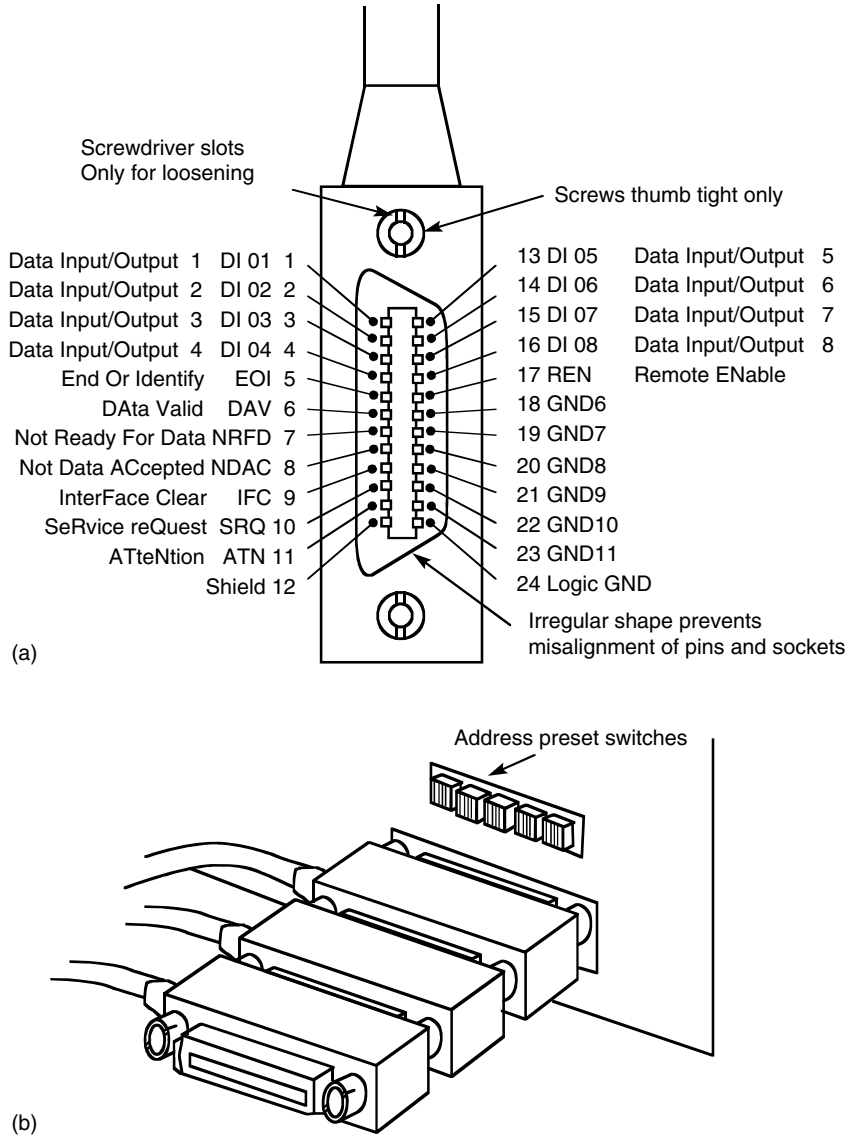

Figure 1. Mechanical and electrical specification for IEEE-488 bus.

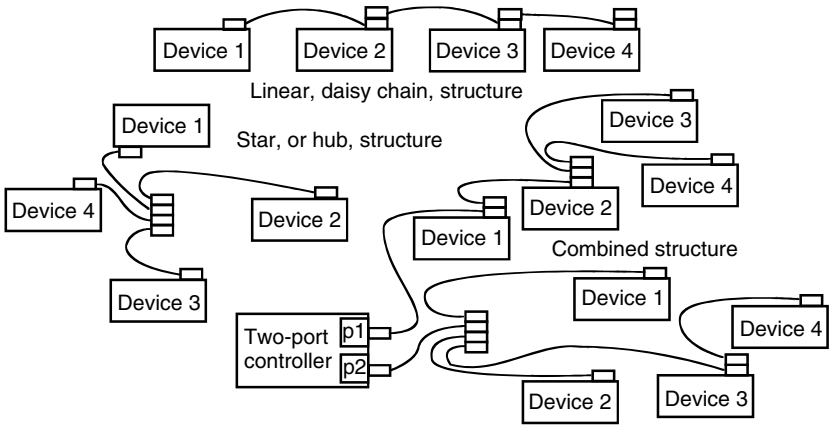

Figure 2. Network connections for the IEEE-488 bus.

2 MECHANICAL SPECIFICATION OF THE IEEE-488 BUS

The 16-line highway cables between devices are terminated in 24-way connectors of the *Amphenol micro ribbon* type with the pin assignments shown in Figure 1(a). These connectors, usually located at the instrument rear, can have further *piggy-backed* connectors, as shown in Figure 1(b), where the address setting switches are also conveniently located. The piggy-backed structure allows *linear systems*, *star systems* or *combined systems* to be configured as shown in Figure 2, where the address setting switches are also conveniently located.

3 ELECTRICAL SPECIFICATION OF THE IEEE-488 BUS

The highway is terminated within each device in a specific manner as in Figure 3. The bus, which is TTL compatible, uses a negative logic convention so that logic *high* is $> +2\,\text{V}$ to indicate a *false* state, whilst '*low*' is $< 0.8\,\text{V}$ to indicate *true*. The line drivers may be either of the open collector or the tristate variety. Their specified drive capability permits bus lengths of up to 20 m or 2 m times the number of instruments connected to the bus, whichever is less. The specification also covers details of screening, cable resistance and capacitance, and so on.

Physically the bus is a 16-line bidirectional passive highway to which up to 15 instruments, including a controller may be connected in parallel to form a *party line* structure. All lines are functionally grouped into the three component buses summarized in Table 2. These include 3 lines for data transfer timing, also called *handshake lines*, 5 internal control signal lines and 8 data lines for 8-bit parallel data. The 8 lines, forming the *data bus*, allow data

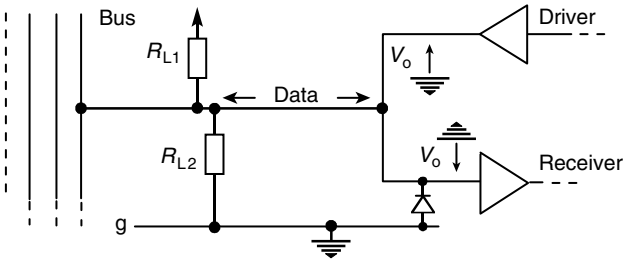

Figure 3. TTL compatible connection between the IEEE-488 bus and the devices input/output circuit.

Table 2. Summary of bus signals for IEEE-488 bus.

Classification	Signal line		Function
Handshake signal	DAV	DAta Valid	Data is valid

	EOI	End Or Identify	End-of-data
Data	DIO 01 to 08	Data input/output	Data

transport in bit parallel word serial form with the data being transmitted byte after byte. This may be between talkers, which are transmitting devices, and listeners, which are receiving devices, or between the system controller and subordinate devices. The controller, which talks and listens, designates the status of controlled instruments. The overall system direction is controlled by commands, to or from the controller, via the 8 data lines in conjunction with the 5 management lines. There may be a number of listeners operating on the bus at the same time, but only one talker operating at a time. The data may be commands for the selected instruments or measurement data. One message may comprise several bytes. The remaining 3-byte transfer lines control the *handshake* routine by which data is transferred from one device to another. This process is necessary since the rates at which the various bus devices can transmit or receive data may vary considerably. These 3 lines permit a talker to synchronize its data transmission with the readiness of the appropriate listeners to receive.

4 GENERAL FORMAT OF THE IEEE-488 BUS

Figure 4 represents the general format of the bus. Although only four devices are shown, up to five can be used on a single bus system. If more than five instruments are required in the system, additional bus loops may be used.

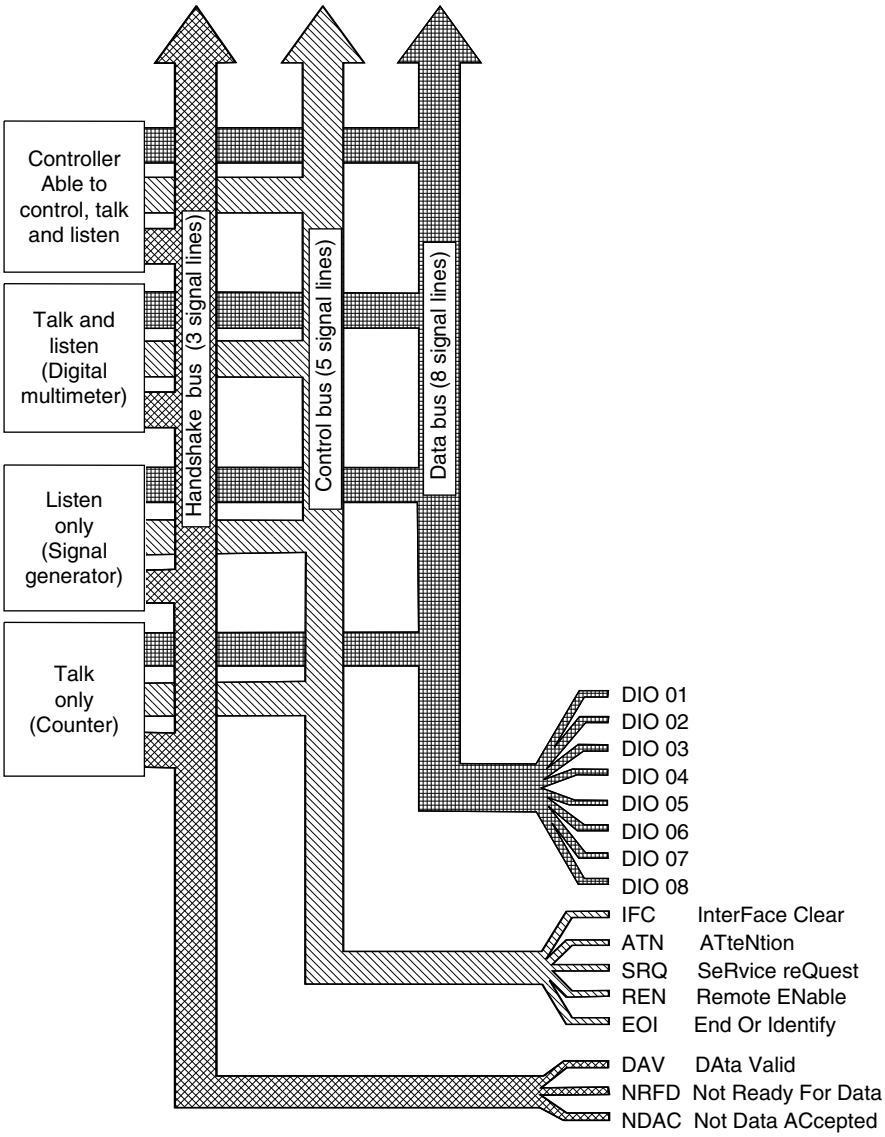

Figure 4. General format and structure of the IEEE-488 bus lines.

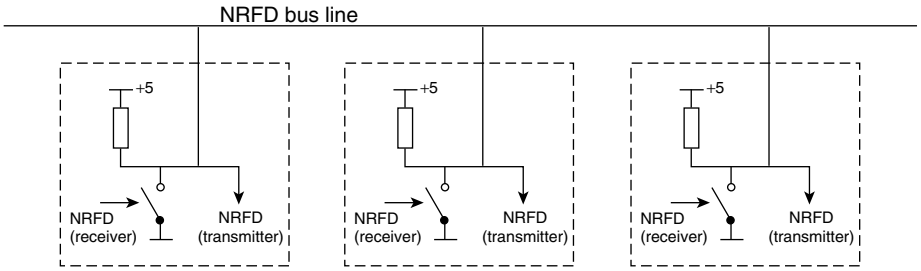

Figure 5. Wired OR lines for the NRFD lines. When the listener is not ready to accept data, the switch is off, the line voltage is low (0) and the talker is waiting.

The data transport over the bus is asynchronous. Due to the handshake procedure, instruments with diverse processing times can be connected to the bus, so the transport speed is determined by the slowest of the connected instruments.

Some bus lines are connected in a wired OR manner as in Figure 5. The bus lines for the *Not Ready For Data*, or NRFD, line in Figure 5 are all connected to the positive power supply voltage via a resistor. Each instrument contains a switch that can connect the lines to ground. The line voltage is only *high*, or '1', if none of the instruments has short circuited the line. The line is *low*, or '0', if at least one instrument has asserted the switch on. In this way, the OR function between the NRFD lines is realized without the necessity of separate OR gates so that introducing complex wiring is avoided.

5 IEEE-488 BUS OPERATION–CONTROLLERS, TALKERS AND LISTENERS

Each of the instruments in an IEEE-488 based system must be capable of operating in one or more of the modes as a Controller, a Talker, or a Listener.

Controller: The Controller addresses other devices to listen or talk. It can send interface messages as well as device independent commands or device-dependent commands. It will generally hold a *control program*, which schedules the system devices and also captures data under predetermined conditions. The data may be stored, processed, and then displayed by the controller using its own output devices, such as a CRT display or plotter, or by using a dedicated peripheral connected to the bus such as a high-speed printer. There is normally one controller on the bus directing data between talkers and listeners using interface messages. These can be multiline messages using the 8 data lines and/or '*line messages*, using the 5 management lines. Each device on the bus has its own address code, which is usually set up on rear panel switches as shown in Figure 1(b). This allows device-dependent messages to be addressed to that particular instrument. Addressing, which schedules instruments as talkers or listeners, may involve multiline talk or listen commands. Universal interface commands, which can be multiline or uniline, such as InterFace Clear, or IFC, Remote ENable, or REN, ATteNtion, or ATN, and so on, affect all interfaces on the bus.

Talkers and listeners: A *Talker* is a device, which can transmit data on the bus but can not receive it, while a *Listener* can receive data but cannot transmit. Typical examples might be a simple DVM as a talker and a printer as a listener. Some instruments can function as talkers and listeners. For example, most DVMs can *Listen* to remote programming instructions sent via the bus. Subsequently, having taken measurements, the DVM then *Talks* by transmitting that data to other listeners on the bus. Clearly, the simplest possible system consists of one as a *Talker* and another as a *Listener*. For example, a device taking measurements and capable of, or manually set to, a *talk only mode* where data is transmitted over the bus to a device in *listen only mode*. An expansion of this may be with one talker transmitting to a number of listening devices.

However, it is not until an intelligent controller is included in a system that the real value of the bus is realized. An intelligent controller, such as a programmable calculator, can both talk and listen as well as act on data to process it and subsequently direct the overall measurement operation to produce a genuinely intelligent system.

6 IEEE-488 BUS OPERATION–BUS MESSAGES

Messages sent over the bus, which are generally based on the ASCII code, are all transmitted via the 8 data lines in conjunction with the 5 management lines. The messages may be classified as either *interface messages* or *device-dependent messages*.

Interface messages: These are commands sent over the bus via the 8 data lines in association with appropriate management line status. For these commands, the ATN management line is always held true so that data is directed to the *instrument interface circuitry*. Contrastingly, *device-dependent commands* direct the operation of the instrument. These *commands* are specified by IEEE-488 and therefore have the same meaning to all bus instruments. If a device does not have a particular bus facility, associated commands are ignored completely. In this mode, the system controller is the 'talker' and all other devices on the bus are awaiting instructions. These commands include

Talk/Untalk; *Listen/Unlisten*; *Remote/Local*; *Clear/Trigger*; and so on.

Device-dependent messages: These messages are transmitted to *command* a particular instrument on the bus to adopt a specific measurement mode or function. Since the functions and capabilities of different units, even of the same general type, vary considerably, it is necessary for instrument designers to use the most appropriate message coding. The IEEE-488 standard therefore specifies only the general format for command transmission. It does not define the exact instrument response to any given command. Consequently, instruments are rarely interchangeable without reprogramming. Moreover, some of the available manual user functions to a unit are not necessarily available on the bus. It is a significant feature of most new DVMs that virtually all the functions available to the manual user can also be controlled remotely on the bus. First addressing the DVM as a listener and then sending a simple alphanumeric ASCII string achieves programming. An alpha character designates the required program area, such as range, function, or even Autocal. A numeric character to specify a particular range or function follows this.

7 IEEE-488 BUS OPERATION–BUS MANAGEMENT PROTOCOL

Five control lines perform the following bus management functions:

- *IFC, or InterFace Clear*: The controller can reset the bus. All connected instruments are set in an initial state and wait for further commands.
- *ATN, or ATteNtion*: The controller can switch from command mode to data mode. In the command mode, instrument control signals are transported over the data lines. In the data mode, the data lines are used to transport measurement data.
- *REN, or Remote ENable*: Here, the controller imposes its command of the instruments. Manually controlled front panel elements are disabled.
- *SRQ, or SeRvice reQuest*: One or more instruments can interrupt the normal operation by signaling the controller for the execution of a particular program.
- *EOI, or End Or Identify*: In the data mode (ATN = false), the EOI means that the current byte is the last byte of the message. In the command mode, the EOI refers to the execution of a service request.

Normally, the user of the bus system has nothing to do with the bus interfaces. Special ICs take care of the communication, including the handshake procedure. The user, however, has to write a program for the controller to execute the desired measurement sequence.

8 IEEE-488 BUS OPERATION–BUS HANDSHAKE PROTOCOL

Handshake lines: To guarantee proper data transport, irrespective of the differences in response times of the instruments, the bus contains three special control lines, called the handshake lines. These three *handshake*, or Data Byte Transfer Control Lines, control the transfer of data bits between talkers and listeners. This allows devices with differing input/output data rates to be connected together. The data transfer rate is always, automatically adjusted to that of the slowest device by a wired OR process. Maximum Transfer rate is one megabyte per second. These three lines, which are NRFD, or Not Ready For Data, DAV, or Data Valid, and NDAC or Data Not Accepted, have the following functions:

- *NRFD (Not Ready For Data)*: All instruments use this line to indicate whether they are ready to accept data. It goes high, or *false*, to indicate that the listener(s) are now ready for data. If any device is not ready, it forces the line to be held low. A talker on the bus puts data on the bus, after it has used this line to determine when all listeners are ready. The talker must wait until all listeners are ready, which is indicated by a false NRFD. Logically speaking, this signal is the OR operation on all connected NRFD lines: $\text{NRFD} = \text{NRFD}(1) + \text{NRFD}(2) + \cdots + \cdots$.
- *DAV (Data Valid)*: This signal is asserted true by the instrument assigned as talker, just when all active listeners are ready to receive data. This is indicated with NRFD false. It goes low when the talker has placed data on the bus, but only after a short time interval to allow for settling. The DAV line thus tells the listeners that data is on the bus and is fit to be read. Thus, all

receiving instruments know that the data on the data lines contain relevant information.

- *NDAC (No Data Accepted)*: Each listener attempts to assert this signal false as soon as data transmission takes place. However, it is held low, that is, remains *true* corresponding to NDAC, by the slowest listener until it has received and accepted the data from the data lines, or has completed data transfer. The talker must maintain the data on the data lines at least until that moment. Once this is pulled high again, the talker may change the data so that a new byte of data can be sent over the bus. Because a possible next byte can only be put on the data lines when NDAC is false, NDAC is a logic OR function. In other words:

$$\text{NDAC} = \text{NDAC}(1) + \text{NDAC}(2) + \cdots.$$

Handshake timing: Figure 6 shows a handshake routine with the relative timing of each line, although not to scale. The dotted lines show the state of faster devices and the solid lines the change of state, which results when the slowest device on the bus finally reacts:

- A – As each listener device becomes ready to accept data, NRFD is set false. By 'A', the slowest device is ready to accept data and NRFD is set false.
- B – DAV is set true by the talker to indicate to the listener(s) that data is on the lines, has settled and is fit to be read.
- C – As each listener accepts data, its NDAC is set high. When the slowest device has accepted data, the NDAC line goes false to indicate to the talker that all the listeners have accepted data.

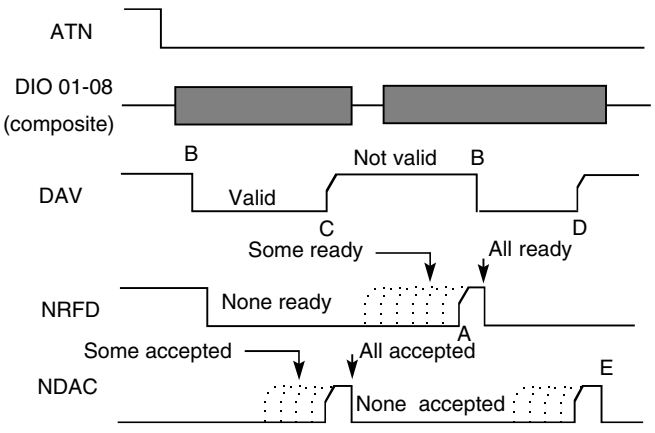

Figure 6. Handshake routine with relative timing of each line in IEEE-488 bus.

- D – The talker now sets DAV false to indicate that the data on the lines is no longer valid.
- E – All listener(s) respond to DAV going false and set their NDACs true. After 'E', NRFD can be reset high so that a further handshake can occur.

The IEEE-488 standard has recently been upgraded (IEEE 2003), enabling buses transfer data at rates of up to 8 Mbps.

1 INTRODUCTION TO LOCAL AREA NETWORKS

Compact, high-speed data exchange through a single medium places special requirements on distributed measurement systems where peer-to-peer communication may be necessary. Peer-to-peer communication between each station does not require the intervention of a separate bus controller to intervene and manage the communication process as occurs in the IEEE.488 system. Local area networks, or LANs, which were developed to meet this need, are generally used to interconnect computers on the same floor of a building, within a building of an organization, or between local buildings as in a factory complex. They may also be used for process-control interfacing with intelligent nodes on the network. The LAN provides a high-speed data link over a limited working area. Many types of LAN have been developed for various purposes, but they can be simply classified according to their physical configuration, or topology. The four main topologies are the star, the ring, the bus, and the hub configurations. More details are given later.

The access methods or techniques for transferring data to the transmission medium, include the token passing or baton passing scheme and the carrier wave multiple access with collision detection, or CSMA/CD method. In the token pass method, a frame, or token, makes rounds to all the devices on the LAN. Only the device that is to receive the token can send a signal to the medium. In the CSMA/CD method, any device can send a signal at any time if there is no signal on the medium, thus signal collisions may occur. At such times, each device is made to wait for a set time, which is different for each device.

The CSMA/CD method is efficient when the traffic load is light. However, when the load increases, multiple conflicts develop regardless of the waiting. As a result, efficiency is lost and response time is lengthened. Degradation of response time beyond this limit is unacceptable in a network for factory control and management. Thus, the token passing method is most often used for factory networks. The Manufacturing Automation Protocol, or MAP, and the Process Data-way, or PROWAY, are examples. The ETHERNET method, which is a bus-type connection used extensively for light-load situations, such as in offices and in research and design facilities, is a typical example of CSMA/CD.

The two main standards commonly used are the IEEE-802.4 and the PROWAY. Brief specifications for the IEEE-802.4 method, which is intended for factory use and is also

Table 1. Specification summary of IEEE-802.4 and PROWAY.

Item	IEEE 802.4	PROWAY
Physical		
Structure	Bus	Bus
Transmission medium	75 Ω coaxial cable	75 Ω coaxial cable
Transmission distance	–	2 km max.
Node numbers	–	100 max.
Signals		
Modulation method	Phase continuous FSK Phase coherent FSK Broadband	Phase continuous FSK
Control method	Token passing	Token passing (Baton passing)
Error control	No data error monitoring	Retransmission and recovery by immediate acknowledge monitoring
Timing		
Transmission rate	1, 5, 10 Mbps	1 Mbps
Access time (worst case)	In the case of no transmission error, it is decided by station numbers and working parameter value	50 m or less

employed in MAP, are listed in Table 1, together with the specifications for PROWAY.

2 OPTICAL COMMUNICATIONS

Optical fibers are often used as the transmission medium for LANs. When used as a transmission medium, optical fibers have advantages such as insensitivity to electrical noise, the capability for high-speed transmission over great distances, and safety because they do not transmit electric power. For these reasons, they have great potential for widespread use as a transmission medium in factories.

In the recent past, optical connections were difficult because of their high cost and their poor compatibility among the products of different manufacturers. Previously, optical media have been used for special environments and high-performance communications. However, these difficulties are being steadily overcome. It is inevitable that the use of optical communication media will spread.

When it was difficult to split, or branch, the optical fibers used in communications, they were almost exclusively used in one-to-one communications or in ring-type communication configurations. Nowadays, the production technology has advanced sufficiently to broaden their area of application. Optical fibers have now been introduced to bus LANs and star LANs by using a multiple-branch element called the *star coupler*. Furthermore, RS 232 connectors, with built-in optical modems for a duplex communication, have been developed. Low-cost, convenient optical communication is now becoming more widespread.

3 STAR TOPOLOGY

The best-known star type is the *private automatic branch exchange* or the PABX system shown in Figure 1(a). Many large companies such as electrical generating and gas distribution and processing enterprises, as well as water and sewerage, and petroleum and crude products companies use it. The PABX unit, which uses switching to direct communications between points on the star, is an analog communication system. It was initially designed to route telephone calls. PABXs are being replaced by digital switching exchange units called *private digital exchange* or PDX systems as represented in Figure 1(b). An advantage of this replacement method is that much of the wiring is already in place. The inclusion of computers, ADCs, and DACs – *see* **Article 139, Analog-to-Digital (A/D) Converters, Volume 3** and **Article 141, Digital-to-Analog (D/A) Converters, Volume 3** – in the PDX allows both data and voice signals to be handled. PABXs at different sites may also be linked to form a *wide area network*, or WAN.

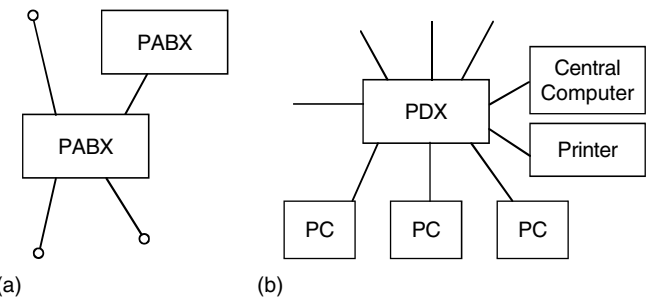

Figure 1. The PABX and PDX local area networks.

Connections between sensors and networks often follow the conventions and standards of the field-bus methods – *see* **Article 172, Fieldbus Systems, Volume 3**.

4 RING TOPOLOGY OR TOKEN RING NETWORK

In the ring topology, shown in Figure 2, the signal is intercepted and retransmitted at the connecting point, or node, for each device. In this network, the communication cable is connected from one node on the network to the next to form a loop or ring. Data passing round the network is seen and processed by each node to determine whether the message is addressed to itself or should be retransmitted to the next node in the loop. One node on the network acts as master, performing management functions, such as token generation. Thus, any node is allowed to communicate directly with any other node on the network.

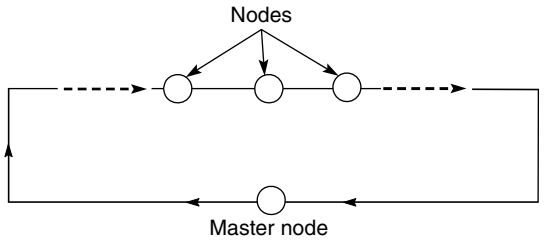

Figure 2. A ring LAN.

The network traffic is unidirectional. Data rates are typically 1 to 10 Mbps.

5 BUS TOPOLOGY

Here, a single cable is passed through nodes on the network so that equipment located in various rooms and floors of an organization can be serially connected. The equipment taps into the cable to receive data on the bus. Data rates are typically 1 to 10 Mbps. The bus topology has high reliability because the transmission route contains no active elements like transistors, LSI circuits, or others in series, unlike the ring and star configurations. Thus, the bus topology is suitable for factory online networks.

A good example of a bus topology is the multifunction vehicle bus, or MVB, which is schematically illustrated in Figure 3. The physical layer of this bus is specified to support a short-distance copper medium and a longer distance optical medium. The copper bus is divided into *bus segments*, with a *bus terminator* at each end. The bus segments may be divided into *bus sections*, which are not terminated. The devices are attached to a segment by passive taps. To extend the bus beyond the limit imposed by electrical constraints, a repeater containing a signal shaper or regenerator may connect segments. Remote bus segments may be connected by an optical repeater link consisting of a pair of point-to-point optical fibers.

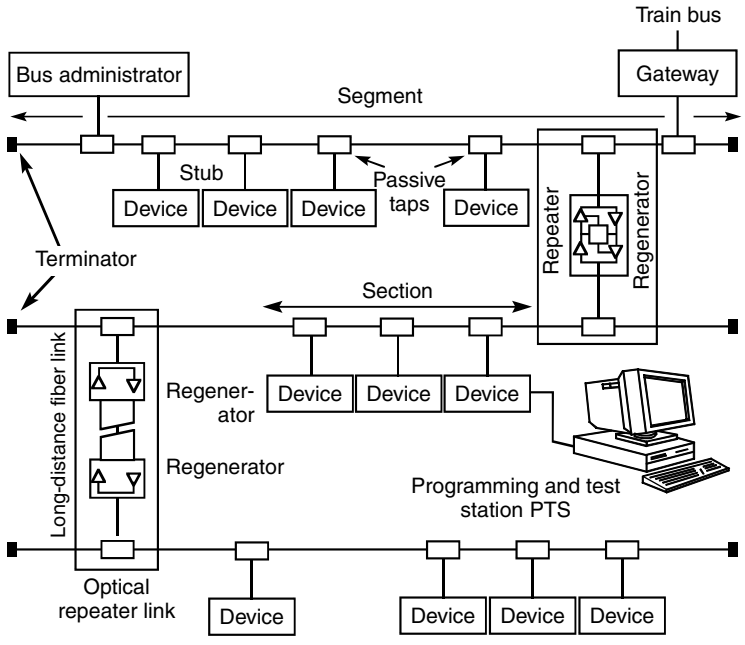

Figure 3. The multifunction vehicle bus used to illustrate a bus configured instrumentation system.

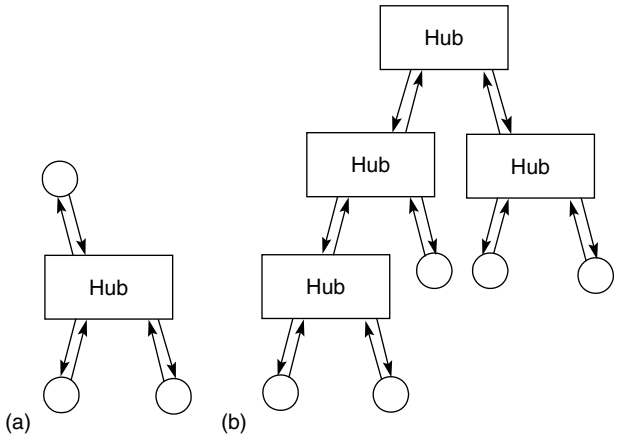

Figure 4. A hub topology LAN.

6 HUB TOPOLOGY

Hubs, which are configured, as shown in Figure 4(a), are simply multiple repeater units for signals received from all the nodes on the network. They perform no switching function as in the star topology. The formation still uses the basic bus and ring topologies. Hub trees, as in Figure 4(b), may also be formed.

7 WIDE AREA NETWORK PRINCIPLES

Local area networks may be connected via gateways to public or private communication networks to form *wide area networks*, or WANs, connecting different business sites of one company across a large city. A gateway, as in Figure 5, allows two systems having different methods or protocols, to communicate with each other. The gateway handles differences in speed, coding, and protocols.

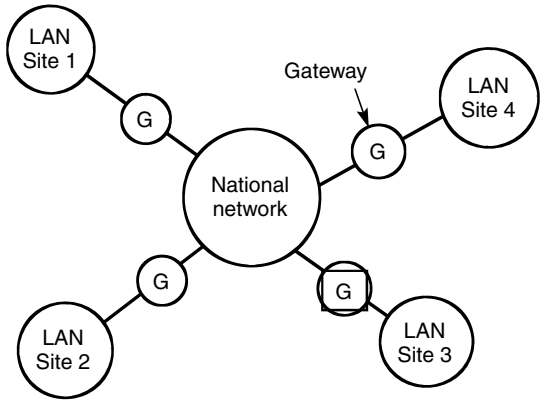

Figure 5. A wide area network, or WAN, topology.

A WAN may be either a publicly or a privately operated network or possibly a mixture of the two. In the United Kingdom, the main network is private. To control and protect the passing of data, the Council of Europe issued a Convention on Data Protection in 1981. This restricts the free flow of data within the EU.

Networks are costly to install and use because of telecommunication charges. Careful thought must be given to the extent to which communication and information via networks is necessary. IBM is an example where instant communication and information is considered important by management. They installed a network in 1987 to satisfy the five point '*any*' rule for their employees. The five '*anys*' are

> *That* **any** *employee at* **any** *IBM location should be able to go to* **any** *terminal and log onto* **any** *IBM application running in* **any** *IBM computer centre*.

This system caters for 20 000 IBM employees in the United Kingdom. The high cost and security aspects have prevented other companies having such an open policy. Is such a system necessary and do all employees need to have access to such a wide range of applications and information? Company IT costs can be very high due to the information demands of staff who do not have a real need for such information. Strategic use of IT funds is necessary.

1 INTRODUCTION TO THE FIELDBUS

The fieldbus is a digital means of integrating field devices into the information and control system of the entire plant. Thus, the fieldbus communication systems have access to the physical medium by the use of Data Link Layer (DLL) and the communication takes place by the protocols. Fieldbus protocols are largely developed for distributed processes with centralized control philosophy (as in the IEC/ISA fieldbus), or distributed processes with distributed control philosophy (as in the Profibus).

Many versions of the fieldbus are offered by a diverse range of vendors driven by commercial interests or application-specific reasons. There is a worldwide attempt to standardize fieldbus protocols so that it becomes independent of vendors or application specific requirements, a situation that has existed for many years.

Although this had been realized by the IEC-61158 standards in the year 2000, its effect and wide acceptability is yet to be seen. A common fieldbus standard will allow the implementation of control strategies universally, thus giving advantages such as improving intrinsic safety, giving better security, enabling easy installation, maintenance, monitoring and diagnostics of the equipment resulting in interoperability, and yielding cost reduction for the vendors, and ultimately for the end users.

This article discusses the fieldbus as a part of a digital control system, provides a short market survey of the existing fieldbuses, and analyzes future trends.

2 COMMUNICATING SENSORS TO NETWORKS

The fieldbuses interconnect field devices. A typical interconnection of field devices is illustrated in Figure 1. In a complete fieldbus configuration, a variety of components such as sensors, instruments, analog and digital components, and controllers are connected to the system for measuring, monitoring, and control purposes. These interconnected field components can be grouped into three major categories:

1. traditional analog and discrete input/outputs (I/O)
2. hybrid analog and digital devices, and
3. purely digital devices.

Analog devices are usually connected to controllers by means of dedicated 4 to 20 mA analog current loops. The hybrid components are capable of using both analog and digital communication techniques. For example, a protocol called *Highway Addressable Remote Transducer* (*HART*)

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

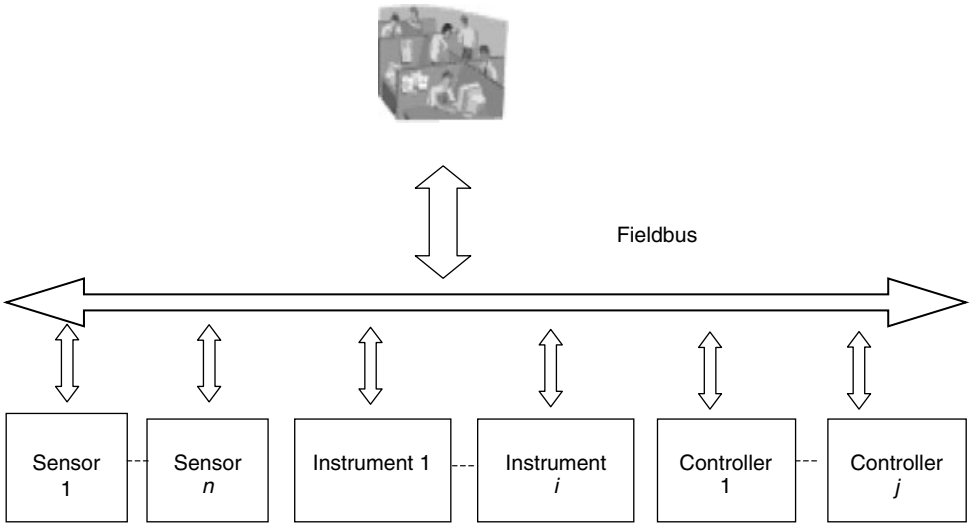

Figure 1. Connection of sensors, instruments, and controllers to a fieldbus.

uses digital communication signals onto a conventional 4 to 20 mA analog signal. The third type, purely digital components, usually requires digital interface hardware and software such as the RS-232, USB, and IEEE 488 parallel buses.

In the wake of relatively new technology on intelligent or smart sensors – *see* **Article 160, Smart Sensor System Features, Volume 3** – the communication may be realized by new wired-in techniques, such as I^2C or I^2S, Integrated Smart Sensor buses, and many others. Some of these buses have the following features:

- they are simple, requiring only two lines for communication (clock line and data);
- the required supporting electronic componentry is at a minimum;
- the transmission can be terminated either by the master or the sensor, an example being the Motorola MCM20027 color image sensor.

Nowadays, many instruments and intelligent sensors communicate by wireless techniques using protocols such as Bluetooth, UWB; 802.11a/b/g (Wi-Fi); GPRS; ZigBee; 802.15.4; IEEE P1451.5, and so on.

Communication by the use of radio frequencies (RF) is now a well-established field. It can be realized by standardized or nonstandard methods. The choice of these methods depends on the application requirements and complexity of the instruments, and on the sensors and capabilities of the host fieldbus system. Some RF techniques have a high level of power consumption so it may not be convenient in some applications such as in portable wireless instrumentation systems.

3 ELEMENTS OF CONNECTING SENSORS

Almost all modern fieldbus systems operate on digital and computerized systems. As yet, the majority of sensors still produce analog signals thus requiring analog-to-digital (A/D) conversion by means of suitable converters. Similarly, many controllers require analog signals; hence, digital signals from the bus need to be converted back into analog forms – *see* **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**.

Typical elements needed for the connection of sensors to the digital environment are illustrated in Figure 2. Front-end analog-signal processing is necessary for amplification or attenuation and filtering of signals generated by the sensors. In addition to analog-signal processing, the A/D conversion process takes place with the aid of appropriate sample-and-hold devices and multiplexers. Multiplexers allow the connection of many sensors and transducers to the same signal-processing media.

Analog-to-digital conversion involves three stages: sampling, quantization, and encoding. In all-digital instruments, the Nyquist sampling theorem must be observed; that is, 'the number of samples per second must be at least twice of the highest frequency present in the continuous signal'. As a rule of thumb, depending on the significance of the high frequencies, the sampling must be about 5 to 10 times of the highest frequency component in the signal. The next stage is the quantization, which determines the resolution of the sampled signals. Quantization involves errors that decrease as the number of bits increases. In the encoding stage, the quantized values are converted to binary numbers to be processed digitally.

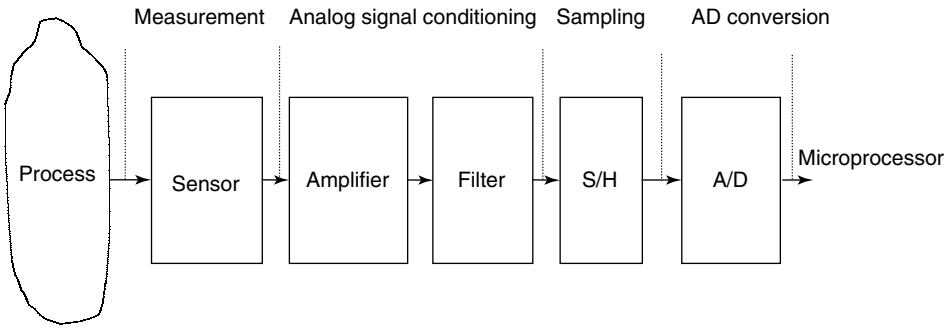

Figure 2. Basic elements of a sensor linking to a fieldbus.

For the process actuators and controllers, the digital signals are converted to analog waveforms by D/A converters and then filtered and amplified before being applied to the controllers.

Nowadays, due to easy and cost-effective availability of advanced microprocessors and the supporting components, many sensors and instruments are based on powerful digital systems integrated at various stages, starting right from the sensing elements through complex communication capabilities. Therefore, microprocessors, microcontrollers, and digital signal processors constitute the other essential elements for interconnecting sensors to the fieldbuses. The use of microprocessors makes the sensors and controllers self-supporting allowing them to take local decisions under the instruction of the fieldbus system. Microprocessors also allow convenient man–machine interface, diagnostic capabilities, self-configuration, and self-identification.

4 NETWORK PROTOCOLS

Field instruments are connected to digital systems and computers, thus forming networks such as Direct Digital Control (DDC) systems, Supervisory Control (SC) systems, Distributed Control Systems (DCS), Hybrid Control Systems (HCS), Supervisory Control and Data Acquisition (SCADA) systems, and so on.

The interconnected devices communicate through a particular common bus network using communication protocols (defined ways of doing things) that are developed to guarantee precise intended information flows between components.

In industrial systems, different control units may need to share the data collected by a sensor, and disseminate the processed data to the various actuation units. Thus, transactions involving one producer on the field and several consumers of a real-time variable have to be supported. In this respect, a focus on the group communication on the shop floor bears particular importance. These types of communications are realized by the data link layer protocols or the Fieldbus protocols. These protocols provide a series of facilities, which help the application process to check that the real time operation–requirements are met.

The messages that sensors generate can be divided into short and long messages. While the short messages are usually processed locally, the long messages are processed by the central computers or remotely located computers. The length and type of messages is fairly important in the configuration of fieldbus. In this respect, the fieldbus forms the first stages of information gathering, data flow and decision making about the process under control. Some examples are the integration of the fieldbus with Computer-aided Facility Management (CAFM) systems and the integration of fieldbus systems into Distributed Object-oriented Systems (DOOS).

As mentioned earlier, the information flow between the nodes, individual instruments, and the computers are regulated by protocols. According to the IEEE, a networking protocol is ‘a set of conventions or rules that must be adhered to by both communicating parties to ensure that information being exchanged between two parties is received and interpreted correctly’. The protocol defines the following issues:

1. Network topology supported: star, ring, or bus (tree), and so on.
2. ISO reference model layers implemented: physical, datalink, network, transport, session, presentation, and application.
3. Data communication modes: simplex, half-duplex, or duplex.
4. Signal types: digital or analog.
5. Data transmission modes: synchronous (include bit-oriented and character-oriented), or asynchronous, and so on.
6. Data rate supported: several bps (bits per second) to several Gbps (gigabytes per second), it depends on both oscillator frequency and transmission medium.
7. Transmission medium supported: twisted pair, coaxial cable, optical or microwave, and so on.

Table 1. ISO 7-layer reference model for communication and networks.

No	Layer	Application	Protocols
7	Application	Common application service elements (CASE); Manufacturing message services (MMS); File transfer and management (FTAM); Network management.	ISO 8650/2 (DP), RS-511, ISO 8571 (DP), IEEE802.1.
6	Presentation	Transformation of information such as file transfer. Data interpretation, format and code transformation.	Null/MAP transfer. ISO 8823 (DP).
5	Session	Communication and transaction management, synchronization, administration of control sessions between two or more entities.	ISO Session Kernel. ISO 8237 (IS).
4	Transport	Transparent data transfer, mapping, multiplexing, end-to-end control, movement of data elements.	ISO Transport, Class 4. ISO8073 (IS).
3	Network	Routing, switching, segmenting, blocking, error recovery, flow control. Wide area relaying.	ISO DIS 8473, Network services, ISO DAD 8073 (IS).
2	Link	Transmission of data in local network. Establish, maintain and release data links, error and flow.	IEEE 802.4 Token Bus. IEEE 802.2 Type 1 Connection services.
1	Physical	Electrical, mechanical and packaging specifications. Functional control of data circuits.	ISO/IEEE802.4, phase Coherent Carrier, Broadband, etc.

8. Medium access control methods: Carrier Sense Multiple Access with Collision Detection (CSMA/CD), or control token, and so on.
9. Data format: mainly based on data transmission modes and individual protocol specifications.
10. Error detection methods: parity, block sum check, or Cyclic Redundancy Check (CRC), and so on.
11. Error control methods: echo checking, Automatic Repeat Request (ARQ), or sequence number I, and so on.
12. Flow control methods: X-ON/X-OFF, window mechanisms, or sequence number II, and so on.

Table 1 shows ISO seven-layer reference model layout for the protocols and some of the protocols that are relevant to that particular layer. The ISO reference model has seven layers of which each is an independent functional unit. Each one uses functions from the layer below it and provides functions for the layer above it. The lowest three layers are network-dependent layers, the highest three layers are network-independent layers (application-oriented) while the middle layer (transport layer) is the interface between the two.

Most fieldbuses use only a few of these layers, being usually the physical, data link, network, and application layers.

5 THE FIELDBUS CONCEPT AND SYSTEMS

The fieldbus is an industrial communication system that is configured and supported by single companies or groups of companies or private and government agencies. In the course of development of the fieldbus, unfortunate proliferation took place because many different technology approaches existed among the vendors serving their commercial desire for market dominance.

Implementation of a fieldbus involves hardware as well as software, with a trade-off being necessary between the two. Most fieldbuses have associated chips for implementing all or portions of system specifications. For example, in LonWorks protocol, all layers can be implemented by chips and associated software. The software defines all the objects and libraries that are readily available for the customer. But, for another CAN, the lower two layers are implemented by protocol chip (82C200); all the software has to be done by the user.

There are now more than 50 different fieldbus products or standards in the marketplace being reported by manufacturers in conferences, magazines, and exhibitions. Table 2 lists some of the most commonly used fieldbuses. Other fieldbus products not included in the table are the I/O-lightbus, Foundation Fieldbus, ICE 61 158, P-NET, INSTA

Table 2. Some examples of commonly available fieldbuses.

(EIB), Modbus, Bitbus, ArcNet, HART, and so on. The list continues to grow with movement toward any form of Open Systems Interconnect (OSI) methodology, like the technology that made computers easy to use and is still to come. In the mean time, users will need to cover the extra cost of customizing applications with additional middle-ware code and hardware to connect devices to communication channels, where they are not all made to the same standards.

6 CHARACTERISTICS OF FIELDBUS IMPLEMENTATION

Implementations of fieldbuses vary from system to system as vendors offer different forms of supporting hardware and software. Also, the nature and requirements of processes differ from each other. In order to explain characteristics of fieldbus implementation, Foundation Fieldbus will be taken as an example.

The Foundation Fieldbus is an all digital, serial, two-way communication system, which interconnects field equipment such as sensors, actuators, controllers, and computers. It is essentially a Local Area Network (LAN) for instruments used in the manufacturing, automation, and process industries, which has built-in capability to distribute the control application across the network. It is supported by an independent nonprofit corporation, known as the *Fieldbus Foundation* consisting of over 100 of the world's leading suppliers, manufacturers, and end users. Foundation Fieldbus, created in 1994, is a joint effort of two major organizations; the Interoperable Systems Project (ISP) and WorldFIP/North America. Its committee is formed by the members of the IEC and ISA, backed up by Profibus of Germany and FIP of France.

Foundation Fieldbus is particularly suitable in systems where the communication traffic involved is the periodic exchange of short information frames. However, purely periodic exchange of short information frames is not sufficient to meet all the communication requirements of the process. In this respect, the implementation of the communication models offered by the application layer through the access medium mechanisms are made available at the data link level. Therefore, asynchronous message (e.g. alarms, operator commands) transmissions are allowed as well as synchronous transmission. This approach is the key point in the definition of this particular protocol, as only correct mapping between the application layer communication models and data link layer mechanisms can guarantee to meet the time-critical requirements of the processes.

An important characteristic of the Foundation Fieldbus is the function block that defines the inputs, outputs, mode structures, and event subsystems for common control systems. These blocks provide a consistent and easy-to-use method for modeling standard control system functions. As far as the control computers are concerned, the system is seen as a collection of function blocks rather than as a collection of instruments. An important contribution of the Foundation Fieldbus is the flexibility of creating field devices that are capable of storing and executing the software routines in their own way. With the use of such intelligent devices, the function blocks permit the distribution and integrated execution of process functions among the field devices themselves.

The Foundation Fieldbus topology comprises two basic parts: a lower speed fieldbus called $H1$ and a higher speed fieldbus, the $H2$. These two fieldbuses can be connected together via a device called a *bridge*. The device descriptions are a standard mechanism that permits a control system to acquire the definitions of messages from a field device. Foundation Fieldbus is equipped with information on the device characteristics such as manufacturer's details, supporting software capabilities, available function blocks, and diagnostic capabilities. Such information is developed in Device Description Language (DDL), which originated from the HART protocol. This approach is expected to enable vendors to describe the functions of their devices in a standard way. They can also add new capabilities and novel features to the devices that can easily be accessed by the existing systems and users.

7 CASE STUDY OF FIELDBUS APPLICATION FOR A MEASUREMENT SYSTEM

Fieldbuses are applied across all cross sections of industry ranging from under the bonnet in cars to complex manufacturing plants consisting of tens of thousands of sensors, transducers, and controllers. Many companies offer interoperable products with a particular fieldbus. For example, the System Integration Specialist Company (SISCO) of Michigan, USA, offers a broad range of fieldbus products including adapter cards, servers, interface boards, programming tools, bus analyzers, protocol source codes, and so on. The company also offers fieldbus pressure transmitters, temperature transmitters, programmable logic controllers, fieldbus-to-current converters, fieldbus-to-pneumatic-signal converters, valve petitioners, and other accessories. Also, many companies are producing wireless connections for accessing distant sensors and actuators.

As an example of implementation of fieldbuses, Fuji Electric of Japan has developed open systems in the field of instrumentation control and promoted the establishment of Foundation Fieldbus standards. The company has been working on fieldbus specifications, hardware developments,

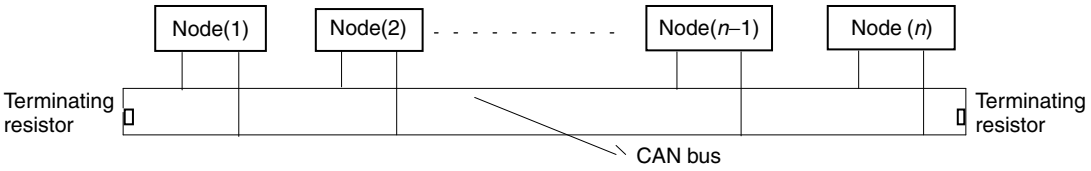

Figure 3. A typical CAN network layout in a laboratory environment.

promotions for increased usage, and public relations. Fuji Electric has started the fiber optic fieldbus working group, and the results of the work have been finalized as a final specification in the Fieldbus Foundation.

In a laboratory environment, the author implemented the CAN protocol, as illustrated in Figure 3. This particular system contains a number of sensors and actuators. From amongst many other CAN controllers, the 82C200 chip from PHILIPS was selected.

In this project, the implementation was realized by three sublayers. These were the Logical Link Control (LLC) and Medium Access Control (MAC) sublayers for the data link layer. This CAN implementation allowed messaging between sensors, actuators, man–machine interfaces, controllers, and other control activities. This architecture provided a communications environment upon which a high-speed, real-time centralized or distributed control platform could be created.

8 DESIGNING, IMPLEMENTATION, AND TESTING OF FIELDBUSES

Designing: In the design of a fieldbus system, the process characteristics must be well understood. Once the measuring, monitoring, and control objectives are identified, selection of the appropriate fieldbus will be dependent on costs of the system and integration of the selected fieldbus to the existing instrumentation in the plant. As indicated in Table 2, a suitable fieldbus must be selected for a particular application, such as BACnet for intelligent buildings, Profibus for industrial applications, and so on. Once the decision is made, manufacturer's instructions for installation, commissioning, and maintenance must be followed closely. It is important that in the selection process the interoperability of sensors and instruments offered by different manufacturers must be observed.

Implementation: There are many methods of implementing fieldbuses, some of which will be described here. Apart from the hard-wired connections, wireless implementations of fieldbuses are becoming popular as many of today's instruments often have wireless communication features built in. The most popular means of transmission using wireless systems are the LAN adapters, radio modems, and packet controllers. The difference between the three is in the way that the data is processed between and during the transmission. Wireless transmission devices are used to create complete wireless networks or partial networks with wireless segments of wired networks. Simple fieldbuses such as those based on RS-232C standard (e.g. Modbus) can easily be realized with use of radio modems or packet controllers.

If the network is more complicated or the required transmission speed is higher, LAN cards and more powerful processors are used. A number of reports describe solutions for wireless transmission in the networks such as LonWorks, CAN, or FIP.

The possibility of having wireless transmission is also included in the Foundation Fieldbus standard. At the moment, only low speed radio networks are standardized, but inclusions of higher speed radio networks are planned to be implemented in the near future.

Another implementation uses fuzzy component networks such as fuzzy sensors, fuzzy actuators, and fuzzy inference on fieldbuses. These fuzzy components are formed in groups to form fuzzy cells. Depending on its configuration, each fuzzy cell is able to perform the functions of one or several fuzzy components. Fuzzy cells are characterized by their ability to handle and exchange fuzzy symbolic information. Their configuration is performed via the fieldbus using the language Prototype of Integrated Language for Symbolic Actuators and Sensors (PLICAS), which is specially designed for this purpose. A PLICAS compiler is integrated inside each cell, thus conferring interoperability properties to the cell.

In time-critical communication systems, the Hopfield Neural Network (HNN) is extensively used. In time-critical systems, the correct implementation of proper scheduling sequence is very important. The implementation of the sequence must cater for the instants at which each transmission requirement must be fulfilled within the time constraints. Generally, the length of the scheduling sequence is equal to the minimum common multiple of the periods of the processes and needs to be memorized for later implementation. During this process, some problems arise if the sequence is large. The computational complexities arising in the sequences are overcome by adopting an HNN integrated with the fieldbus.

One important implementation is the integration of fieldbuses with the Internet. There are many examples of such systems that combine the benefits of the two to create synergy. It appears that the protocol Simple Network Management Protocol (SNMP), originally designed for the Internet, can be suitable for this purpose. This combination provides access to the fieldbus system from local or global computer networks by the use of common LAN management tools.

Testing: Testing of the operations of a fieldbus is conducted during the commissioning stage. Manufacturers supply self-testing and diagnostic capabilities under normal operating conditions. For testing and troubleshooting, manufacturer's recommendations must be adhered to.

9 CONCLUSIONS

Fieldbuses are industrial communication protocols that come with appropriate hardware and software for interconnecting field devices to computer or digital networks. There are many types of fieldbuses offered by a diverse range of manufacturers. In the implementation of fieldbuses, the interoperability of devices is important. Fieldbuses can be integrated with wireless instrumentation systems and the Internet.

1 TIMING ANALYSIS IN NETWORKED MEASUREMENT–CONTROL SYSTEMS

NMCS (networked measurement–control systems) are widely used in applications ranging from difficult process control to simple discrete manufacturing.

Usually, these systems impose real-time requirements on the nodes and communication networks (Kopetz, 1997; Sha and Sathaye, 1995). Stankovic (1988) defines real-time computing systems as those systems in which the correctness of the system depends not only on the logical result of computation but also on the time at which the results are produced.

There are many examples of real-time computing systems, such as control systems, flight control systems, and robotics. A typical real-time computing system has a real-time program running in the system, which reads inputs from input devices, processes these inputs, and produces outputs to be sent to output devices – *see also* **Article 78, Embedded Systems, Volume 2**.

The time between the arrival of an input from a device and the completion of the processing for that input is called the *response time* for the device (Joseph and Pandya, 1986).

The relative deadline for the device can be defined as the maximum interval between the instant of the input arrival and the completion of the processing for that input. The required response time for a device must be smaller or equal to its relative deadline.

In NMCS, the relative deadline is often assumed to be equal to the period. The task deadline value is set by object requirements but the value of the worst-case response time is a result of simulation methods or analytical techniques used to do the timing analysis.

It is assumed that each input and output device is assigned a task of the application program and that the tasks share the same processor. The problem of determining whether the processor will meet its peak-processing load becomes one of schedulability analysis of tasks in NMCS (Burns, 1991).

If the input (sensor node) and output (actuator node) devices are network components, then the input device processes events and generates messages to the output device. The problem of determining whether the communication system will meet its peak load is one of schedulability analysis of tasks.

Consideration of priority levels is crucial to a real-time system. If different inputs have different response time requirements, we need to consider different priority levels to schedule the related processing tasks. The problem is to determine whether for a given assignment of priority levels, the system will meet its peak load – *see also* **Article 165,**

2 INTRODUCTION TO SCHEDULING SYSTEMS

Developers and integrators of NMCS face the challenge of meeting end-to-end real-time requirements. This requires techniques to ensure timing correctness both in embedded nodes and in the communication network. Schedulability analysis can be applied to prove that time requirements are satisfied.

Scheduling is defined as a resource (processor, network) allocation required to task (program, message) execution and its termination in the required time.

The general problems are to find a sequence in which tasks pass between the resources, that there is a feasible schedule, and that it is optimal with respect to some decided economic and/or performance criterion.

Reliable timing behavior is crucial in NMCS with real-time requirements. In many cases, designers and/or developers have had to rely on testing to establish timing reliability. Using suitable scheduling methods, system developers can verify timing behavior at the design stage and implement the required timing behavior into the application right from the start. Scheduling allows estimate resource utilization and establishes relationships between the task's worst-case response times and their deadlines. It determines whether a designed system is schedulable and indicates the margin by which a deadline is met or might be missed.

A large number of approaches to modeling and solving scheduling problems have been reported in the literature for this topic. This article focuses on the static approach because this methodology best fits the NMCS. Scheduling theory provides a well-founded way of predicting whether a designed system having real-time requirements will meet their deadlines or not.

3 SCHEDULING THEORY

3.1 Classification

The schedulability analysis can be performed online or offline as it is shown in Figure 1. In the online case, the schedulability of the task set is analyzed at run time, whereas in the offline case, it is performed prior to run time.

Offline scheduling requires little run-time overhead and the schedulability of the task set is guaranteed before execution. However, it requires prior knowledge of the tasks timing characteristics. If the tasks characteristics are not known prior to the run time, schedulability analysis must be performed online.

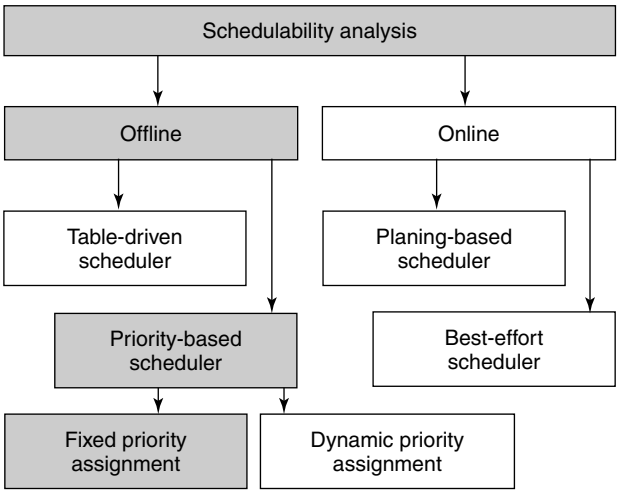

Figure 1. Basic types of schedulability analysis.

Ramamritham and Stankovic (1994) distinguish two basic types of online schedulers: planning-based and best-effort schedulers. In the planning-based type, when a new task arrives, the scheduler tries to redefine a new schedule, which is able to comply with both the requirements of the new task and the requirements of the previously scheduled tasks. The new task is only accepted for execution if the schedule is found feasible.

In the best-effort type, when a new task arrives, the scheduler does not try to perform a new schedule. The new task is accepted for execution; the system tries to do its best to meet deadlines.

Offline scheduling paradigms depending on whether the schedulability analysis produces a schedule according to which tasks are dispatched at run time.

The table-driven approach is the best-known example of an offline scheduling that produces a schedule.

The priority-based approach is an example of offline scheduling where no explicit schedule is constructed.

At run time, tasks are executed in a highest-priority-first basis. Priority-based approaches are much more flexible and accommodating than table-driven approaches.

3.2 Priority assignment schemes

The most used priority assignment scheme is to give the tasks a priority level based on its period: the smaller the period, the higher the priority. Thus, if they have smaller periods, their worst-case response time must also be smaller. This type of priority assignment is known as the RM (rate monotonic assignment).

RM scheduling theory ensures that, for a given fixed set of tasks with fixed and known priority ordering, as long as the system utilization of all tasks lies below a certain bound and appropriate scheduling algorithms are used, all tasks meet their deadlines. This puts the development and maintenance of real-time systems on an analytical basis, making these systems easier to develop and maintain. RM theory was introduced by Liu and Layland (1973) for scheduling independent, periodic tasks with end-of-period deadlines. RM is an optimal static priority scheduling algorithm for independent periodic tasks with end-of-period deadlines.

If some of the tasks are sporadic, it may not be reasonable to consider the relative deadline equal to the period. A different priority assignment can then be to give the tasks a priority level based on its relative deadline: the smaller the relative deadline, the higher the priority. This type of priority assignment is known as the DM (deadline monotonic) assignment (Leung and Whitehead, 1982).

In both RM and DM priority assignments, priorities are fixed, in the sense that they do not vary along time. At run time highest priority tasks are dispatched first. A similar dispatching policy can be used if the task, which is chosen to run, is the one with the earliest deadline. This also corresponds to a priority-driven scheduling, where the priorities of the tasks vary with time.

Thus, the EDF (earliest deadline first) method is a dynamic priority assignment scheme. Pre-run time–schedulability analysis of tasks dispatched according to the EDF assignment scheme was introduced by Liu and Layland (1973).

In all three cases, the dispatching phase will take place either when a new task is released or when the execution of the running task ends.

3.3 Preemptive and non-preemptive systems

A common implementation for embedded node software and for a Master/Slave communication system is to use a static cyclic system.

This involves the static creation of the schedule that typically consists of a number of tasks running one after another to form an overall schedule. The cyclic system does not make effective use of the CPU and worst-case response time for each task exceeds its period.

In a cyclic system, all tasks must run at harmonic processing rates. Such a solution can be used for nodes with a small number of tasks and for implementations without real-time requirements. To improve effective use of the node CPU, and to optimize worst-case response time, a task's priority levels with preemptive or non-preemptive scheduling policy can be used.

In a priority-based scheduler, a higher-priority task may be released during the execution of a lower-priority one. If the tasks are being executed in a preemptive context, the higher-priority task will preempt the lower-priority one.

In a non-preemptive context, the lower-priority task will be allowed to complete its execution before the higher-priority task starts execution.

This situation can be described as a priority inversion because a lower-priority task delays a higher-priority task.

3.4 Offline schedulability analysis

There are two basic types of analytical methods to perform pre-run time–schedulability analysis.

One is based on the analysis of the processor or network utilization. The other is based on the response time analysis for each individual task.

In Liu and Layland (1973), the authors demonstrated that by considering only the processor or network utilization of task set, a test for pre-run time–schedulability analysis could be obtained.

An analytical approach is used to predict the worst-case response time for each task. The obtained values are then compared with the relative deadlines of the tasks. Lechoczky (1990) and Audsley *et al.* (1993) improved the schedulability analysis introduced by Liu and Layland (1973).

The utilization-based test needs a simple computation procedure, which is applied to the overall task set. For this reason, they are very useful for implementing schedulers that check the feasibility online. However, utilization-based tests do not give task's response time values. It constitutes sufficient, but not necessary, conditions. For more complicated task models, the utilization-based tests cannot be used, see Tindell (1992).

3.5 Basic utilization-based test

For the RM priority assignment, Liu and Layland (1973) proved that a set of N independent periodic tasks characterized by a worst-case computation time C and a period T scheduled by the rate monotonic algorithm will always meet their deadlines for all tasks, if a utilization-based pre-run time–schedulability test is following.

$$U = \sum_{i=1}^{N} \frac{C_i}{T_i} \leq N \times (2^{1/N} - 1) \tag{1}$$

where: C_i is the worst-case computation time of task τ_i, and T_i is the minimum time between task τ_i releases (period).

Utilization-based tests are sufficient but not necessary conditions. This utilization-based test is valid for periodic independent tasks having relative deadlines equal to the period and for preemptive systems.

For the non-preemptive case Sha, Klein and Goodenough (1991) shows that similar analysis can be adapted to include task τ_i blocking time B_i, during which high priority tasks are blocked by low-priority tasks:

$$U = \sum_{i=1}^{i} \left(\frac{C_i}{T_i} \right) + \frac{B_i}{T_i} \leq i \times (2^{1/i} - 1), \quad \forall_{i,1 \leq i \leq N} \qquad (2)$$

where B_i is the maximum, blocking a task τ_i by lower-priority tasks than task τ_i.

3.6 Response time tests

The task response time test, for determining the interval between its minimum and worst-case values, is a very important time parameter to determine in difficult and safety-critical real-time projects.

To confirm that each task meets its deadline, the worst-case completion time of each task is calculated taking into account the influence of the other tasks. It was proven by Joseph and Pandya (1986) that the worst-case response time R_i, of task τ_i is found when all tasks are synchronously released at their maximum rate. For that instance, R_i can be computed using the following recursive equation:

$$R_i^{n+1} = \sum_{j \in hp(i)} \left(\left\lceil \frac{R_i^n}{T_j} \right\rceil \times C_j \right) + C_i \qquad (3)$$

where *hp(i)* denotes the set of tasks of higher priority than task i priority. The symbol $\lceil \rceil$ is the ceiling function: it is a roundup function.

Consider the initial value for R_i is zero. Recursion ends when $R^{n+1} = R^n = R_i$. If the worst-case response time R_i exceeds T_t (in the case of RM priority assignment) or D_i, (in the case of DM priority assignment) the task τ_i is not schedulable. This result is valid in the preemptive context.

For the case of non-preemptive tasks, the utilization-based test using (3) was updated by Sha, Klein and Goodenough (1991) to include a blocking factor, during which higher-priority tasks can be blocked by low-priority tasks.

Taking into account the blocking factor B_i the worst-case response time for non-preemptive approach can be derived from the following recursive equation:

$$R_i^{n+1} = B_i + \sum_{j \in hp(i)} \left(\left\lceil \frac{R_i^n}{T_j} \right\rceil \times C_j \right) + C_i \qquad (4)$$

where $B_i = \max C_j$ for *lp(i), lp(i)* denotes tasks with lower priority than task τ_i.

4 FUNCTIONAL MODEL OF NMCS

An NMCS is implemented by a set of embedded nodes. Each node runs a number of tasks. These tasks communicate with each other by passing messages between nodes across the shared network. In order to meet the timing requirements, the end-to-end communication delay, composed of sender node generation delay, queuing delay during accessing network, transmission delay, and delivery delay in receiver node, must be bounded.

Now consider the techniques that can be applied both to software within nodes, and to messages passing on shared buses, to determine that deadlines will be met.

To analyze the time constraint of a networked, distributed system, we can distinguish three functional layers: node application layer, communication stack layer and network layer shown in Figure 2 (Michta, 2002).

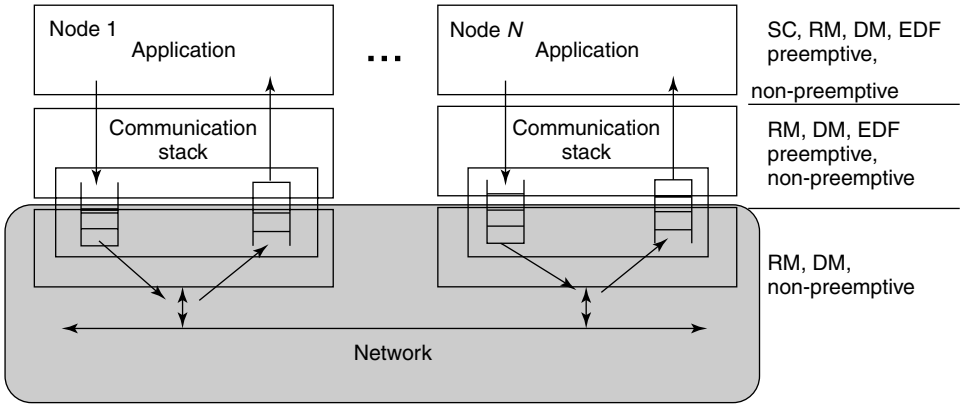

Figure 2. Functional model of NMCS and scheduling approaches.

During analysis of each layer, a combination of different scheduling policies can be used. For example, the network layer may be priority driven with use of nonpreemptive RM or DM polices: nodes may be priority or time driven with use in both preemptive and nonpreemptive approaches. Different nodes may have different scheduling policies due to manufacturer's preferences; thus, during the NMCS designing phase, there exist many influences on the choice of a communication system.

RM, DM, and EDF are a priority-based scheduling algorithm, so the system must have an adequate number of priority levels that can be assigned to tasks on each layer.

The primary objective during designing phase is to decouple the scheduling of resources and analyze the scheduling of each node processor and each network. As we can see in Figure 2, the same techniques of analysis for task scheduling on the processor node and message scheduling across the network can be used. Decoupling resources allow us to separate the scheduling problems and simplify the development and maintenance of nodes and NMCS.

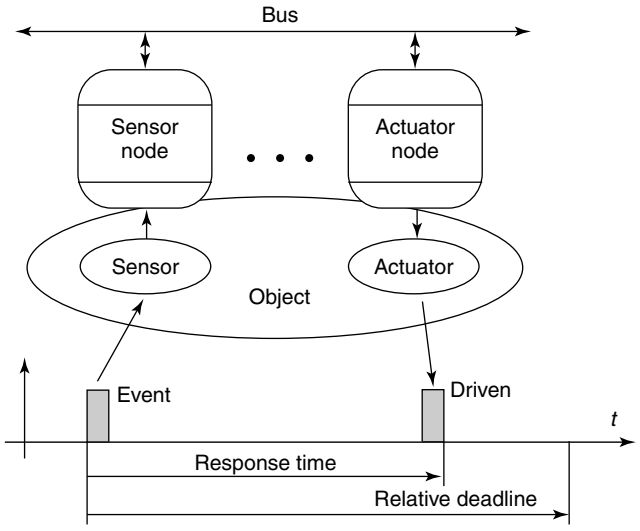

Figure 3. Two nodes NMCS.

5 TASKS MODELING

Consider the simple NMCS shown in Figure 3 with three basic components: communication bus and two nodes: source node (sensor node) and destination node (actuator node). The nodes cooperate throughout the network to provide the end-to-end functionality. In a real-time system, this end-to-end functionality, from event to response, must be provided within a specified deadline. The response time R_i on event i should be lower than deadline D_i. Timing analysis is applied to a resource being shared between multiple activities. According to the NMCS model shown in Figure 2, on an application level, the several sensor and actuator node functions are executed by a single microprocessor. On a communication stack level, the output and input messages wait in queue to be served and finally carry a number of messages sent by nodes on a network layer on one bus.

To simplify timing analysis of a sensor to actuator node communication, we partition the analysis into components that can be analyzed independently, as shown in Figure 4.

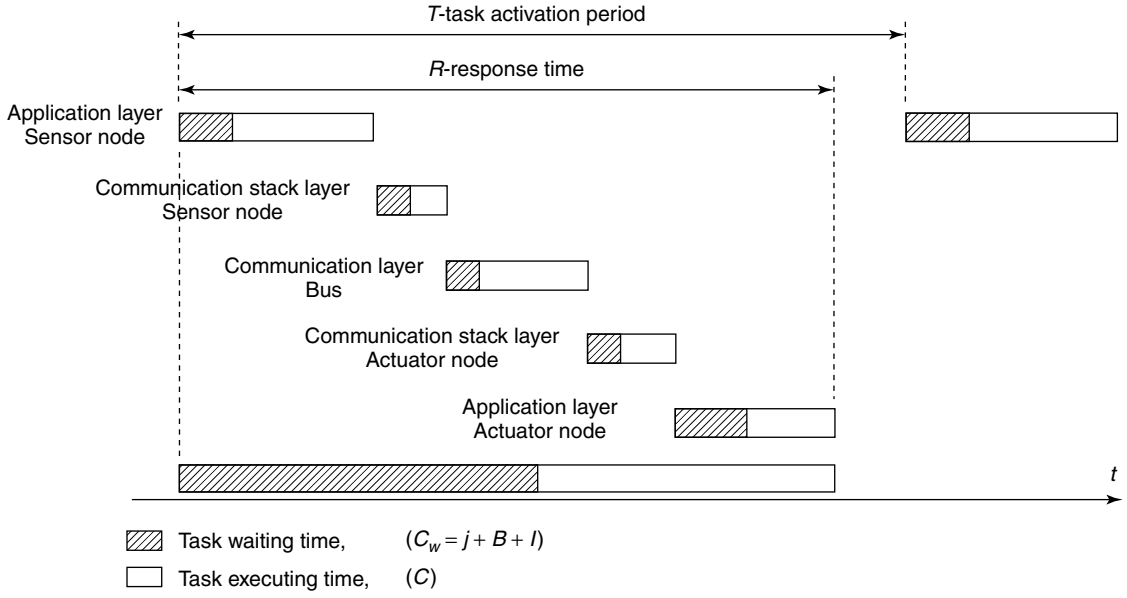

Figure 4. End-to-end communication timing analysis.

For task τ_i, release jitter time J_i, blocking time B_i, and interference time I_i are joined together and represented by the gray area (waiting time) to the left of the execution time windows shown in Figure 4.

End-to-end response time depends on the response time of each component involved in meeting the deadline.

Different offline scheduling policies could be investigated using this simple control loop as an example. If preemption is used, the blocking time corresponds to the longest duration of a low-priority code sequence that must run in mutual exclusion of the task. Without preemption, blocking is the duration of the longest lower-priority task. The interference time equals the total execution time of higher-priority tasks that may appear during the maximum response time.

In Figure 4 are shown execution times of tasks on the two nodes (sensor and actuator), and the communication task execution time on the bus.

An execution window represents each activity. The left end of the box represents task arrival and the right end represents the latest task completion. The length of the box represents the task response time on a given level. The activity may be finished at any time after the minimal execution time represented by the length of the white box. In the worst case, release jitter and blocking and interference from other tasks may delay task execution.

6 SCHEDULING TASKS ON NODE

In this section, the application of the scheduling theory to the design of a hypothetical, simple distributed real-time NMCS is reviewed.

Before going into the analysis, a few assumptions about tasks and node real-time operating system (RTOS) are needed:

- The set of tasks and their priority is fixed and known.
- Each task must have unique priority.
- The task deadline is no longer than its period.

During the designing stage, we can decouple scheduling of resources and analyze independently the scheduling of each node processor and each network. The same analysis technique for task scheduling on a processor node and message scheduling across the network will be used.

Consider that the utilization-based test and the worst-case response time evaluation, assuming a set of four independent, periodic tasks, with deadline lower than the period, is implemented in single processor node as shown in Figure 5.

Each task τ_i is characterized by a worst-case computation time C_i a period T_i and relative deadline D_i. The tasks deadline is lower than their period, so preemptive contexts

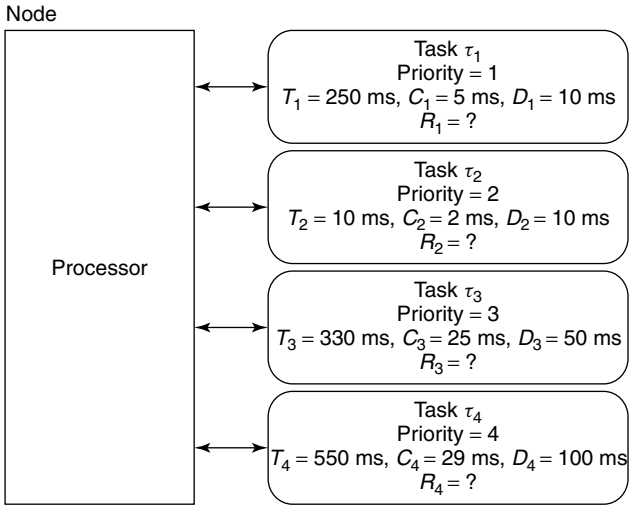

Figure 5. Single processor node. A set of node tasks with priority assignment according to DM priority order.

with both RM and DM scheduling policy can be used. Tasks shown in Figure 5 are in DM priority order.

To determine if a given set of independent tasks is schedulable, we use (1) and (3) introduced in Section 3. According to (1), the total processor utilization by four tasks $\tau_1-\tau_4$ is 0.29, which is less than 0.76, the bound for four tasks. Hence, these four tasks are schedulable.

In the next step, the worst-case response time for each task should be calculated. In Figure 6 is shown the results of the worst-case response time analysis, obtained from (3) for $\tau_1-\tau_4$ tasks with priority assignment according to the DM method and preemptive context.

The worst-case response time of a task for the preemptive context was introduced in Section 3. For each task, τ_i the

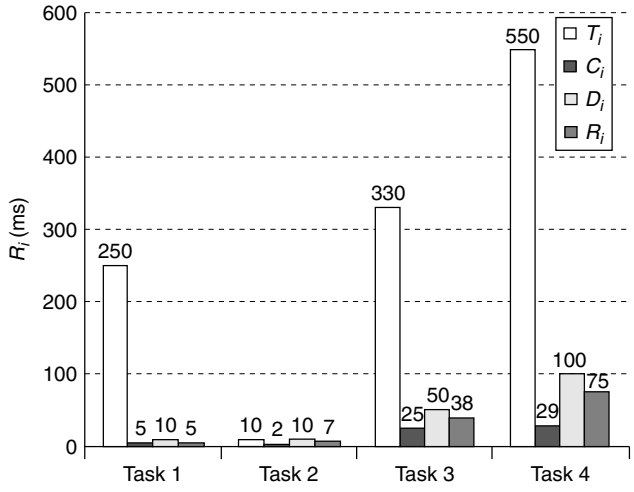

Figure 6. Results of a task scheduling with DM priority order for single processor node with task preemption.

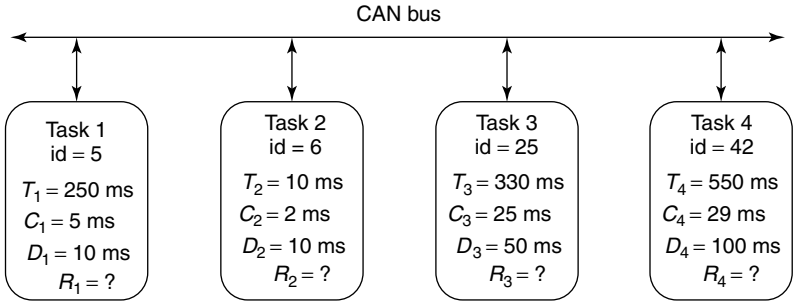

Figure 7. CAN network and a set of node messages with id assignments according to DM priority order.

worst-case response time R_i is lower than the task relative deadline D_i, so analyzed tasks set up in single processor node are schedulable. We can find that worst-case response time for task τ_2 is $R_2 = 7$ ms which is lower than the task deadline $D_2 = 10$ ms but, comparing with other tasks gives the smallest margin of safety $S_2 = 3$ ms.

7 SCHEDULING MESSAGES ACROSS A NETWORK

Suppose we have a four node network as shown in Figure 7, each with one independent, periodic task with given time parameters (T, C, and D). Here we have four periodic messages to be transmitted on a CAN network. CAN is a peer-to-peer communications bus for sending and receiving short real-time messages of up to 1 Mbps.

Each frame starts with an identifier that uniquely marks the frame – see Tindell, Hansson and Wellings (1994).

In our example, task τ_1 has id = 5, task τ_2 id = 6, task τ_3 id = 25 and the last one id = 42. This identifier is the transmitted most-significant bit first. It is important that no two nodes transmit frames with the same identifier as otherwise the arbitration will not work.

The effect of the arbitration scheme is to assign a priority to each frame, being the value of the identifier, where a smaller number is a higher priority. This priority-based scheduling of network is suited to the application of schedulability analysis.

Results of analysis and prediction of the worst-case response timing behavior of the NMCS based on a CAN bus, with non-preemptive DM approach for the communication level are shown in Figure 8.

Analysis was carried out by the use of (2) and (4) for the non-preemption approach. The analysis was done for each task and completed when the recurrence equation had converged to a consistent response time. Only the task τ_4 time requirements are met. Time requirements for the task τ_3 are almost met; for soft real-time systems it could

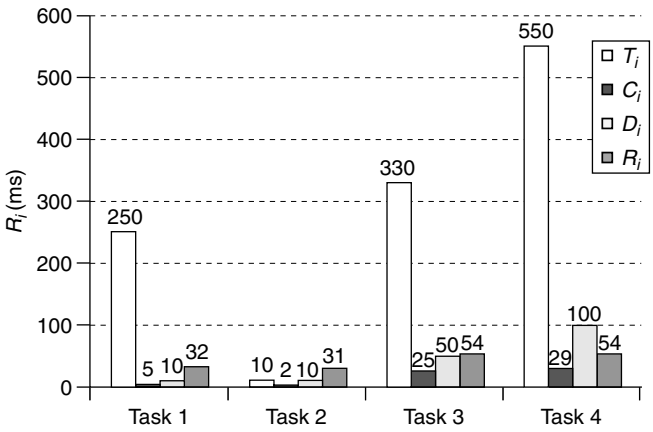

Figure 8. CAN network. Results of tasks scheduling with DM non-preemptive method.

be acceptable. Task τ_1 and task τ_2, for the DM offline scheduling approach, exceed its deadline significantly.

To reach schedulability on the CAN bus level we should increase the transmission rate to shorten the tasks execution time C.

As we can see, tasks with the same time parameters on the node and network level are scheduled only on the node level: this uses the preemption approach in access of its resources and thus can miss its deadlines on the CAN bus level for the three tasks.

8 TRENDS

The scheduling methods presented rely on deterministic techniques, which are based on worst-case execution times of tasks. This approach is sufficient for some types of timing constraints but is inadequate when relative constraints exist between tasks, and when execution times can range between lower and upper bounds. Developing novel techniques to solve this problem is needed.

Most of the real-time scheduling algorithms are based on the assumption that no error occurs in real-time systems. In order to make the real-time scheduling algorithm

more realistic, task precedence constraints need to be taken into account.

In mission critical applications, real-time tasks must tolerate faults. It would be interesting to combine proposed real-time analysis with real-time fault-tolerant scheduling algorithms for periodic real-time tasks in distributed systems.

With the popularity of the Internet and the Ethernet, a new design tool for Web embedded real-time systems is needed. Switched Ethernet can deliver IP packets deterministically at low cost. Ethernet and IP networking is becoming a good choice for real-time working.

1 RELATIONS BETWEEN TEST SIGNALS IN THE TIME DOMAIN

In the time domain, especially for testing measuring systems, three forms of signals are used as often as an approximation. They also are used as typical model signals, see Section 3. These are

1. the unit pulse signal or the Dirac impulse $x(t) = \delta(t)$ (1a)
2. the unit step signal $x(t) = w(t)$ (1b)
3. the unit ramp signal $x(t) = ct; \quad c = 1$ (1c)

and last but not least, the sinusoidal test signal as treated in **Article 27, Signals in the Frequency Domain, Volume 1**.

The three signals are shown in Figure 1.

The three functions (1a, b, c) are related to each other: they are each the integral of the other

$$\int_0^t \delta(\tau)\,\mathrm{d}\tau = w(t) \tag{2a}$$

$$\int_0^t w(\tau)\,\mathrm{d}\tau = cx \text{ with } c = 1 \tag{2b}$$

Consequently, the inverse function yields

$$\frac{\mathrm{d}}{\mathrm{d}t} w(t) = \partial(t) \tag{3a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t} cx = c = 1 \rightarrow w(t) \tag{3b}$$

It may be remarked that using classical analysis, (3a) is not strictly realizable because the unit step function is a discontinuous function and, therefore, cannot be differentiated at $t = 0$.

This difficulty is overcome using the modern distribution theory (Posthoff and Woschni, 1984; Smirnow, 1979). Here, the discontinuous function is replaced by a continuous one and then the limit $\Delta t \rightarrow 0$ is realized as Figure 2 shows.

These relations between the test functions are very important in system theory because in linear systems, the output signals resulting from these inputs must have the same relations with each other.

2 TABLE OF IMPORTANT SIGNALS

The essential properties of important signals are summarized in Table 1. Individual signals have already been presented as examples in the relevant articles. The harmonic oscillation, the unit impulse, and the unit step are typical test signals for system identification. White noise (wideband noise) has been included in the summary as it is the most important interfering signal. For this signal, there is no amplitude density $\hat{X}(\mathrm{j}\omega)$, as has already

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

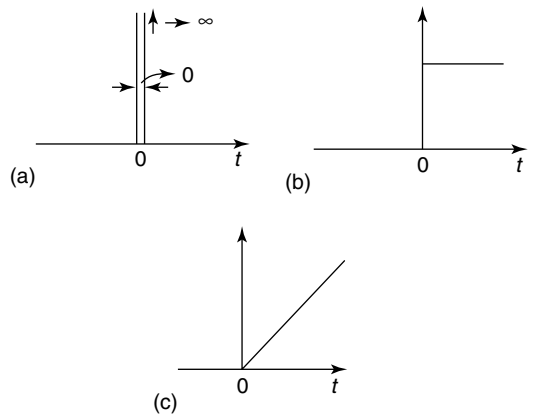

Figure 1. (a) Unit pulse signal; (b) unit step signal; (c) unit ramp signal.

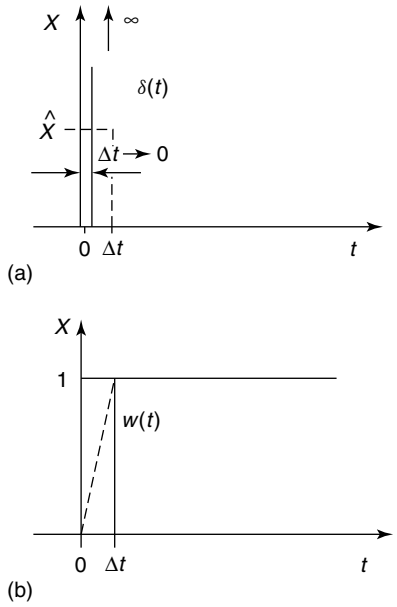

Figure 2. Interpretation of the relationship between unit pulse (a) and unit step; (b) function due to (3a).

been discussed in **Article 27, Signals in the Frequency Domain, Volume 1**. The relationships that have already been pointed out between time and frequency functions as Fourier transforms become evident: the narrower the time signals, the wider the band of the frequency signals present with the extreme case between the constant behavior in the frequency domain and the function behavior in the time domain, *see* **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**.

3 APPROXIMATIONS AND ESTIMATIONS

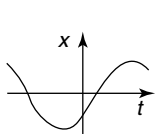
Of importance in measurement technology, in particular, are estimates and approximate considerations. In contrast to other fields of information engineering, for instance, control engineering is where input signals are given (i.e. they are known) and it is the output signals that are to be calculated; in measuring technology, the opposite has to be done for the input signal is the unknown system variable.

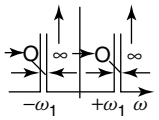
For this reason, before choosing a suitable measuring device and processor, it is necessary to make an assessment of the signal behavior to be expected, on the basis of a priori information, and to then choose the device.

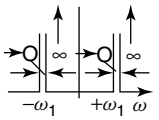
To this end, it is usual to approximate the quantity to be measured by either a pulse-shaped or a ramp-shaped signal. Therefore, these two signals have also been included in Table 1. The pulse duration and the duration of the ramp function respectively, can be taken from data on the technological process to be investigated, for instance, the speed in rotating machines. The ramp is a useful test signal for systems that cannot respond rapidly due to high inherent inertia.

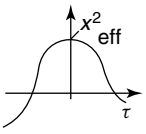
According to the sampling theorem, a threshold frequency ω_g corresponds to signal duration $2T_1$

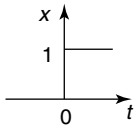
$$\omega_g = \frac{\pi}{2T_1} \tag{4}$$

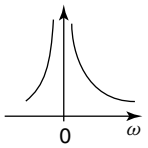


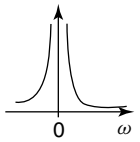


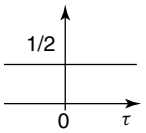


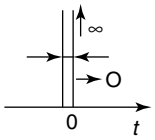


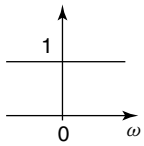


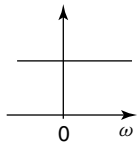


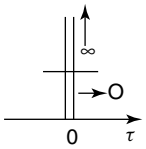


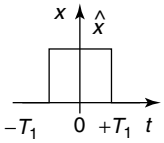


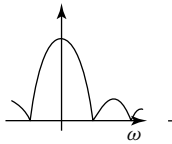


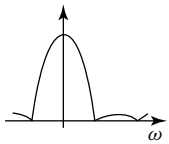


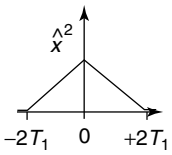


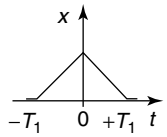


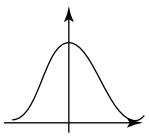


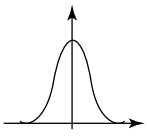


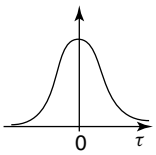


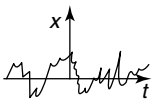


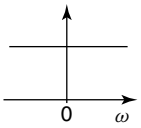


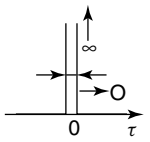












Above this frequency there are only spectral oscillations having a relatively low amplitude; the amplitude or power spectrum mainly lies below this threshold frequency (called *band-limited signals*). To avoid major measurement errors, it is therefore sufficient for the measuring device to cover this frequency domain, that is $0 \geq \omega > \omega_g$ (*see also* **Article 36, Systems in the Frequency Domain, Volume 1**). The dynamic response of typical linear systems is analyzed in detail in **Article 59, Introduction to the Dynamic Regime of Measurement Systems, Volume 1**; **Article 60, Zero-order System Dynamics, Volume 1**; **Article 61, First-order System Dynamics, Volume 1**; **Article 62, Second-order System Dynamics, Volume 1**.

4 NOISE SIGNALS

Noise signals are important in measurement technique firstly as test signals, and secondly because disturbances and electronic noise are inevitable in any measuring system. To describe these signals, Table 1 shows the power density function $S(\omega)$ and the autocorrelation function $\psi(\tau)$ of them. Between both exist relations that are treated in detail in **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**, see especially Table 2 – the so-called Wiener–Chinchine theorem.

$$\Psi(\tau) = \int_{-\infty}^{+\infty} \delta(\omega) e^{j\omega\tau}\, d\omega \tag{5a}$$

Table 1. Properties of important signals.

Characteristic	Time function $x(t)$	Amplitude density $\lvert\hat{X}(\mathrm{j}\omega)\rvert$	Power density $S_{xx}(\omega)$	Autocorrelation function $\psi_{xx}(\tau)$	Remarks
Harmonic vibration					Test signal
Unit step $w(t)$					Test signal
Unit pulse $\delta(t)$					Test signal
Pulse					Important for approximations
Ramp function					Important for approximations
White noise					Typical disturbance

$$S(\omega) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \Psi(\tau)\mathrm{e}^{-\mathrm{j}\omega\tau}\,\mathrm{d}\tau \tag{5b}$$

Furthermore, there are the mean square value $\overline{x^2(t)}$ and the effective value

$$X_{\mathrm{eff}} = \sqrt{\overline{x^2(t)}} \tag{5c}$$

with the relation to the autocorrelation function of

$$\overline{x^2(t)} = \Psi(0) \tag{5d}$$

as dealt with in **Article 30, Statistical Signal Representations, Volume 1**.

Often the signals can be assumed to be of Gaussian type. Wideband or white noise, having a constant power density S_{o} – see Table 1, is important because it arises in all electronic components and devices. To measure the value of S_{o}, a color filter – also called *shaping filter* – as shown in Figure 3(a) is used, leading to the generation of colored noise

$$S(\omega) = \frac{S_{\mathrm{o}}}{1+\omega^2R^2C^2} \tag{6a}$$

Figure 3(b) demonstrates its nature. Often met names of colored noise types are pink and gray noise.

From (6a) it follows the whole power is at the output if the limiting frequency of the measuring device at the output is ω_{c}

$$P_{\omega_{\mathrm{C}}} = \int_{-\omega_{\mathrm{c}}}^{+\omega_{\mathrm{c}}} \frac{S_{\mathrm{o}}}{1+\omega^2R^2C^2}\,\mathrm{d}\omega = \frac{2S_{\mathrm{o}}}{RC}\arctan\omega_{\mathrm{c}}RC \tag{6b}$$

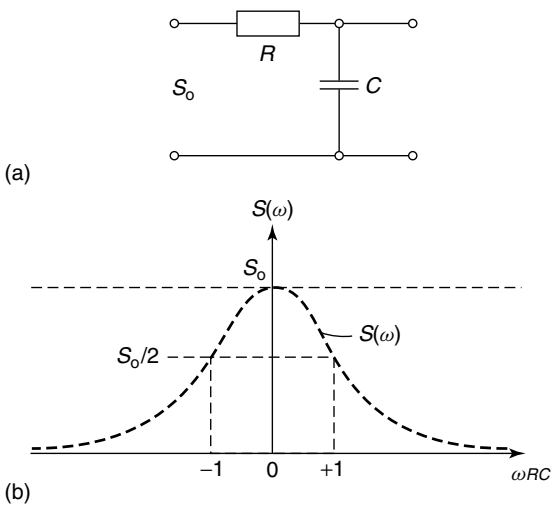


Figure 3. (a) Shaping filter (low-pass filter) and (b) colored noise.

and thus leading to the value of S_o

$$S_o = \frac{P_{\omega_c} RC}{2 \arctan \omega_c RC} \tag{6c}$$

The limiting case $\rightarrow$ yields (Woschni, 1988)

$$P = \frac{\pi S_o}{RC} \tag{6d}$$

Using this method, for instance, noise sources, such as noise diodes, may be calibrated.

1 COMPARISON OF ANALOG AND DIGITAL SIGNAL HANDLING

The information carrying variable in measurement is a signal. It is beneficial to consider the straightforward case of signal propagation through a channel using either analog or digital signal formats. Figure 1 gives block diagrams, which illustrates a way to compare these two possibilities. First, propose the existence of a channel for analog signal propagation/transmission/storage as shown in Figure 1(a). When the analog signal is applied to this channel, it is contaminated by noise during its passage through the channel. Apart from including a conditioning filter at the output of the channel, there is comparatively little that the channel designer can do to compensate for the intrusion of the noise. Data acquisition systems (DAS), and the various parts as such, are covered in detail in **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**; **Article 133, Amplifiers and Filters for DAS, Volume 3**; **Article 134, Analog Multiplexers, Volume 3**; **Article 139, Analog-to-Digital (A/D) Converters, Volume 3**; and **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**.

When the signal to be transmitted or stored is a digital signal, it is relevant to examine the situation closely. The possibility of noise interference is illustrated in Figure 1(b). Notice the first important difference, which is the increase in the complexity of the process. For digital operation, there needs to be sampling, quantization, conversion using an *analog-to-digital converter* (called an ADC for short), *see* **Article 139, Analog-to-Digital (A/D) Converters, Volume 3**, and encoding at the channel input. The process of encoding results in *pulse code modulation*, or PCM – *see* **Article 34, Modulation Theory, Volume 1**. This complexity is also an essential feature at the output of the channel, where reconstruction is followed by decoding, conversion to analog using a *digital-to-analog converter* (called a DAC for short) and probably filtering – *see* **Article 141, Digital-to-Analog (D/A) Converters, Volume 3**. However, because of the insensitivity of the digital signal to noise and drift, the channel input signal can be reproduced with higher fidelity after reconstruction at the channel output than in the analog system of Figure 1(a).

2 ANALOG AND DIGITAL SIGNAL PROCESSING

Signal processing, which is now an established area of electronic and electrical engineering, is concerned with the extension of the human abilities to extract and interpret the information content of a signal. Different and diverse classes of signals may be processed using either *analog signal processing* (ASP) methods or *digital signal processing* (DSP) methods – *see* **Article 144, DSP Chip Sets, Volume 3** and **Article 145, DSP Tools, Volume 3**.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

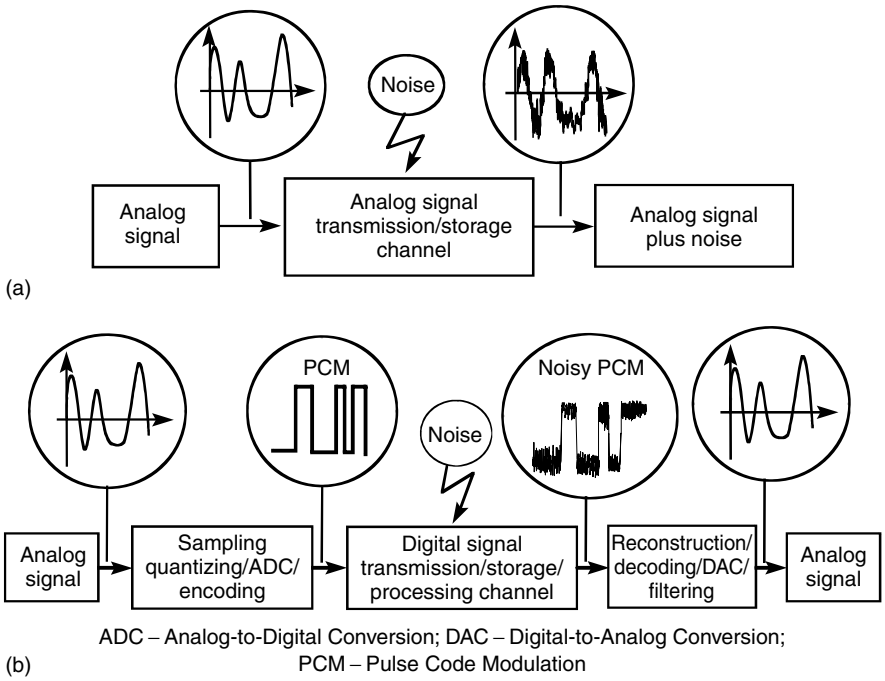

Figure 1. Transmission of (a) an analog signal through a noisy analog channel and (b) a digital signal through a noisy digital channel.

ASP, which involves the operations of amplification and filtering in the electrical energy domain, may also use optoelectronic methods, surface acoustic wave technology, and charge-coupled device technology. Alternatively, in the electrical energy domain, they may be converted into the digital form using an ADC, processed using digital techniques, and converted back into analog form using a DAC. This successive conversion between the two types of signal uses sophisticated electronic elements.

Digital signals are processed using digital computing methods, which involves the use of micro, mini or mainframe computers or nowadays more commonly with *personal computers* (PCs). The requirement for fast processing of digital signals has also contributed to the development of computers with a very fast processing capability called *array processors and supercomputers*. Special DSP devices such as the Texas Instruments TMS320 or the Motorola DSP56000 are also becoming widely used for certain applications.

Examples of ASP and DSP can be found in many different areas of application such as radar and sonar techniques, seismography, communications, optoelectronics, biomedicine, and all forms of measurement. Consumer applications, as occurs in sound and video recording and reproduction, are two additional areas in which signal processing is rapidly advancing. Radar and sonar systems, which may contain many analog filters in the receiver and demodulation stages, also contain increasing amounts of DSP technology to enhance the extraction of useful information from the signals. Because of this, they may be referred to as *HYBRID*. In seismography, the survey is processed and interpreted to detect the potential existence of oil and gas reserves. Data is recorded in digital format on magnetic tape. It is then processed '*off line*' in a data processing center. Many of the DSP techniques used in other areas of application originated in seismic data processing. In data measurement (DM), the DSP usually has to be performed in real time.

There are many situations in which it is necessary to maintain galvanic isolation between low voltage instrumentation circuits and the higher voltage, higher current levels associated with final control actuators. This can be arranged easily using optocouplers when the control signals are digital. In the case of analog control signals, the isolation barrier normally needs to be provided by a transformer. Rapid developments have occurred in digital signal processing hardware and software. Accompanying these developments are diverse methods that allow digital instruments to incorporate what may be loosely referred to as intelligence. In fact, this 'intelligence' is really an expansion in 'functional diversity'. In conclusion, it may be observed that digital DM systems are generally superior in most respects to analog instrumentation – *see* **Article 161, Knowledge-based Systems, Volume 3**; and **Article 128, Nature and Scope of AI Techniques, Volume 2**.

When analog signals are being processed, there is often an advantage in converting the signal to digital form so that the processing can be done digitally. For example,

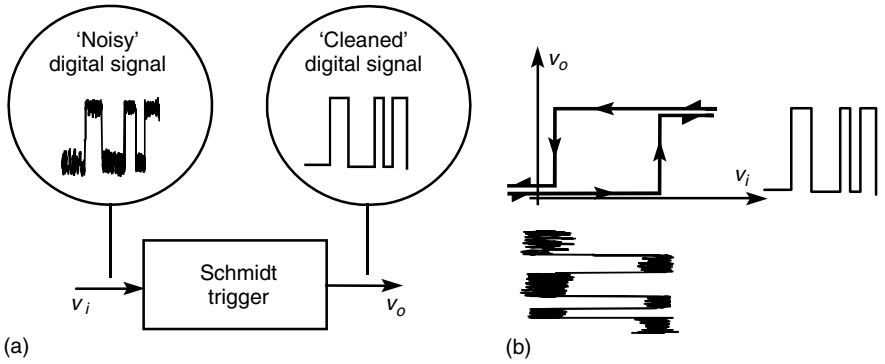

Figure 2. Illustration of the use of a Schmidt trigger in the restoration of digital signals (a) block schematic and (b) voltage transfer function.

the processing may consist simply of measuring an analog direct voltage. Using an analog voltmeter, the measurement is carried out by determining the position of a pointer on a scale. This measurement is usually subject to certain errors such as parallax. However, using a digital voltmeter, a more convenient and accurate numerical indication is given on a digital display panel.

The second example, which is illustrated in Figure 1(b), is based upon the ability to recover noisy digital signals using the method given in Section 3. The digital method enables an uncorrupted replica of a binary sequence to be recovered from a signal consisting of the originally uncorrupted sequence and a contaminating additive noise.

3 RESTORING NOISY DIGITAL SIGNALS

Information is the basis of all operations in machines for measurement, calculation, communication, and control. Propagation, transmission, storage, processing, and retrieval of information using digital signals have many advantages. One of these is the ability to detect the presence of a binary digit, or BIT, of information in the form of a noisy pulse even when the noise causes considerable distortion of the pulse. Using threshold detection circuits transforms a noisy digital signal into a 'cleaned' version of the same signal by arranging that the signal has only one of two possible levels. This operation, which is shown in Figure 1(b), is very similar to the tolerance in transistor–transistor logic, or TTL, logic circuits. For example, assume that the signals are active LOW, with 0 V as the '1'-level. When the signals are within the two prescribed ranges, they are regarded as either a logic HIGH, or '0', or as a logic LOW, or '1'. It is not permissible for the voltage to be anywhere between the lower threshold of the HIGH, '0'-level, and the upper threshold of the LOW level. When digital signals undergo attenuation due to loading effects, they can be restored or reconstructed to their correct TTL levels using a TTL circuit known as a *Schmidt trigger*. A Schmidt trigger is a special circuit that exhibits hysteresis in its voltage transfer function.

Consider Figure 2(a), where a noisy digital signal is applied to the input of the Schmidt trigger. The trigger circuit's operation latches the output to one particular level until the value of the input signal exceeds some designed threshold level. When this value is reached, the Schmidt circuit latches to the opposite polarity, where it will remain until the input signal reaches the reverse level switching threshold. The changes in signal level are shown in Figure 2(b). This illustrates the insensitivity of a digital signal to noise. It is also important to note that this insensitivity to noise is accompanied by insensitivity to drift. This ability to restore the levels of a digital signal allows the transmission, storage, and retrieval of signals much more easily. The fidelity of the digital data is preserved, whereas the fidelity of analog signals always degrades, sometimes quite substantially, with noise and drift.

1 SIGNAL FORMS

Suppose we were to look at a complex waveform on an oscilloscope. What is the signal? Is it the complete waveform? The peak (or rms or average) amplitude? The depth of modulation? The implied frequency spectrum? The difference in time or amplitude between two features of the waveform?

The answer, of course, is that the information-bearing signal could be any or none of the above. In this article, discussion is restricted to some commonly encountered types of signal for which enhancement is often required. Together with the enhancement technique normally used and described later in this section – **Part 12, Elements: F – Signals and Noise, Volume 3** – these are

1. base-band DC signals: low-pass filtering or autocorrelation;
2. amplitude modulated signals: band-pass filtering or phase-sensitive detection;
3. repetitive (not necessarily periodic) swept signals: signal averagers;
4. photon, electron, or ion beam signals: photon-counting systems.

The word signal is often used rather ambiguously to mean either the total signal being measured or a noise-free, information-bearing component of it.

2 SIGNAL-TO-NOISE RATIO

The following definitions should avoid such confusion. We will normally talk in terms of a total signal consisting of an rms signal component (S) accompanied by an rms noise component (N). Thus,

$$\text{Signal-to-noise ratio, SNR} = \frac{S}{N} \tag{1}$$

Note that

$$\text{measurement uncertainty, or inaccuracy} = \frac{1}{\text{SNR}} \tag{2}$$

$$\text{Signal-to-noise improvement ratio (SNIR)} = \frac{\text{SNR}_{\text{out}}}{\text{SNR}_{\text{in}}} = \frac{S_{\text{o}}/N_{\text{o}}}{S_{\text{i}}/N_{\text{i}}} \tag{3}$$

For unity gain (i.e. $S_{\text{o}} = S_{\text{i}}$), band-limited white input noise of bandwidth B_{ni} and output noise bandwidth B_{no},

$$\text{SNIR} = \frac{N_{\text{o}}}{N_{\text{i}}} = \sqrt{\left(\frac{B_{\text{ni}}}{B_{\text{no}}}\right)} \tag{4}$$

1 PURPOSE OF GROUNDING AND SHIELDING

Grounding and shielding increase safety and reduce noise within the operation of electronic circuits. Grounding and shielding also reduces the possibility of damage to components and circuit elements caused by electrostatic discharge (ESD).

General and specific accounts that review grounding and shielding, provide practical solutions for grounding and shielding, and provide key references are Fowler (1996), Johnson and Graham (1993), and Ott (1988).

Grounding has a two-fold purpose; it provides both reference for signals and safety for operators and personnel. The purpose for shielding is to prevent or reduce the transmission of disruptive electrical charge and signals.

2 GENERAL PRINCIPLES OF GROUNDING

The most important goal for grounding is to minimize the voltage differential between a circuit (or device, or instrument) and a reference point (Figure 1). Reducing the voltage differential provides both safety and signal reference.

An important distinction exists between a ground and a return. Ground connections and lines conduct no current during normal, undisrupted operation. Grounding provides a path for stray or harmful currents during times of atypical, disrupted operation. A ground is not a return path for either power or signal. A return path routinely conducts current; it completes the circuit for purposeful and designed current flow.

2.1 Safety ground

A safety ground must be a permanent, continuous, low-impedance conductor with adequate capacity that runs from the power source to the load (your instrument). Your aim is to reduce the voltage differential between external conducting surfaces (Figure 2).

Consider the following when developing a wiring and the grounding scheme for powering an instrument:

- Consider the instrument and the power mains as an integrated system.
- Draw the ground scheme with all possible circuit paths.
- Do not blindly rely on building steel to be the ground conductor; it can conduct significantly large currents, but through faulty installation and design elsewhere, it can be noisy or dangerous.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

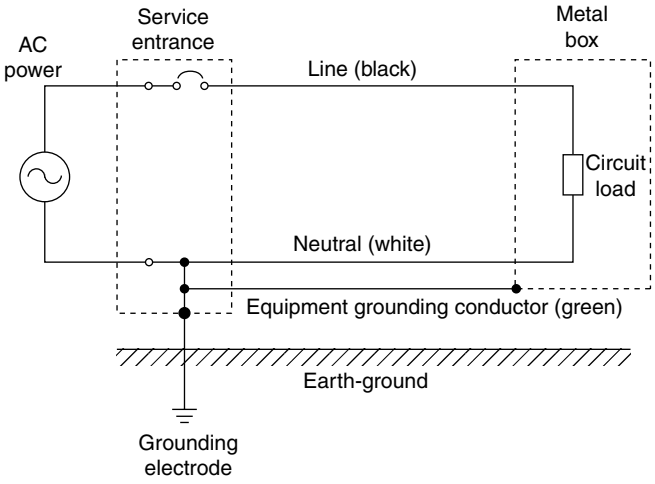

Figure 2. General scheme for safety ground in buildings. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

2.2 Ground configurations

Grounding may have different configurations depending on the application and the operation. The main configuration used in small circuits and instruments is the single-point ground. For larger installations and high frequencies, a multipoint configuration maybe more appropriate.

2.2.1 Single-point grounding

Single-point grounding connects one conductor from the ground structure, possibly the return conductor, in each circuit or subsystem to a single point for the entire instrument or system. It looks like a star pattern with a point and radiating conductors to the various circuits or subsystems. The point connects through a single conductor to chassis and safety ground. Figure 3 illustrates an example of a single-point ground.

The main purpose for single-point grounding is signal reference. Single-point grounding is useful in low current and low-frequency (typically less than 1 MHz) applications.

2.2.2 Multipoint grounding

A multipoint ground plane or grid is better for high-frequency (generally above 100 KHz) or high-current

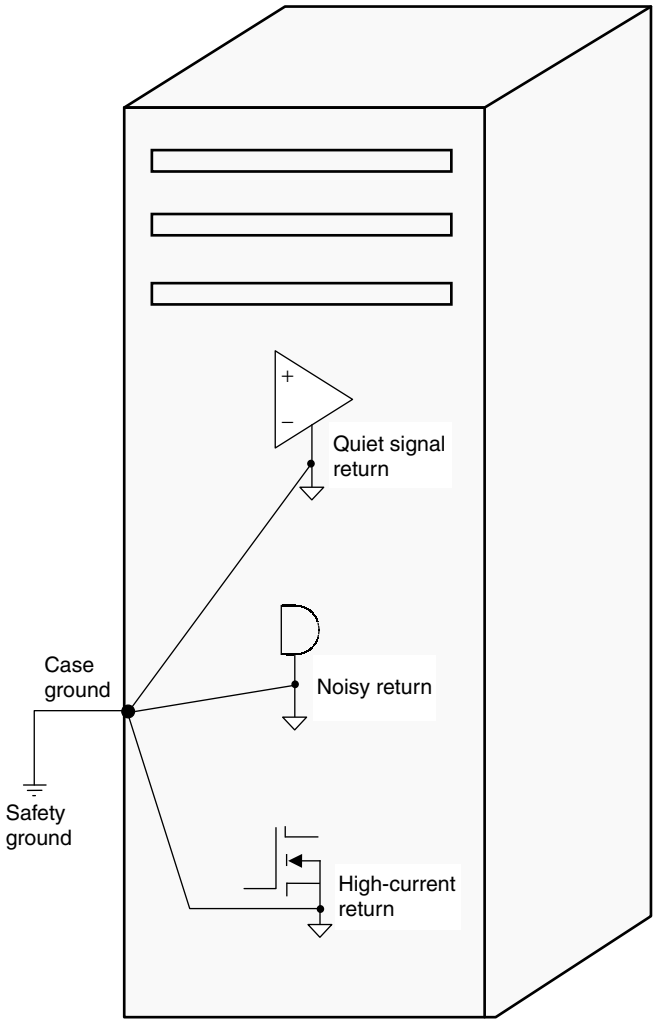

Figure 3. An example of a single-point ground. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

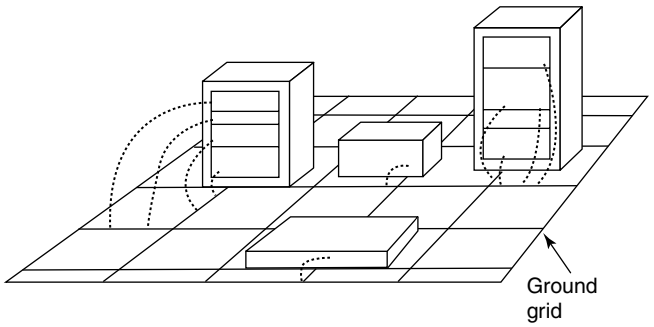

Figure 4. An example of a multipoint ground. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

fault applications. Multipoint grounding provides lower impedance than a single cable in single-point grounding. Figure 4 illustrates an example of multipoint grounding.

2.3 Ground loops

A ground loop is a complete circuit comprising both signal path and part of the ground structure. External currents in the ground can generate potential differences between the ground connections and introduce noise into the signal circuit, see Figure 5.

Generally, the problem arises at low frequencies (below 10 MHz); high frequencies tend to follow the path of minimum impedance that might avoid higher-impedance ground loops.

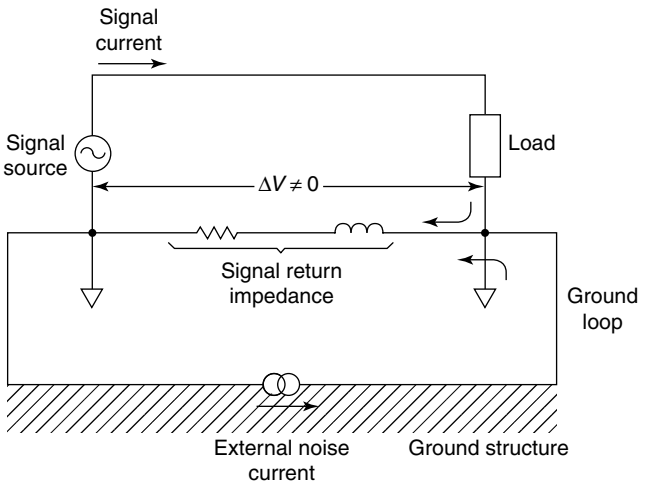

Figure 5. A ground loop occurs when a circuit makes several connections to the ground structure. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

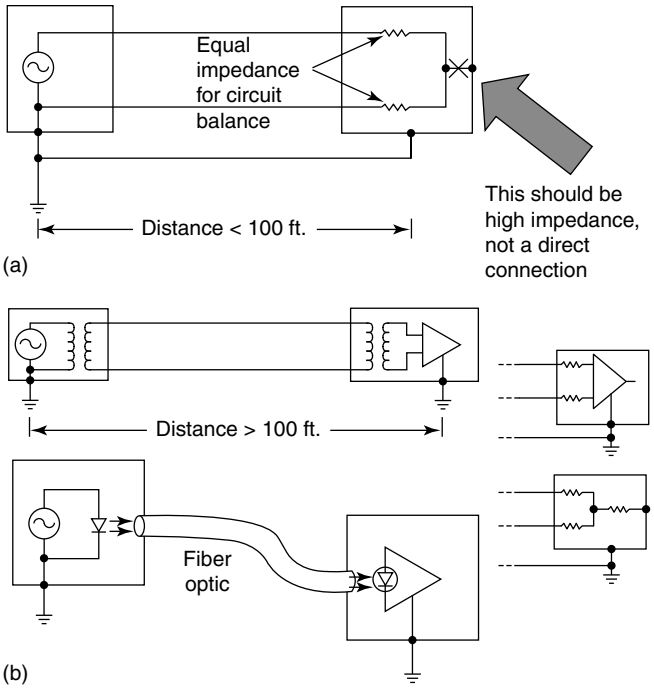

Figure 6. Examples of circuit balance and isolation that eliminate ground noise. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

2.4 Remove ground problems in signal transmission

Long length signal transmission circuits suffer from ground loop problems. Circuit balance or isolation can eliminate the problems that arise from ground noise. For short distances of less than 30 m, a balanced transmission line and single-point grounding can reduce noise and safety concerns.

For distances over 30-m long, use of isolated signal transmission, through fiber optics or transformer isolation, allows multiple safety grounds while eliminating ground loops. Figure 6 illustrates some examples of circuit balance and isolation.

3 GENERAL PRINCIPLES OF SHIELDING

3.1 Analysis

First analyze the situation, *see* **Article 17, EMC and EMI, Volume 1**, for a practical basis on which to analyze the potential EMI. Four types of EMI problems exist:

- conductive
- inductive
- capacitive
- electromagnetic.

Once the problem situation is known, the appropriate shielding can be selected. Merely adding shields without that understanding can, in fact, lead to worsened situations.

Conductive problems can often be addressed by using more appropriate circuit connections (e.g. to eliminate ground loops) or filtering (e.g. to remove spikes). The various types of EMI problems and their shielding are addressed below.

3.2 Inductive shielding

Inductive shielding eliminates the generation, coupling, and reception of changing magnetic flux. It often is referred to as *self-shielding*. Do the following to achieve inductive shielding:

- Minimize the loop area between signal lines and their return paths.
- Separation can help reduce the problem somewhat.
- Understand that shielding enclosures help very little in preventing inductive coupling. Use of magnetic material shielding is an art and a science needing sophisticated materials, special treatment, and careful life management to maintain its magnetic shielding properties.

Twisting a signal wire with its return, for example, will eliminate the loop area. Running the twisted pair close to the ground will reduce the common-mode current, I_c in Figure 7, by reducing the loop area for inductive coupling.

3.3 Capacitive shielding

Capacitive shielding reduces and reroutes stray electrical charge. It prevents capacitive coupling, which provides a path for the injection of noise changes. Remember that a capacitance to ground reduces in its impedance as the frequency rises so at high frequencies and large capacitance sizes a low-impedance connection results in a situation apparently open circuited.

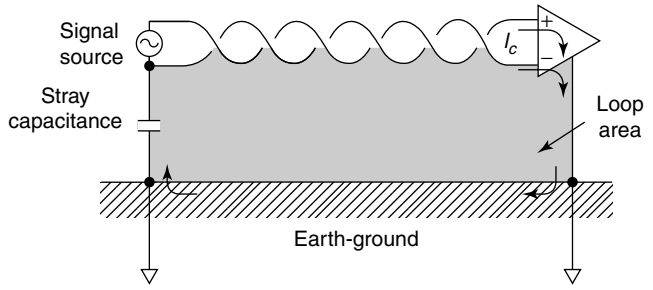

Figure 7. Twisting the signal with its return and running the pair close to ground will reduce the loop area. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

An appropriately placed shield prevents the coupling of electrical charge between circuits by shunting the charge to ground (Figure 8).

3.4 Electromagnetic shielding

Electromagnetic shielding works to prevent the generation, coupling, and reception of high-frequency (above 20 MHz) signals. Remedies for EMI areas follows:

- Reduce EMI generated emissions and detected receptions within the circuits.
- Reduce the bandwidth of the circuits.
- Apply good signal routing within circuit boards.
- Use shielded enclosures with premeditation and care.

4 LINE CONDITIONING

One particular concern is the transmission of noise and disruption through local power lines. Power itself may suffer from a number of problems: dropout, low voltage, surge, overvoltage, and high voltage spikes.

Filtering the AC power source at the power converter will eliminate differential-mode and common-mode noise from the input conductors. An electrostatic shield in the transformer, appropriate chassis connections, and balancing impedances in the leads will help the filter eliminate common-mode noise from the output lines. These are conductive coupling problems – *see* **Article 17, EMC and EMI, Volume 1**.

Filtering can reduce high-voltage spikes and high frequency ripple. Only a battery-backed uninterruptible power supply can eliminate the other problems of dropout, low voltage, surge, and overvoltage.

Carefully selected, the power conductors within an instrument can help reduce EMI and inductive coupling – *see* **Article 17, EMC and EMI, Volume 1**. Reducing the separation between the power conductors or twisting the power cables will reduce the inductive loop and any magnetic coupling. Power and return planes do this effectively within circuit boards.

A problem often caused by instrumentation is the injection of noise harmonics into the AC power. This can happen because the input filter capacitors charge only near the voltage peaks. Such charging forces the current waveform into a nonsinusoidal form, thus generating harmonics. These harmonics do not contribute real power but increase the apparent power required; the ratio of real power to apparent power is the power factor. Power harmonics reduce the power factor of an instrument. Circuitry for correcting the power factor will ensure that the instrument does not generate power line harmonics.

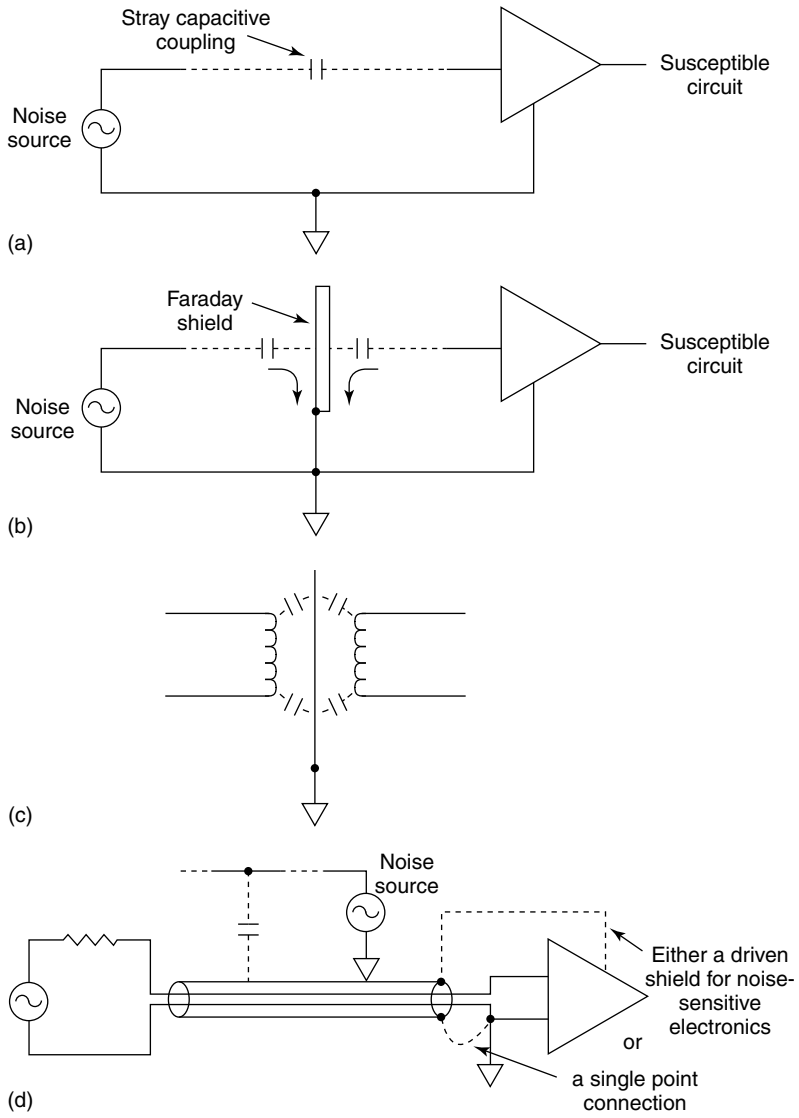

Figure 8. Examples of capacitive coupling and shielding. (a) outline of capacitive coupling, (b) proper placement of a shield to shunt noise charge, (c) a shielded transformer prevents capacitive coupling between windings, and (d) a cable shield usually should be connected at only one place to prevent coupling or shunt charge. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

5 NOISE REDUCTION IN CABLING AND OTHER CIRCUIT ELEMENTS

Designing cables and laying out circuits is a matter of care and understanding. Fundamental principles, in more detail, are given in **Article 17, EMC and EMI, Volume 1**.

5.1 Cables

Cable configurations that best attenuate noise depend on the frequency of operation (Figure 9). The twisted-pair cable is usually effective for low frequencies up to 1 MHz, but it becomes lossy at higher frequencies. Its main advantage over coaxial (coax) cable is that it is cheaper and mechanically more flexible. Coax cable has low loss and less variance in its characteristic impedance from DC to very high frequencies (above 200 MHz).

Ribbon cable is suitable for low-frequency operation (below 1 MHz) when the signals are not a pair with return lines. For low-level signals or higher frequencies, pair each signal conductor with a return conductor or use a return plane (Figure 10).

Coaxial terminations must be carefully made to reduce leakage and ensure lowest signal reflection as the frequency rises (Figure 11). The pigtail connection is fine

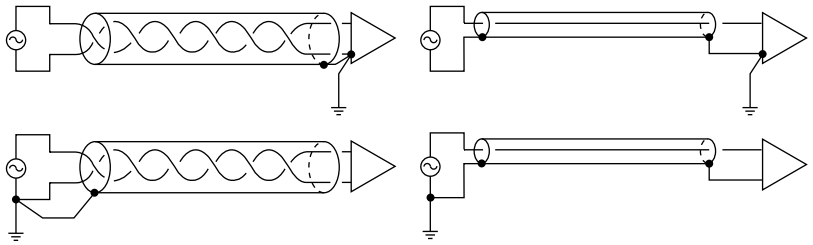

Figure 9. Cable configurations for shielding against noise. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

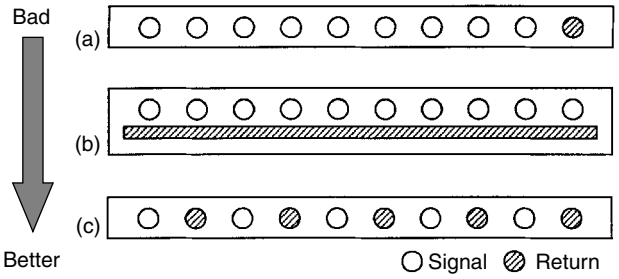

Figure 10. Ribbon cable configurations. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

for low-frequency applications below 1 MHz. A complete 360° conducting seal is necessary for high frequencies above 1 MHz.

5.2 Component placement

Careful layout of components within circuits can provide a measure of self-shielding. Follow these guidelines for self-shielding:

- Place high-current circuits near the connectors to isolate stray currents.
- Place high-frequency circuits near the connectors to reduce signal path length, cross talk, and noise.
- Group the low-power and low-frequency circuits away from the high-frequency and high-current circuits to avoid disruption.
- Group analog circuits separately from digital circuits.

5.3 Signal lines and layout

A corollary to good component placement is to distribute the signal and return lines carefully to maximize self-shielding. Usually, this means pairing each signal line with a return line or plane. This will reduce large loop inductances and consequently the inductive impedance and coupled noise. This means one should not separate return lines long distances away from the signal line within connectors.

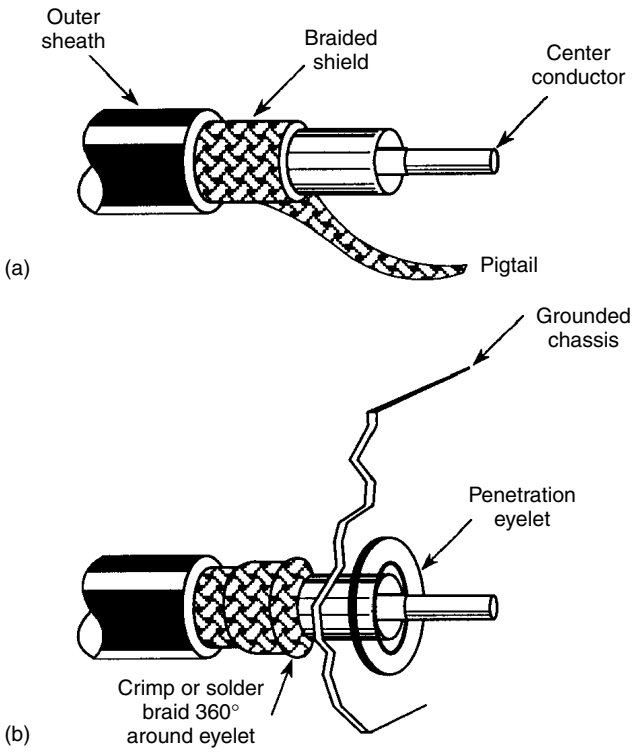

Figure 11. Coaxial cable terminations, the pigtail is only good for low frequencies below 1 MHz. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

6 ENCLOSURES FOR NOISE REDUCTION

A shielded enclosure should ideally be a completely closed conducting surface. An effective enclosure is one that has watertight metallic seams and openings. Openings leak electromagnetic radiation all too easily (Figure 12). This will also help with ESD reduction. The design of enclosures that do not leak needs sophisticated design based on high-frequency transmission line design principles.

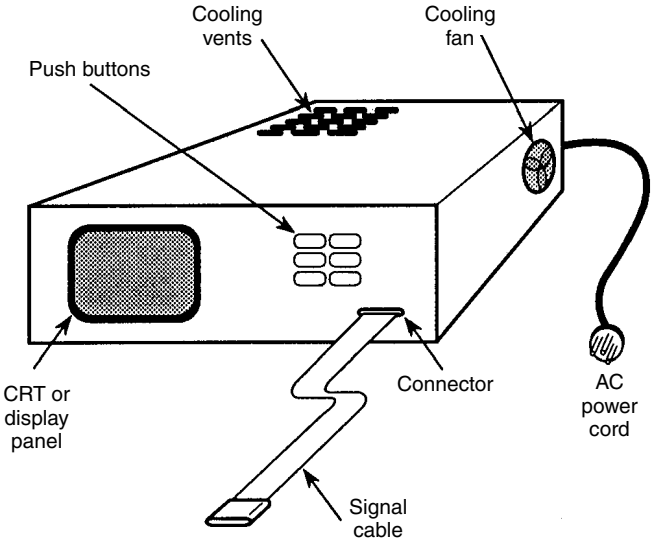

Figure 12. Examples of entry and exit points for electromagnetic energy. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

7 PROTECTING AGAINST ELECTROSTATIC DISCHARGE (ESD)

Electrostatic discharge (ESD) is the transfer of electrical charge at very high voltage (100 s to 1000 s V) and very low current. ESD can easily damage sensitive electronic circuits. Any instrument containing integrated circuits is susceptible to ESD if not protected. Please refer to **Article 17, EMC and EMI, Volume 1** for more detail.

Control methods for ESD eliminate activities and materials that create high static charge and provide transient protection to sensitive circuits. Eliminating high static charge requires appropriate grounding, using protective handling and materials, and maintaining humidity.

Table 1. Checklist to reduce ESD.

Check activities
Wear a wrist ground-strap and use a static-free workstation.
Discharge static before handling devices.
Keep parts in their original containers.
Minimize handling of components.
Never slide a component over any surface.
Use conductive containers for storage and transport of components..
Clear all vinyl, plastic, and Styrofoam from the work area.

Source: Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.

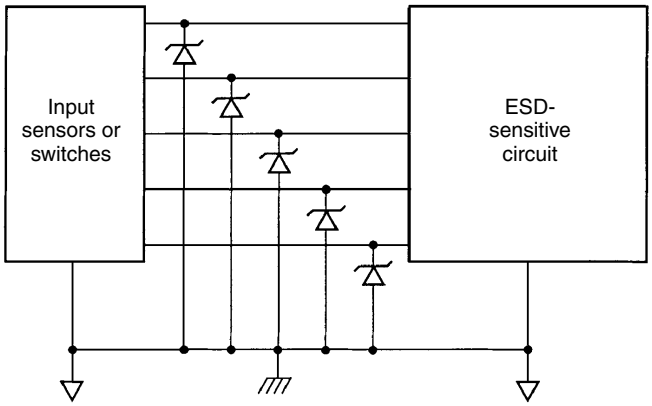

Figure 13. Preventing damage by shunting high-voltage transients away from circuits. (Reproduced from *Electronic Instrument Design: Architecting for the Life Cycle*, Fowler, K.R. Copyright (1996) © Oxford University Press.)

The checklist in Table 1 lists some of the activities that will reduce problems with ESD. Figure 13 illustrates one way to protective sensitive circuits by shunting ESD to chassis ground.

8 LIMITATIONS OF GROUNDING AND SHIELDING

No one method is a cure-all for EMC and EMI. It is necessary to carefully analyze the particular situation, understanding the modes and frequencies of operation, and the possible coupling mechanisms. Only then can a design begin to be an appropriate grounding and shielding system.

1 PREAMPLIFIER SELECTION

All preamplifiers add some additional noise. Whether this additional noise is significant will depend, of course, upon the noise level from the signal source. Since uncorrelated noise adds vectorially (in an rms fashion), the preamplifier noise can be neglected if it is less than about one-third of the source noise

$$\sqrt{[(1.0^2) + (0.3^2)]} \approx 1.0$$

We can think of a practical preamplifier as consisting of an ideal, noise-free amplifier with a (frequency-dependent) noise-voltage generator of voltage spectral density v_n (V/$\sqrt{}$Hz), and a noise-current generator of current spectral density i_n (A/$\sqrt{}$Hz), connected to its input as shown in Figure 1.

Figures 2 and 3, respectively, show separately the gain seen by the amplifier internal noise-voltage and -current generators. For voltage noise $v_{ov} = v_n(1 + Z_f/Z_s)$, where $Z_s = R_s/(1 + j\omega R_s C_s)$. Hence, any input shunt capacitance (see Figure 2) will decrease the input impedance and cause output noise that increases with frequency if Z_f is resistive.

The preamplifier noise may also be defined (Faulkner, 1966) in terms of an equivalent series noise resistance R_e, and an equivalent parallel noise resistance, R_i, where (from (2) in **Article 121, Signals in the Presence of Noise, Volume 2**.)

$$R_e = \frac{v_n^2}{4kT\Delta f} \text{ ohms}$$

and (from (3) in **Article 121, Signals in the Presence of Noise, Volume 2**.)

$$R_i = \frac{4kT\Delta f}{i_n^2} \text{ ohms}$$

2 NOISE FIGURE

Also defined is the noise figure (NF) of the preamplifier to be (when in dB units)

$$\text{NF} = 10\log_{10}\left(1 + \frac{R_e}{R_s} + \frac{R_s}{R_i}\right) \quad (1)$$

A perfect or noiseless preamplifier would have a 0 dB noise figure. Figure 4 shows the noise-figure contours that result when the noise figure of a particular practical preamplifier (the ***SIGNAL RECOVERY*** model 5113) is plotted as a function of source resistance and frequency. Notice from (1), that with high source resistance, $R_e/R_s \to 0$, and then

$$\text{NF} \approx 10\log_{10}\left(1 + \frac{R_s}{R_i}\right) \quad (2)$$

and the amplifier noise current, i_n, predominates.

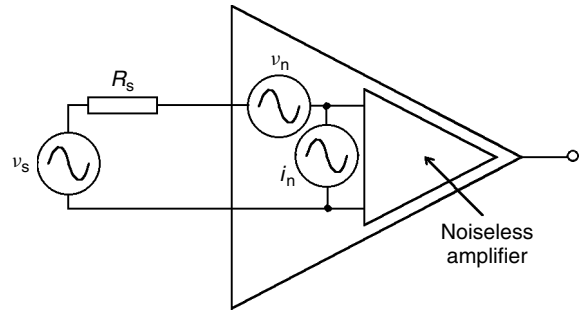

Figure 1. Amplifier noise – equivalent circuit. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

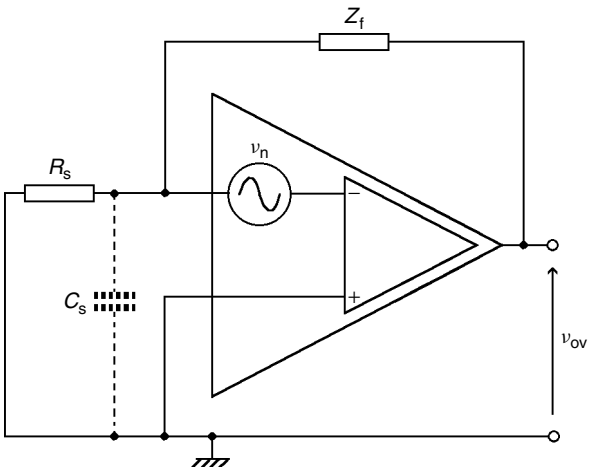

Figure 2. Amplifier noise – voltage noise. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

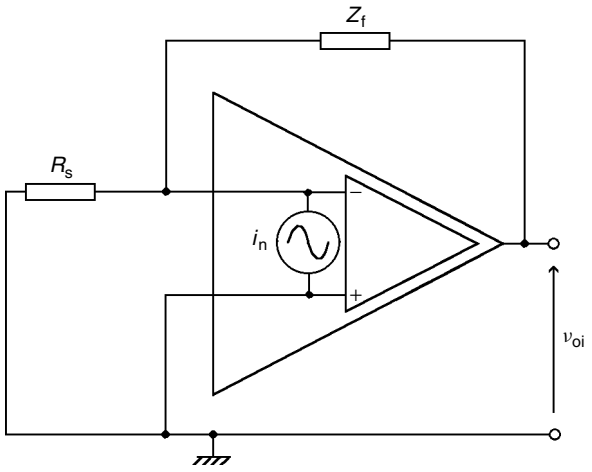

Figure 3. Amplifier noise – current noise. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

With low source resistances, the amplifier noise voltage, v_n, becomes the major noise source. Wherever possible, preamplifiers should be chosen so that their 3 dB noise-figure contour encloses the expected range of source resistance and frequency.

For a given preamplifier, the optimum source resistance, R_s, is given by

$$R_s(\text{opt}) = \frac{v_n}{i_n} = \sqrt{(R_e R_i)}\ \text{ohms} \tag{3}$$

Note that adding a series or parallel resistance between the signal source and the preamplifier always reduces signal and adds noise, and so cannot be used to obtain a better match.

Preamplifiers can be classified in many ways, one basic division being, for example, between differential input and single-ended input. All other things being equal, a differential preamplifier generates 3 dB (41.4%) more noise than a single-ended version. However, this disadvantage is significant only in situations in which preamplifier noise predominates and, in many cases, is outweighed by the flexibility of a differential input and its ability to remove ground-loop problems (*see* **Article 179, Input Connections; Grounding and Shielding, Volume 3**).

3 NOISE MATCHING WITH A TRANSFORMER

Transformers are often used to match very low source impedances (0.1 Ω–1 kΩ). Figure 5 shows an amplifier with an optimum, $\sqrt{(R_e R_i)}$, source resistance value of 1 MΩ being matched to a 100 Ω thermopile by means of a 100:1 voltage step-up transformer (10 000:1 impedance transformation). Note that, in general, such noise matching does not result in the same circuit values as would power matching; that is, the amplifier input resistance is not normally equal to $\sqrt{(R_e R_i)}$.

Transformers are a classic solution where high performance amplifiers are not available. Their use, however, should be avoided if possible since they reduce frequency response, may pick up magnetically induced interference, and may be microphonic (that is, they may generate noise when mechanical shock or vibration causes disturbance of their magnetic circuit).

4 PREAMPLIFIER CHOICES

For sources of approximately 100 Ω–10 kΩ, preamplifiers are available that use an operational amplifier with an input

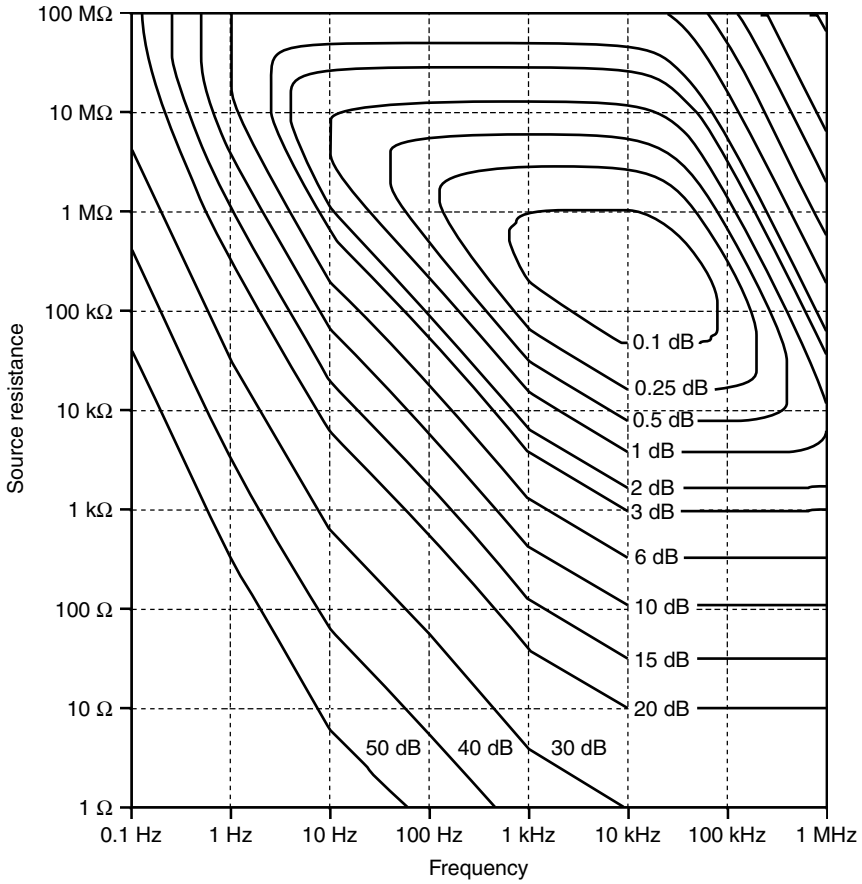

Figure 4. Noise-figure contours for a ***SIGNAL RECOVERY*** model 5113 voltage preamplifier. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

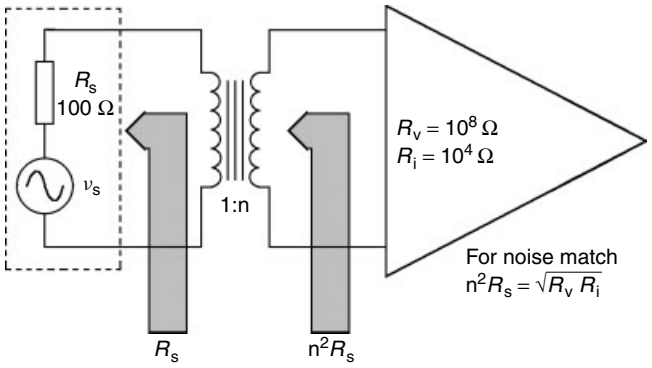

Figure 5. Transformer noise matching. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

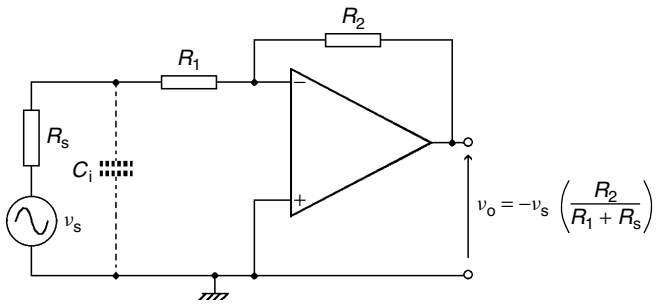

Figure 6. Inverting voltage amplifier. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

stage consisting of multiple bipolar transistors connected in parallel to provide a lower value of $\sqrt{(R_e R_i)}$.

Such preamplifiers avoid the bandwidth constraints imposed by input transformers. For higher impedance sources (1 kΩ–100 MΩ), preamplifiers usually employ junction-FETs as input devices and are available as voltage preamplifiers, charge amplifiers (for use with capacitive transducers), or current-input (transimpedance) amplifiers, see Figures 6, 7, 8, and 9 for these forms.

5 CABLE CAPACITANCE

In Figures 6 and 7 any cable capacitance or stray capacitance, C_i, will form a low-pass filter with the source

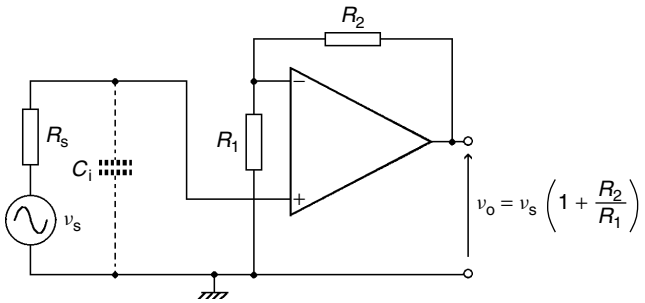

Figure 7. Noninverting voltage amplifier. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

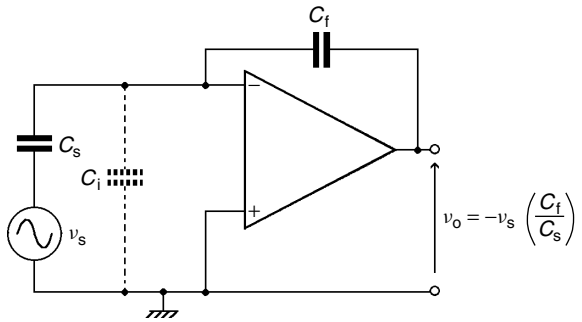

Figure 8. Charge amplifier. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

resistance, R_s, having a – 3 dB frequency given by

$$f_c = \frac{1}{2\pi R_i R_s C_i/(R_i + R_s)} \tag{4}$$

(refer to Figure 6)
or

$$f_c = \frac{1}{2\pi R_s C_i} \tag{5}$$

(refer to Figure 7)

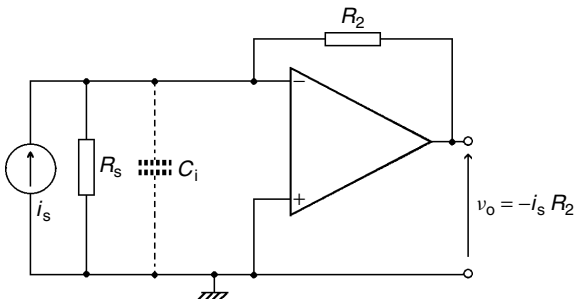

Figure 9. Transimpedance amplifier. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

In Figures 8 and 9, such shunt capacitance appears at first sight to have no effect since it is effectively short-circuited by the virtual-ground input. However, as shown in Figure 2, shunt capacitance will cause deterioration in the output signal-to-noise ratio, and also (by introducing an additional pole into the loop gain) may cause ringing in the amplifier response, or even oscillation.

By careful design (which usually includes adding a capacitor across the feedback resistor), these effects can be minimized and with high source impedance, commercial current and charge amplifiers usually provide significantly greater bandwidth than that given by the corresponding voltage amplifiers.

1 COMMON-MODE SENSORS

Ideally, all grounds should have a zero-impedance connection to each other and to wet earth; in practice, they do not.

Owing to voltage drops existing across their finite impedance to earth, capacitively or inductively coupled interference, and other reasons, each ground point connection tends to be at a different potential from other nearby grounds. If two (or more) such adjacent grounds are connected together to form a ground loop (Figure 1), then the potential difference between the two grounds will cause a circulating current in the input of the detector stage.

The potential difference between grounds (v_{CM}) is called the *common-mode source* since it is common to both the signal (via loop 2) and ground (via loop 1) inputs of the preamplifier.

2 GROUND LOOPS

Figure 2 rearranges the circuit of Figure 1 and assumes the signal source v_s to be zero.

Note that the low resistance of the connecting coaxial cable shield (the braid) R_{CG} is in parallel with the series combination of the source resistance R_S, the coaxial cable center conductor resistance R_{CS}, and the preamplifier input impedance Z_{IN}.

Under normal circumstances, $(R_S + R_{CS} + Z_{IN}) \gg R_{CG}$ and $Z_{IN} \gg (R_S + R_{CS})z$ so that, as shown in Figure 3, the common-mode voltage dropped across R_{CG} is also applied across the preamplifier input terminals. More generally, with $v_s = 0$, the preamplifier input voltage, v_i, is given by

$$v_i = v_{CM} \frac{R_{CG}}{R_{CG} + R_{SG} + R_{PG}} \tag{1}$$

3 REDUCTION OF GROUND-LOOP INPUTS

From (1), the common-mode input to the preamplifier can be removed (i.e. $v_i = 0$) by making

1. $v_{CM} = 0$. This can be attempted by grounding the source and preamplifier to the same ground point (all connected at one point) and by using shielding to remove capacitively or inductively coupled interference. However, this procedure is rarely completely successful.
2. $R_{CG} = 0$. The usual approach here is to bolt both source and preamplifier chassis to a large metal plate. Unfortunately, it is fairly easy to develop large potential differences between points as small as a centimeter or two apart on a large metal plate, such as a mounting rack.
3. $R_{SG} = \infty$. Floating or disconnecting the source from ground is a good approach where practicable, but this

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

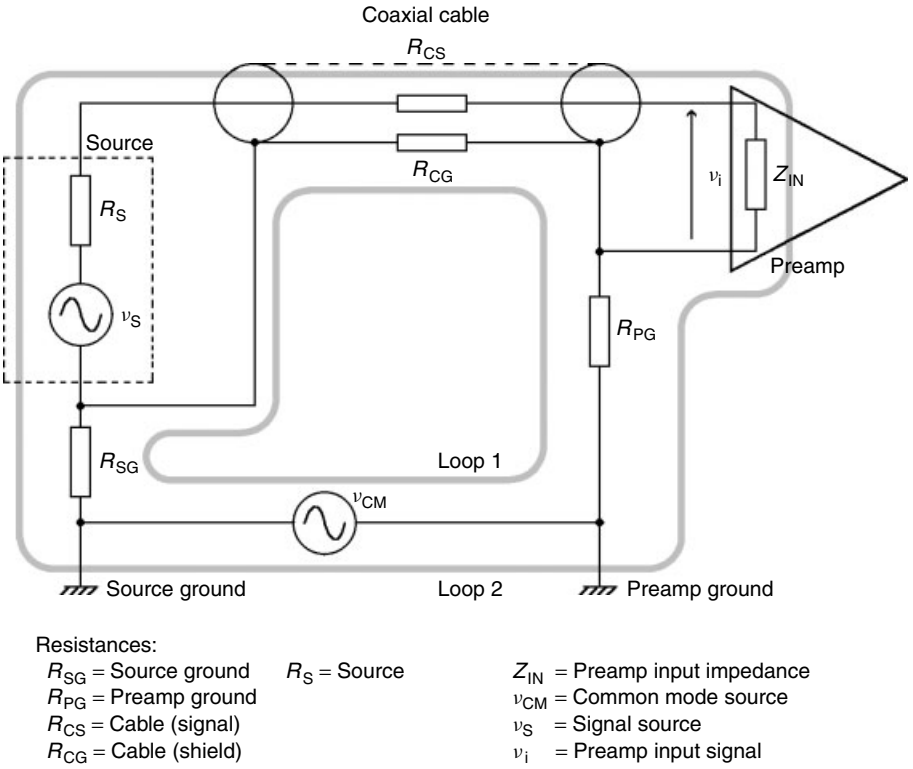

Figure 1. Ground loops – physical occurrence. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

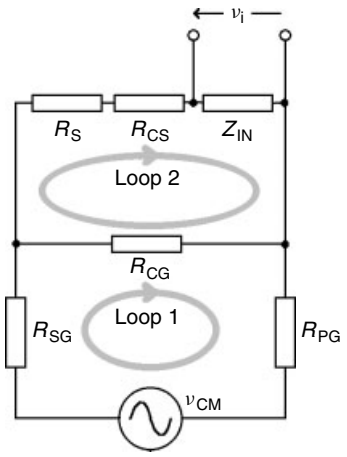

Figure 2. Ground loops – schematic equivalent circuit. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

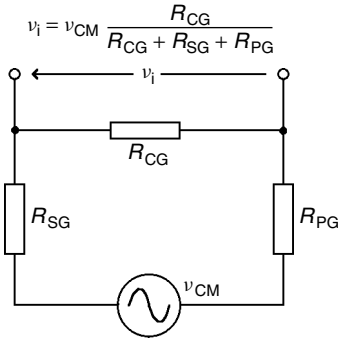

Figure 3. Ground loops – reduced equivalent circuit. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

needs careful design and maintenance to ensure it is truly floating.

4. $R_{PG} = \infty$. The preamplifier may also be floated – particularly, if it is battery powered. Note that disconnecting the power-line ground from an instrument can be extremely dangerous, and in some countries it could be illegal. In many instruments, R_{PG} consists of an internal 10 Ω to 1 kΩ resistor that can be switched into the circuit to effectively float the amplifier input terminals.

None of the above methods is usually able to produce perfect results. Ground loops are an important and challenging design issue that need specific measures to be applied for each application.

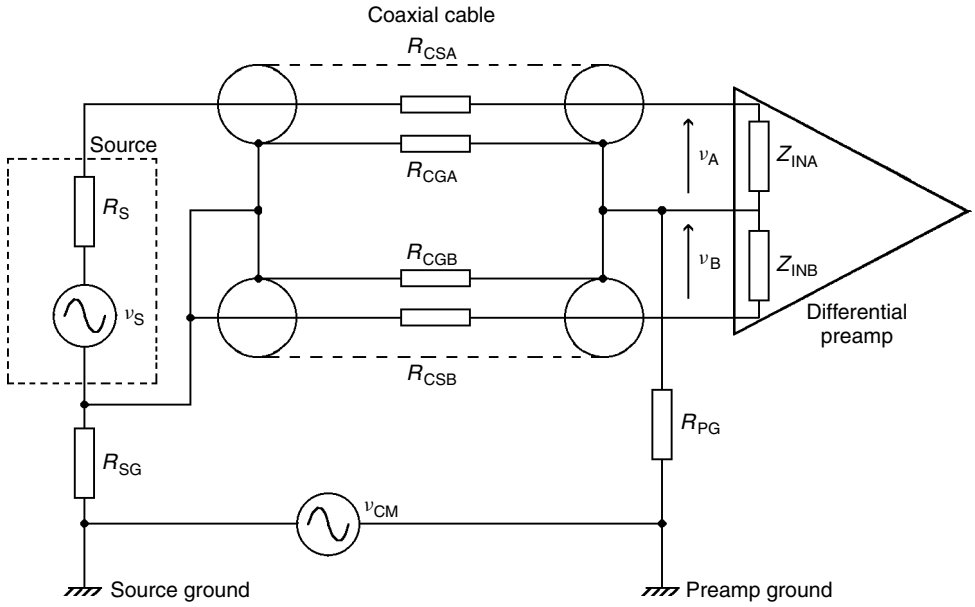

Figure 4. Differential preamplifier used with single-ended source – physical occurrence. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

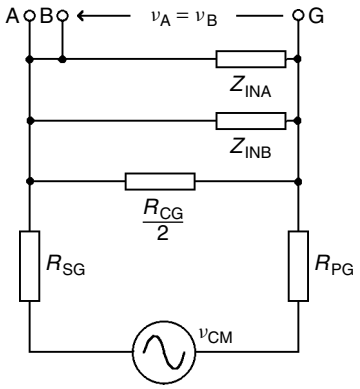

Figure 5. Differential preamplifier used with single-ended source – schematic equivalent circuit. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

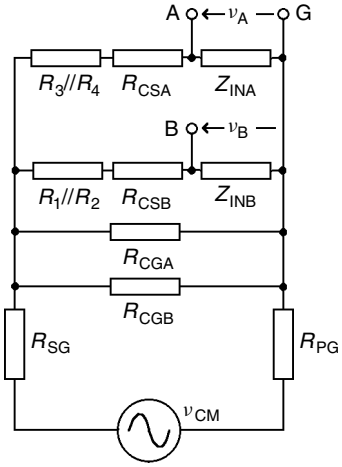

Figure 6. Differential preamplifier used with single-ended source – reduced equivalent circuit. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

4 IMPROVING GROUND-LOOP SITUATIONS

Figure 4 illustrates the use of a differential amplifier with an unbalanced (single-ended) source to eliminate or reduce ground-loop problems. As in Figures 1 to 3, the circuit simplifications shown in Figures 5 and 6 assume that the input impedance of each side of the differential amplifier (Z_{INA} and Z_{INB}) is much larger than source or cable resistances.

At low frequencies, this differential connection results in equal common-mode voltages at the amplifier's input terminals (A and B), and the amplifier's ability to discriminate against common-mode signals (i.e. its common-mode rejection ratio, CMRR or CMR) will determine the effectiveness of this configuration in suppressing ground-loop interference.

At higher frequencies, the cable capacitances will act with the unequal resistances in the A and B input circuits to form unequal low-pass filters so that v_A will no longer be equal to v_B and there will be a spurious differential (A – B) input to the preamplifier.

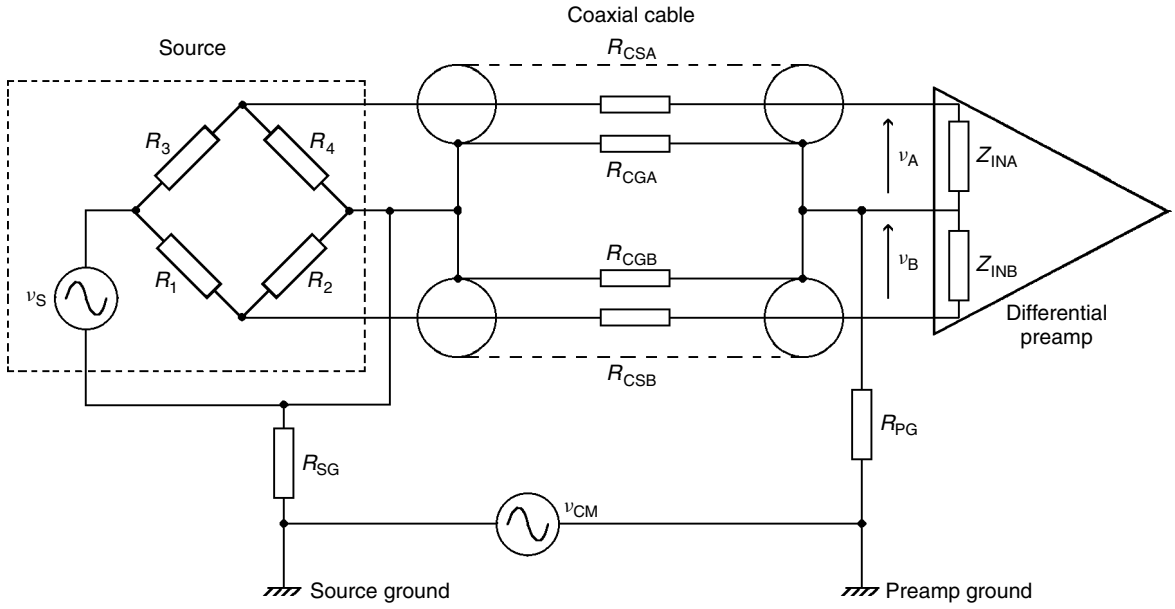

Figure 7. Differential preamplifier used with balanced source – physical occurrence. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

Although cable resistances and capacitances are shown for convenience as lumped parameters, it should be remembered that they are in fact distributed. As shown in Figure 7, high-frequency unbalance problems can be avoided by using a balanced source. Specific comment on connecting stages together is to be found in Morrison (1977), *see also* **Article 177, Grounding and Shielding, Volume 3**.

5 OTHER REDUCTION MECHANISMS

To end this article, here are a number of miscellaneous recommendations regarding good wiring and grounding practices.

1. Keep cable lengths short; for differential connections, keep them equal and following the same route.
2. Interference can be coupled into the ground (shield) or the outer conductor of a coaxial cable. Consider coiling the cable to form an RF choke to suppress high-frequency interference of this kind, use a transformer, or use a balun (which allows DC continuity).
3. Remember that a circuit loop of wire acts as an antenna; reduce the area of such loops as much as possible.
4. Separate low-level signals/cables from noisy ones. Where such cables must cross, cross them at right angles and with maximum separation.
5. For noncoaxial connections, use shielded twisted wire pairs.
6. Consider placing low-noise instruments in a shielded (screened) room when they are used with high-energy RF sources, such as pulsed lasers.
7. Keep analog and digital grounds separate.

1 BANDWIDTH REDUCTION TO IMPROVE SIGNAL-TO-NOISE RATIO, SNR

The term DC signal is often used (and is in this article) to mean a signal that has a frequency spectrum that includes zero frequency DC.

Technically, of course, a truly DC voltage or current is unvarying and, therefore, cannot carry information (other than that it exists). Here, we are concerned with signals that are close to DC; an example is the temperature variation seen by a thermal detector as a person moves across its sensor in a room.

Such signals are also termed *baseband signals*, particularly when they are to be used to modulate a carrier frequency. They may also be referred to as a *pseudo-DC signal*.

Where the unwanted noise has a wider bandwidth than the signal, the simplest way to improve the signal-to-noise ratio SNR is to use a low-pass filter to reduce the noise bandwidth to the point where any further reduction would also change the wanted signal to an unacceptable extent. The total noise energy is thereby reduced but that of the signal is hardly altered. Thus, the SNR improves.

2 SNR IMPROVEMENT FROM PHOTO MULTIPLIER TUBE (PMT) DETECTOR

Figure 1 shows a typical source and preamplifier system for such a pseudo-DC signal. We will use this circuit – for a PMT detector – to show how the output SNR may by estimated and also how the SNR may be improved by reducing the noise bandwidth.

In this example, it is assumed that the photomultiplier tube PMT anode current consists of both a 5-Hz signal component with source current of ($i_S = 1\,\text{nA rms}$) and a DC current component of ($I_{DC} = 5\,\text{nA}$); typically, such DC currents in the PMT are due to stray light and dark/leakage currents.

The adjustable direct-current generator (I_{ZS}) is used to null, that is set the zero offset to zero, the DC component of the PMT current such that I_{ZS} is made equal and opposite to I_{DC}. This kind of zero suppression is often called *background subtraction*. Note in this simple arrangement that I_{ZS} must be readjusted manually each time the background changes.

The coaxial cable shown that connects the PMT and preamplifier has its own capacitance. Note that the virtual-ground input of this preamplifier configuration offers the following advantages in addition to those discussed in **Article 178, Noise Matching and Preamplifier Selection, Volume 3**. In this case then,

1. with zero volts existing across it, the cable capacitance cannot be charged and the cable will, therefore, be less microphonic than otherwise;

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

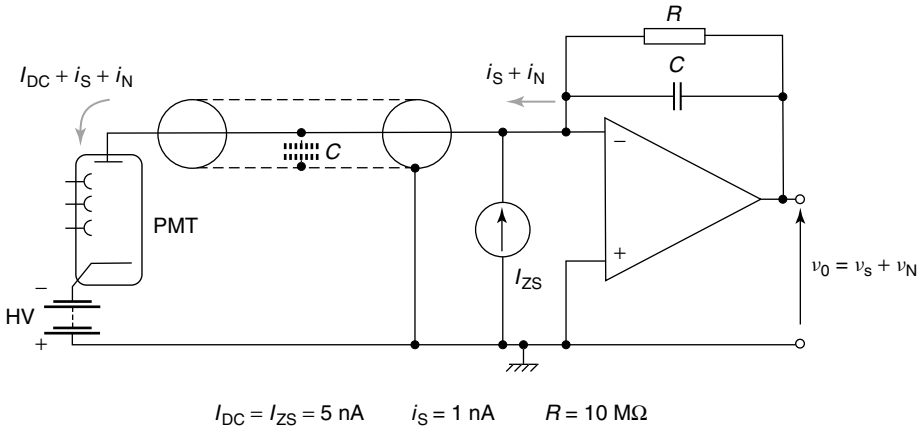

Figure 1. DC measurement example using photomultiplier (PMT) detector. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

2. since the PMT anode voltage is clamped at zero volts, the anode-to-last-dynode voltage is also held constant regardless of i_S (assuming that the dynode voltage remains fixed). Signal currents will, therefore, not change the PMT gain.

3 NOISE SOURCES IN PMT DETECTORS

There are five uncorrelated sources of noise in this circuit. These are as follows:

1. The DC component of the PMT current (I_{DC}) is produced by integrating anode pulses, each of charge $Q = Ae$ where A is the mean PMT gain. The interval in time between successive pulses arriving at the anode is random and governed by Poisson statistics (*see* **Article 184, Photon Counting, Volume 3**, Section 4). Assuming no additional dynode noise exists in the PMT, the rms value of the PMT shot noise current spectral density i_{N1} is given by

$$i_{N1} = \sqrt{(2AeI_{DC})} = \sqrt{A} \times \sqrt{(2eI_{DC})} \qquad (1)$$

For $A = 10^6$ (say), $R = 10^7\Omega$, $e \simeq 1.6 \times 10^{-9}$C, and $I_{DC} = 5$ nA, the resulting output noise voltage density, v_{N1} is given by

$$\begin{aligned} v_{N1} &= Ri_{N1} = 10^7 \times 10^3 \times \sqrt{2eI_{DC}} \\ &\simeq 10^{10} \times 4 \times 10^{-14} \\ &= 4 \times 10^{-4} = \frac{400\,\mu\text{V}}{\sqrt{\text{Hz}}} \end{aligned} \qquad (2)$$

2. For purposes of this example, we can assume that the zero-suppress current, I_{ZS}, is obtained from a transistor current source circuit so that it has a shot noise current spectral density, i_{N2}, given by

$$\begin{aligned} i_{N2} &= \sqrt{2eI_{ZS}} = \sqrt{(2eI_{DC})} \left(= \frac{i_{N1}}{10^3}\right) \\ &= \frac{4 \times 10^{-14}\text{A}}{\sqrt{\text{Hz}}} \end{aligned} \qquad (3)$$

Note that although $I_{DC} = I_{ZS}$, the shot noise component from the PMT is much larger than that from the transistor current source. It is thus detector limited. The resulting output noise voltage spectral density, v_{N2}, is given by

$$\begin{aligned} v_{N2} &= Ri_{N2} \simeq 10^7 \times 4 \times 10^{-14} \\ &= 4 \times 10^{-7} = \frac{400\,\text{nV}}{\sqrt{\text{Hz}}} \end{aligned} \qquad (4)$$

3. The feedback resistor, R, will generate (at $T = 290$ K) a Johnson noise output voltage density, v_{N3} given by

$$v_{N3} = \sqrt{(4kTR)} \approx 4 \times 10^{-7} = \frac{400\,\text{nV}}{\sqrt{\text{Hz}}} \qquad (5)$$

4. At 5 Hz, a typical value for the spot noise voltage density of the amplifier's internal noise voltage generator is $30\,\text{nV}/\sqrt{\text{Hz}}$. This amplifier voltage noise will experience unity gain (*see* **Article 178, Noise Matching and Preamplifier Selection, Volume 3**, Figure 2) since Z_{IN} (the PMT current source) is very high. The output noise voltage density v_{N4} due to this noise source is therefore given by

$$v_{N4} = \frac{30\,\text{nV}}{\sqrt{\text{Hz}}} \qquad (6)$$

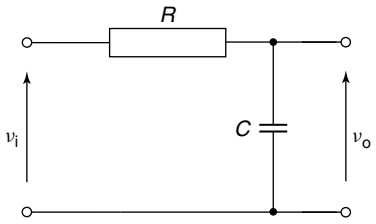

Figure 2. Low-pass filter, single pole. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

5. At 5 Hz, a typical value for the spot noise current density, i_{N5} of the amplifier internal noise current generator is $5fA/\sqrt{\text{Hz}}$. The resulting contribution v_{N5} to the amplifier output noise is given by

$$v_{N5} = Ri_{N5} = 10^7 \times 5 \times 10^{-15} = 5 \times 10^{-8} = \frac{50\,\text{nV}}{\sqrt{\text{Hz}}} \tag{7}$$

The total output noise voltage spectral density, v_N is given by

$$v_N = \sqrt{(v_{N1}^2 + v_{N2}^2 + v_{N3}^2 + v_{N4}^2 + v_{N5}^2)} \tag{8}$$

Since $v_{N1}^2 \gg v_{N2}^2$, v_{N3}^2, v_{N4}^2, and v_{N5}^2, then

$$v_N \approx v_{N1} \tag{9}$$

and the system is said to be detector limited or shot noise limited. An electrometer, an instrument characterized by extremely low leakage currents, is often used as a low-noise amplifier in DC measurements of this kind.

While discussing the limit of detection of radiant energy sensors, it is appropriate to cover the situation wherein the detector has geometry that also decides the sensitivity. Each design type and individual unit will then have different apparent sensitivities, but by addition of suitable optical and electrical set ups their differences can be normalized. Thus, it is not so meaningful to talk of their individual sensitivities without some means to normalize them all to a common method of comparison. For sensitive optical and other wavelength radiation detectors, this is often done using their detectivity or D* rating.

4 STRATEGIES FOR SNR IMPROVEMENT IN PMT DETECTORS

In Figure 1, the parallel resistor and capacitor in the feedback loop cause the circuit to act as low-pass filter of time constant RC seconds, so that the -3 dB cutoff frequency is given by $1/2\pi RC$ and $B_N = 1/4RC$ (*see* **Article 121, Signals in the Presence of Noise, Volume 2**, Section 2).

If no discrete capacitor is connected across R, the typical stray capacitance will (say) be about $C = 2.5$ pF, so that $RC = 10^7 \times 2.5 \times 10^{-12} = 25\,\mu\text{s}$ and $B_N = 10^4$ Hz. The output noise voltage (V_N) will, therefore, be

$$V_N = v_N\sqrt{B_N} = 4 \times 10^{-4} \times \sqrt{10^4} = 40\,\text{mV} \tag{10}$$

The output signal

$$v_S = i_S R = 10^{-9} \times 10^{-7}\,\text{V} = 10\,\text{mV} \tag{11}$$

Therefore,

$$\text{SNR} = \frac{S}{N} = \frac{10}{40} = \frac{1}{4} \tag{12}$$

The capacitance can be increased to 2.5 nF by adding discrete capacitors so that the noise bandwidth becomes $B_N = 10$ Hz. The -3 dB corner frequency will now be at 6.4 Hz (i.e. $10 \times 2/\pi$) so that the signal (for which the frequency is 5 Hz) is not significantly attenuated. The output noise voltage (V_N) is now reduced to

$$V_N = v_N\sqrt{B_N} = 4 \times 10^{-4} \times \sqrt{(10)} \approx 1.26\,\text{mV} \tag{13}$$

and

$$\text{SNR} = \frac{S}{N} = \frac{10}{1.26} \approx \frac{8}{1} \tag{14}$$

so that (*see* **Article 176, Signals and Signal-to-noise Ratio, Volume 3**; (3) and (4))

$$\text{SNIR} = \frac{S_o/N_o}{S_i/N_i} = \sqrt{\frac{B_{NI}}{B_{NO}}} = \sqrt{\frac{10000}{10}} \approx \frac{32}{1} \tag{15}$$

5 ROLL-OFF RATE OF PMT DETECTORS

A typical single pole low-pass filter section is shown in Figure 2, and exhibits a 6 dB/octave roll-off with frequency above the cutoff frequency (curve 1 in Figure 3).

The roll-off rate of this filter may be increased by adding more RC sections, and there are several ways of doing this. The simplest is shown in Figure 4, where two single pole stages are connected together via a unity gain buffer amplifier. The component values give a filter with the same overall equivalent noise bandwidth (ENBW) as that shown in Figure 2. This filter has the frequency response characteristic shown in curve 2 of Figure 3.

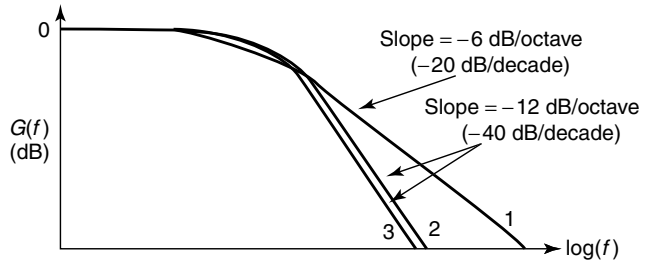

Figure 3. Low-pass filter frequency responses. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

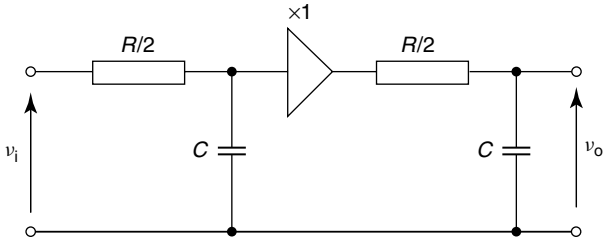

Figure 4. Low-pass filter, two equal buffered poles. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

More sophisticated multipole designs can be used, such as a Butterworth filter as shown in Figure 5, again which has component values giving the same ENBW as for the filter shown in Figure 2. This has the frequency response characteristic shown in curve 3 of Figure 3.

However, it must be remembered that the magnitude response of the filter with frequency is only one aspect of its performance. Its response in the time domain may also be important, particularly when measuring values that are changing as a function of time. Special care should be taken in using some filter configurations (Chebyshev or Butterworth, for example) since many such filters have undesirable overshoot characteristics (see Figure 6, where curves 1, 2, and 3 correspond to the filters shown in Figures 2, 4, and 5 respectively).

Note that the term time constant (τ) is meaningful only in connection with a single *RC* filter section and, even then, does not adequately convey a sense of the response time of the filter. With a voltage-step input, for example, such a single *RC* section requires about five time-constant

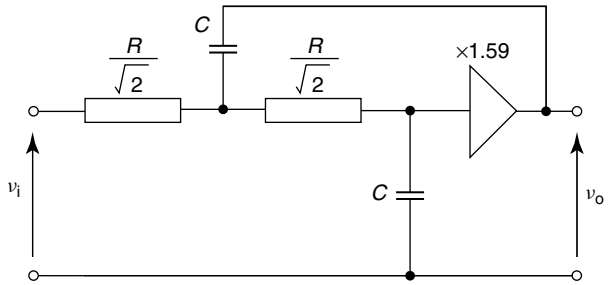

Figure 5. Low-pass filter, two pole Butterworth. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

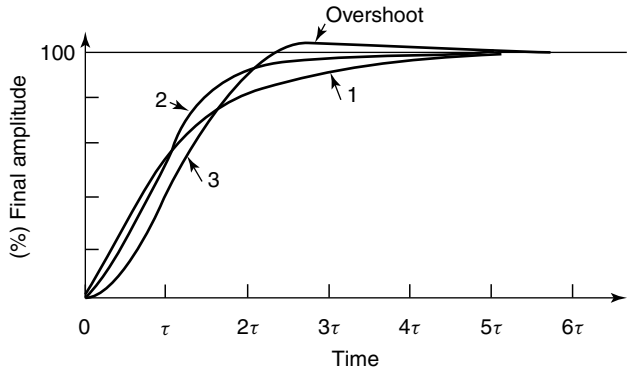

Figure 6. Low-pass filters, time response. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

intervals for its output to rise to within 1% of its final value.

Thus, it has been shown that addition of relatively small circuit changes can significantly improve the SNR in the baseband detection situation. When using other improvement methods, it is still necessary to carry out these kinds of improvements to gain the full effectiveness in signal recovery practice.

1 FLICKER NOISE

Most measurement systems are troubled by $1/f$ or flicker noise. By amplitude modulating the measurand (the quantity to be measured) at some reference or carrier frequency, f_r, the output noise can often be reduced and DC drift problems avoided (see Figure 1).

In optical systems, for example, rotating or vibrating mechanical chopper blades are often used to periodically block a light beam and thereby square-wave modulate the signal amplitude – even though, in most cases, such chopping means losing half of the light (signal). Measuring instruments that respond only to the modulation provide automatic background subtraction; as with DC systems, however, the noise component of the background remains. Such modulation also allows the use of transformers to noise-match preamplifiers to low-resistance sources.

2 BAND-PASS FILTER IN MODULATED SYSTEMS

As with base band signals and low-pass filtering, the SNR of a noisy amplitude-modulated signal can be improved by bandwidth reduction – in this case a band-pass filter is commonly used. In most applications, carrier frequencies are chosen from the 100- to 10-kHz range, where preamplifier and environmental noise is lowest; care should also be taken to avoid frequencies occupied by the fundamental or harmonics of the power-line frequency.

A second-order band-pass filter (see Figures 2 and 3) is specified by its resonant or center frequency f_r and its selectivity Q quality factor. For a given value of f_r, the higher the Q, the narrower will be the filter width.
The -3 dB frequencies are at $f_r \pm f_c$ and the signal bandwidth (B_s) is defined by

$$B_s = 2f_c = \frac{f_r}{Q} \tag{1}$$

For a second-order band pass, the signal bandwidth and the equivalent noise bandwidth (B_n are related by

$$B_n = \frac{1}{2}\pi B_s \tag{2}$$

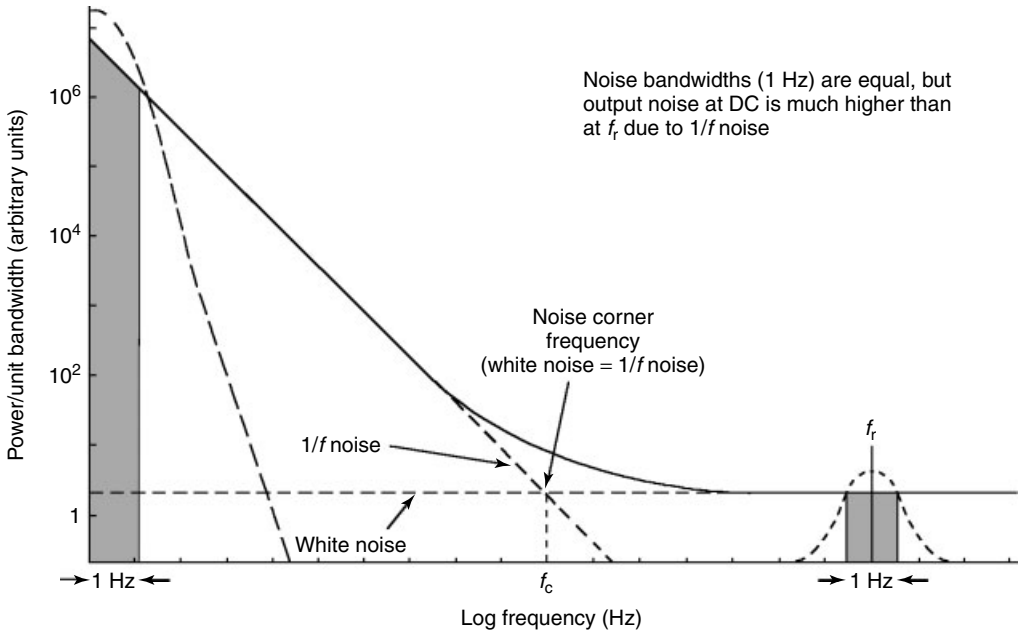

Figure 1. Amplitude modulation to avoid $1/f$ noise.

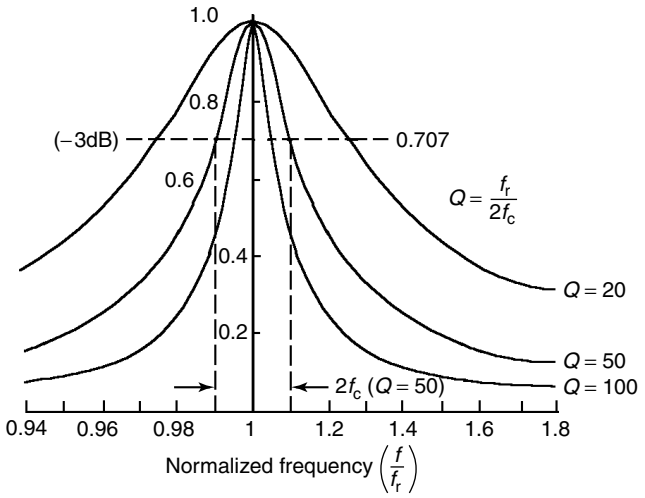

Figure 2. Amplitude transfer characteristics of a second-order band-pass filter.

so that,

$$B_n = \frac{\pi f_r}{2Q} \tag{3}$$

The band-pass filter has associated with it an effective time constant τ, where (as with the low-pass filter case discussed in **Article 121, Signals in the Presence of Noise, Volume 2**)

$$f_c = \frac{1}{2\pi\tau} \tag{4}$$

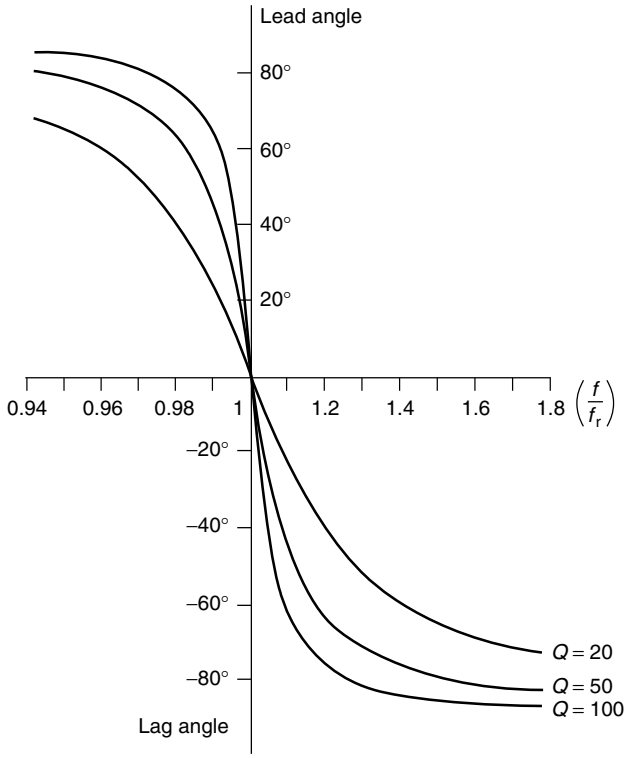

Figure 3. Phase transfer characteristics of a second-order band-pass filter.

so that,

$$B_n = \frac{1}{2}\pi B_s = \frac{1}{2}\pi 2 f_c = \frac{1}{2}\pi\left(\frac{2}{2\pi\tau}\right) = \frac{1}{2\tau} \tag{5}$$

3 EFFECT OF Q FACTOR ON NOISE BANDWIDTH

Also, from (1) and (4)

$$\tau = \frac{1}{2\pi f_c} = \frac{Q}{\pi f_r} \tag{6}$$

From (2), we can see that the higher the Q, the smaller the noise bandwidth and, therefore, for white noise or other broadband noise interference, the smaller the noise, the better the SNR. With a band-pass filter implemented by active *RC* (or *LC)* circuitry, frequency-stability problems limit the maximum practicable value of Q to about 100.

4 THE LOCK-IN AMPLIFIER

The *lock-in amplifier* (Burdett 2002a) can be considered as a tracking band-pass filter and amplifier that overcomes the Q-factor limitations of conventional circuits, offering noise bandwidths of less than 0.001 Hz and Q-factor values of 10^8. The lock-in amplifier can also provide amplification of more than 10^9 (180 dB) over a frequency range from 0.001 Hz to 200 MHz.

In common with most AC indicating instruments, it provides a DC output proportional to the AC signal being measured. In modern units, the DC output may be presented as a reading on a digital panel meter or as a digital value communicated over a computer interface, rather than a voltage at an output connector, but the principle remains the same.

The special rectifier, called a *phase-sensitive detector* (PSD), which performs this AC to DC conversion forms the heart of the instrument. It is special in that it rectifies only the signal of interest while suppressing the effect of noise or interfering components that may accompany that signal.

The traditional rectifier, which is found in a typical AC voltmeter, makes no distinction between signal and noise and produces errors due to rectified noise components. The noise at the input to a lock-in amplifier, however, is not rectified but appears at the output as an AC fluctuation. This means that the desired signal response, now a DC level, can be separated from the noise accompanying it in the output by means of a simple low-pass filter. Hence, in a lock-in amplifier, the final output is not affected by the presence of noise in the applied signal.

In order to function correctly, the detector must be 'programmed' to recognize the signal of interest. This is achieved by supplying it with a *reference* voltage of the same frequency (f_r) and with a fixed phase relationship to that of the signal. This is most commonly done by ensuring that they are derived from the same source. For example, in the case of an optical experiment using a rotating blade light chopper, the signal is generated from a detector focused on the light beam that has passed through the chopper blade, while the reference, at the same frequency, is taken from the chopper's reference output. The use of such a reference signal ensures that the instrument will 'track' any changes in the frequency of the signal of interest, since the reference circuit is 'locked' to it. It is from this characteristic that the lock-in amplifier derives its name.

This inherent tracking ability, allows extremely small bandwidths to be defined for the purpose of signal-to-noise ratio improvement since there is no frequency 'drift', as is the case with analog 'tuned filter/rectifier' systems. Because of the automatic tracking, lock-in amplifiers can give effective Q values (a measure of filter selectivity) in excess of 100 000.

The heart of the lock-in amplifier is the phase-sensitive detector, which is also known as a *demodulator* or *mixer*. The detector operates by multiplying two signals together, and the following analysis indicates how this gives the required outputs.

Figure 4 shows the situation where the lock-in amplifier is detecting a noise-free sinusoid, identified in the diagram as 'Signal in'. The instrument is also fed with a reference signal, from which it generates an internal sinusoidal reference, which is also shown in the diagram.

The demodulator operates by multiplying these two signals together to yield the signal identified in the diagram as 'Demodulator output'. Since there is no relative phase shift between the signal and reference phases, the demodulator output takes the form of a sinusoid at twice the reference frequency, but with a mean, or average, level that is positive.

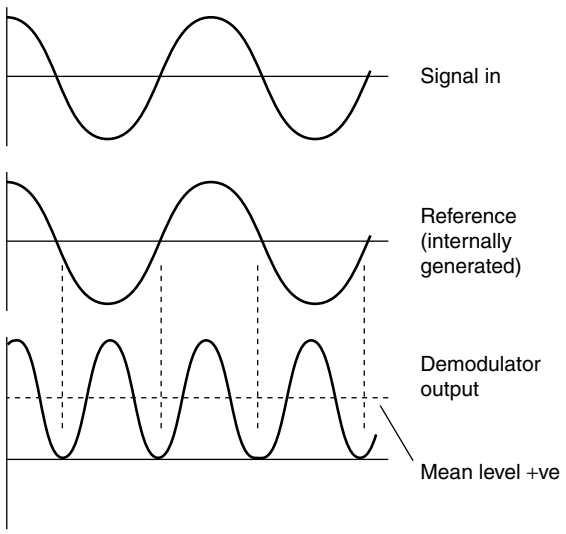

Figure 4. Operation of linear multiplier – signal and reference in-phase.

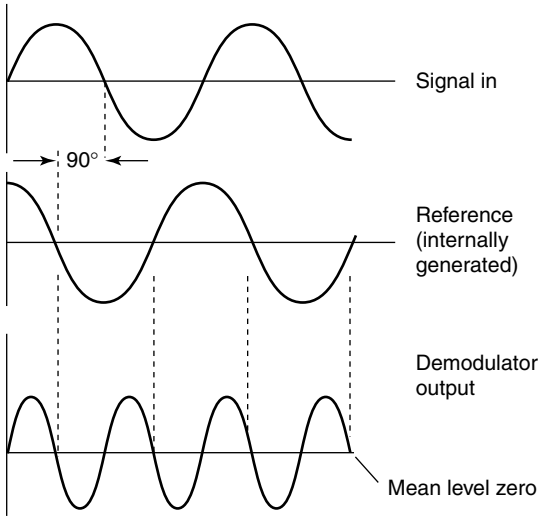

Figure 5. Operation of linear multiplier – signal and reference in quadrature.

Figure 5 shows the same situation, except that the signal phase is now delayed by 90° with respect to the reference. It can be seen that although the output still contains a signal at twice the reference frequency, the mean level is now zero.

From this, it can be seen that the mean level is

- proportional to the product of the signal and reference frequency amplitudes;
- related to the phase angle between the signal and reference.

It will be appreciated that if the reference signal amplitude is maintained at a fixed value, and the reference phase is adjusted to ensure a relative phase shift of zero degrees, then by measuring the mean level the input signal amplitude can be determined.

The mean level is, of course, the DC component of the demodulator output, so it is a relatively simple task to isolate it by using a low-pass filter. The filtered output is then measured using conventional DC voltmeter techniques.

Mathematically, we can derive the same conclusion as follows. Consider the case where a noise-free sinusoidal signal voltage V_{in} is being detected, where

$$V_{in} = A\cos(\omega t) \tag{7}$$

ω is the angular frequency of the signal, which is related to the frequency, f, in hertz by the equality

$$\omega = 2\,\pi f \tag{8}$$

The lock-in amplifier is supplied with a reference signal at frequency f derived from the same source as the signal and uses this to generate an internal reference signal of

$$V_{ref} = B\cos(\omega t + \theta) \tag{9}$$

where θ is a user-adjustable phase shift introduced within the lock-in amplifier.

The detection process consists of multiplying these two components together so that the PSD output voltage is given by

$$\begin{aligned} V_{psd} &= A\cos(\omega t) \times \mathrm{B}\cos(\omega t + \theta) \\ &= AB\cos\omega t(\cos\omega t\cos\theta - \sin\omega t\sin\theta) \\ &= AB(\cos 2\omega t\cos\theta - \cos\omega t\sin\omega t\sin\theta) \\ &= AB((\tfrac{1}{2} + \tfrac{1}{2}\cos 2\omega t)\cos\theta - \tfrac{1}{2}\sin 2\omega t\sin\theta) \\ &= \tfrac{1}{2}AB((1 + \cos 2\omega t)\cos\theta - \sin 2\omega t\sin\theta) \\ &= \tfrac{1}{2}AB(\cos\theta + \cos 2\omega t\cos\theta - \sin 2\omega t\sin\theta) \\ &= \tfrac{1}{2}AB\cos\theta + \tfrac{1}{2}AB(\cos 2\omega t\cos\theta - \sin 2\omega t\sin\theta) \\ &= \tfrac{1}{2}AB\cos\theta + \tfrac{1}{2}AB\cos(2\omega t + \theta) \end{aligned} \tag{10}$$

If the magnitude, B, of the reference frequency is kept constant, then the output from the phase-sensitive detector is a DC signal which is

- proportional to the magnitude of the input signal A;
- proportional to the cosine of the angle, θ, between it and the reference signal;
- modulated at $2\omega t$, that is, it contains components at twice the reference frequency.

The output from the PSD then passes to a low-pass filter, which removes the $2\omega t$ component, leaving the output of the lock-in amplifier as the required DC signal.

5 DESCRIPTION OF THE VARIOUS ELEMENTS OF A LOCK-IN AMPLIFIER

The block diagram of a typical lock-in amplifier is shown in Figure 6. Readers should be aware that the following discussion makes no assumptions as to the technology used to implement each of the circuit elements and that analog, mixed technology, and digital methods may be used.

5.1 Signal channel

In the signal channel, the input signal, including noise, is amplified by an adjustable-gain, AC-coupled amplifier, in order to match it more closely to the optimum input signal range of the PSD. Commercial instruments are usually fitted

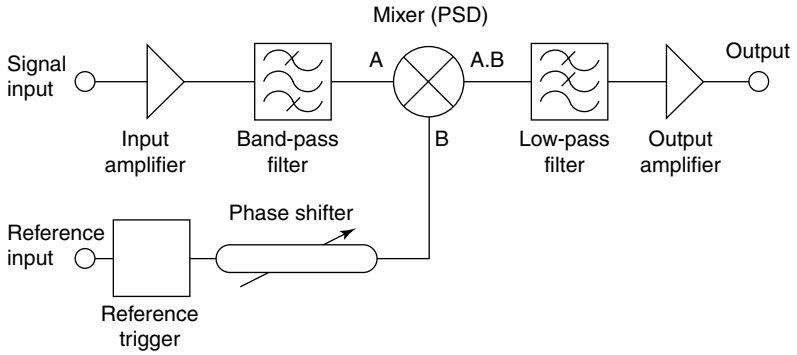

Figure 6. Basic lock-in amplifier (simplified). (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

with high impedance inputs for voltage measurements. Many also incorporate low impedance inputs for better noise matching to current sources, although in some cases the best results are obtained through the use of a separate external preamplifier.

The performance of the PSD is usually improved if the bandwidth of the noise voltages reaching it is reduced from that of the full frequency range of the instrument. To achieve this, the signal is passed through some form of filter, which may simply be a band rejection filter centered at the power-line frequency and/or its second harmonic to reject line frequency pick up, or alternatively a more sophisticated tracking band-pass filter centered at the reference frequency.

5.2 Reference channel

It has been shown that proper operation of the PSD requires the generation of a precision reference signal within the instrument. When a high-level, stable, and noise-free reference input is provided, this is a relatively simple task. However, there are many instances where the available reference is far from perfect or symmetrical, and, in these cases, a well-designed reference channel circuit is very important. Such circuits can be expensive and often account for a significant proportion of the total cost of the instrument.

The reference input waveform to the lock-in may be of almost any wave shape. Its zero crossings are used to define zero phase ($\phi_r = 0$) by the reference trigger circuit, which usually incorporates a phase-locked loop to lock onto the applied reference signal. The output of this phase-locked loop circuit is a precise waveform, locked in phase to the reference input, and at a frequency f_2. Normally, $f_2 = f_r$ (the reference frequency); most lock-ins also provide second-harmonic mode where $f_2 = 2f_r$. This mode is often used for derivative (signal rate of change) measurements. Modern instruments also often allow detection of even higher harmonics, allowing harmonic analysis of the input signal to be performed.

The internally generated reference is passed through a phase shifter, which is used to compensate for phase differences that may have been introduced between the signal and reference inputs by the experiment, before being applied to the PSD.

5.3 Phase-sensitive detector

As already mentioned, the purpose of the phase-sensitive detector is to multiply the signal by the reference waveform. At present, there are currently three common methods of implementing the PSD, these being the use of an analog multiplier, a digital switch, or a digital multiplier. These are discussed in greater depth in the following sections.

5.4 Low-pass filter and output amplifier

As discussed earlier, the purpose of the output filter is to remove the AC components from the desired DC output. Practical instruments employ a wide range of output filter types, implemented either as analog circuits or in digital signal processors. Most usually, however, these are equivalent to one or more stages of simple single-pole 'RC' type filters, which exhibit the classic 6 dB per octave roll-off with increasing frequency.

There is usually also some form of output amplifier, which may be either a DC-coupled analog circuit or a digital multiplier. The use of this amplifier, in conjunction with the input amplifier, allows the unit to handle a range of signal inputs. When there is little accompanying noise, the input amplifier can be operated at high gain without overloading the PSD, in which case little, if any, gain is needed at the output. In the case of signals buried in very large noise voltages, the reverse is the case.

The term dynamic reserve is used to specify noise overload performance and is defined as the ratio of the overload level (peak value of an asynchronous signal that will just cause significant nonlinearity), to the peak value of a full-scale synchronous signal.

5.5 Output

The output from a lock-in amplifier was traditionally a DC voltage that was traditionally displayed on an analog panel meter. Nowadays, especially when the instruments are used under computer control, the output is more commonly a digital number, although the analog DC voltage signal is usually provided as well. Instruments using an analog form of phase-sensitive detector use an analog-to-digital converter (ADC) to generate their digital output, whereas digital signal processor (DSP) lock-in amplifiers use a digital-to-analog converter (DAC) to generate the analog output.

5.6 Internal oscillator

All lock-in amplifiers use some form of oscillator within their reference circuits. Many units, however, also have a separate internal oscillator that can be used to generate an electrical stimulus for the experiment, usually with user-adjustable frequency and amplitude.

5.7 Computer control

All modern instruments include a microprocessor. This can simplify and automate manual measurements as well as support remote control of the instrument over common computer interfaces, such as the GPIB (IEEE-488) and RS232 links. The ability of the microprocessor to perform mathematical manipulations adds such useful functions as vector phase and noise measurements to the basic signal recovery capabilities of the lock-in amplifier.

6 PHASE-SENSITIVE DETECTOR DESIGNS – ANALOG AND DIGITAL TECHNIQUES

The phase-sensitive detector at the heart of the lock-in amplifier can be implemented in various ways, with the three most common methods being detailed in this section.

6.1 Analog multiplier

In an instrument with an analog multiplier, the PSD comprises an electronic circuit, which multiplies the applied signal with a sinewave at the same frequency as the applied reference signal. Although the technique is very simple in principle, in practice it is difficult to manufacture an analog multiplier that is capable of operating linearly in the presence of large noise, or other interfering, signals. Nonlinear operation results in poor noise rejection and thereby limits the signal recovery capability of the instrument. Consequently, instruments using this technique tend to provide only the most basic signal recovery performance.

6.2 Analog switching multiplier

The switching multiplier (Figure 7) uses a simple form of demodulator consisting of an analog polarity-reversing switch driven at the applied reference frequency. The great advantage of this approach is that it is very much easier to make such a demodulator operate linearly over a very wide range of input signals.

However, the switching multiplier not only detects signals at the applied reference frequency but also at its odd harmonics, where the response at each harmonic relative to the fundamental is defined by the Fourier analysis of a square wave. The frequency domain response of this type of multiplier is shown in Figure 8 and is characterized by a series of transmission 'windows' centered around the fundamental and odd harmonics of the reference frequency. Such harmonic responses may well be of use if the signal being detected is also a square wave but can give problems if, for example, the unit is being used at 1 kHz and there happens to be strong interfering signals at 7 kHz.

As discussed earlier, the use of a tuned low-pass or band-pass filter in the signal channel prior to the multiplier modifies the response of the unit so that it primarily detects signals at the reference frequency. However, in order to fully reject the $3f$ response, while still offering good performance at the reference frequency, very complex and

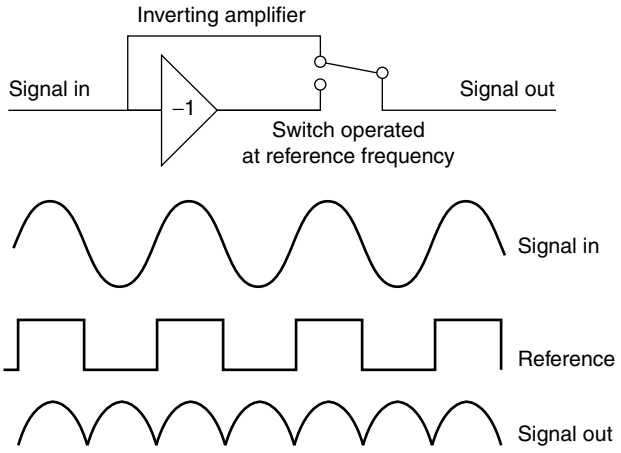

Figure 7. Analog switching multiplier.

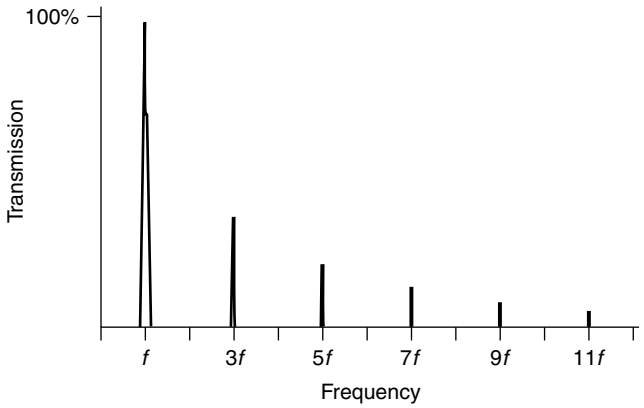

Figure 8. Analog switching multiplier – frequency domain response.

expensive filters would be required, since the filter needs to be tunable over the whole operating frequency range of the instrument. These are impractical for commercial instruments, so units fitted with filters tend to show some response to signals and noise at the third and fifth harmonics of the reference frequency and relatively poor amplitude and phase stability as a function of operating frequency.

Some analog lock-in amplifiers (e.g. the *SIGNAL RECOVERY* models 5209, 5210, 5110A, 5302) use an alternative and more sophisticated type of switching demodulator, which replaces the single analog switch with an assembly of several switches driven by a Walsh function. This may be thought of as a stepped approximation to a sinewave. Careful selection of components allows such a demodulator to offer all of the advantages of the switching demodulator with one additional benefit, which is the complete rejection of the responses at the third and fifth harmonics. The response to higher order odd harmonics is the same as for the normal switching modulator.

Such a demodulator, when used with a relatively slow roll-off, fourth-order, low-pass filter in the signal channel, produces an overall response very near to the ideal, which is an instrument that responds only to signals at the reference frequency. In this case, the demodulator rejects the third- and fifth-harmonic responses, while the signal channel filter removes the higher orders.

6.3 Digital multiplier using digital signal processing (DSP)

In an instrument employing this type of multiplier, the input signal is amplified and then immediately digitized. This digital representation is then multiplied by a digital representation of a sinewave at the reference frequency. A DSP is used for this task, and the output is therefore no longer an analog voltage but rather a series of digital values.

The technique offers the advantages of a perfect multiplication with no inherent errors and minimizes the DC-coupled electronics that are needed with other techniques, thereby reducing output drift. It has been used for a number of years in such applications as swept-frequency spectrum analyzers.

There are, however, a number of major problems with this technique when applied to recovering signals buried in noise. The most important of these is *dynamic range*. Consider the case of an input signal in the presence of 100 dB (100 000 times larger) of noise. If the signal is to be digitized to an accuracy of 'n' bits, then the input converter must handle a dynamic range of $2^n \times 100\,000$ to fully accommodate the signal and noise amplitudes. With a typical value for n of 15, this equates to a range of 3.2×10^9:1, corresponding to 32 bits. An ADC can be built with such accuracy, but would be extremely expensive and quite incapable of the sampling rates needed in a lock-in amplifier operating to 100 kHz.

Practical digital lock-in amplifiers use 14-, 16-, or 18-bit ADCs. Consequently, in the presence of strong interfering signals, the required signal may only be changing the least significant bit (LSB) of the converter, and indeed may actually be so small that there is no change at all in the ADC output. Hence, the measurement resolution of an individual output sample is very coarse. Resolution is however improved by averaging many such samples. For example, 256 samples of 1-bit resolution can average to 1 sample of 8-bit resolution, but this is at the expense of reduced response time. This averaging only operates predictably if the spectral power distribution of the interfering noise is known. If it is not, then noise has to be added by the instrument from its own internal noise source to ensure that it dominates, and to ensure that the signal does cause at least the LSB to change. The addition of this noise is only needed in demanding signal recovery situations, and so is not usually a problem.

7 SINGLE AND DUAL-PHASE LOCK-IN AMPLIFIERS

Descriptions of lock-in amplifiers usually start with the single-phase instrument, but, in recent years, the dual-phase (also known as the *vector lock-in amplifier*) type has become the most popular format. This is not, as initially may be thought, a dual-channel unit. Rather, it incorporates a second phase-sensitive detector, which is fed with the same signal input as the first but which is driven by a reference signal that is phase-shifted by 90°. This second detector is followed by a second output filter and amplifier and is usually referred to as the 'Y' output channel, the

original output being referred to as the 'X' channel. The X and Y outputs are also known as the in *phase* and *quadrature* outputs respectively.

The X and Y outputs can be processed mathematically to derive the vector magnitude R and signal phase θ where

$$R = \sqrt{(X^2 + Y^2)} = \sqrt{[(A\cos\theta)^2 + (A\sin\theta)^2]} \qquad (11)$$

and

$$\theta = \tan^{-1}\left(\frac{Y}{X}\right) = \tan^{-1}\left(\frac{A\sin(\theta_s + \theta_r)}{A\cos(\theta_s + \theta_r)}\right) = \theta_s + \theta_r \qquad (12)$$

where θ_s is the signal phase shift relative to the reference signal phase, and θ_r is the phase offset set by the phase-shift controls. Dual-phase lock-in amplifiers can, therefore, display their output signal in rectangular or polar form, with the phase controls (θ_r) allowing continuous vector rotation.

The principal advantage of the dual-phase unit is that if the signal channel phase (but not its amplitude) changes then the magnitude display will remain constant, even though the X and Y outputs change. Hence, if the lock-in amplifier is set to display vector magnitude R, changes in the signal phase will not affect the reading, and the instrument does not require the adjustment of the reference phase-shifter circuit. This capability is the main reason for the dual-phase instrument's widespread use.

Note that asynchronous signals ($f_s \neq f_r$) with beat frequencies within the response of the output low-pass filter will provide DC outputs and the instrument, therefore, acts as a *wave analyzer.* Commercial wave analyzers are essentially dual-phase lock-in amplifiers that are optimized for convenience in measuring frequency components of a signal rather than recovering a signal from noise.

8 LIMITS OF DETECTION FOR LOCK-IN AMPLIFIERS

8.1 Selection of output filter

The lock-in amplifier's output filter serves two main purposes. First, the action of the phase-sensitive detector generates a signal at twice the reference frequency, which must be rejected. Second, fluctuations caused by noise and interfering signals that are close to the reference frequency are translated down by the PSD to appear as frequencies close to DC. These signals, which do not have any fixed frequency or phase relationship to the reference, are also rejected by the filter and do not result in any change to the mean output DC level.

Consider the case shown in Figure 9, where the asynchronous (noise) of frequency $f_1 = f_2 + \Delta f$ is applied

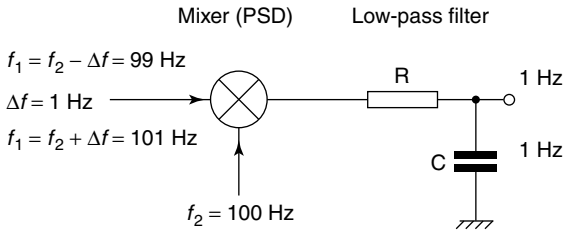

Figure 9. PSD operation with asynchronous (noisy) signal.

to the PSD input. The resulting mixer sum and difference signals will, therefore, be $2f_2 + \Delta f$ and Δf respectively. The output low-pass filter is set to reject all but the Δf component, which therefore appears at the output as noise. Suppose we change the frequency of this input noise to $f_1 = f_2 - \Delta f$. The resulting sum and difference frequencies will respectively be $2f_2 - \Delta f$ and $-\Delta f (= \Delta f)$. Again, only the Δf component can appear as output noise and the low-pass filter 'cannot tell' whether its Δf input resulted from an $f_2 + \Delta f$ input to the mixer or an $f_2 - \Delta f$ input.

In addition to its rectifying and phase-sensitive properties, therefore, the PSD filters noise as though it consisted of a band-pass response centered on f_2, where the effective *band-pass* response consists of the output low-pass filter response and its mirror image. Given that the PSD drive frequency is the reference frequency, the center frequency therefore automatically tracks the reference frequency, f_2.

8.1.1 Signal-to-noise improvement ratio (SNIR)

As with DC measurements using preamplifiers or electrometers, the signal-to-noise improvement ratio (SNIR) to be expected from a lock-in depends upon the input noise bandwidth (B_{ni}) to the lock-in, the noise bandwidth (B_{no}) of the lock-in, and the noise spectral characteristics. For random white noise and unity gain,

$$\text{SNIR} = \sqrt{\left(\frac{B_{ni}}{B_{no}}\right)} \qquad (13)$$

What is meant by the term *bandwidth*? In the simple low-pass filter circuit shown in Figure 10, for example, the transfer function is $G(f) = v_o/v_i$.

The *signal bandwidth* for this circuit (Figure 11) is usually, and somewhat arbitrarily, defined to be the *cut-off frequency,* f_c, where $v_o/v_i = 70.7\%$ (-3 dB) or $v_o^2/v_i^2 = 50\%$ (the half-power point).

In the case of the circuit above, $f_c = 1/2\pi RC$

Notice that frequencies above f_c will obviously pass (though attenuated) through the filter and, therefore, are not really cut off. For noise, it is convenient to think in terms of an equivalent noise bandwidth, B_n, defined by the

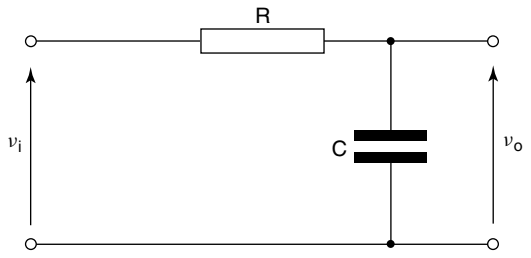

Figure 10. Low-pass filter circuit.

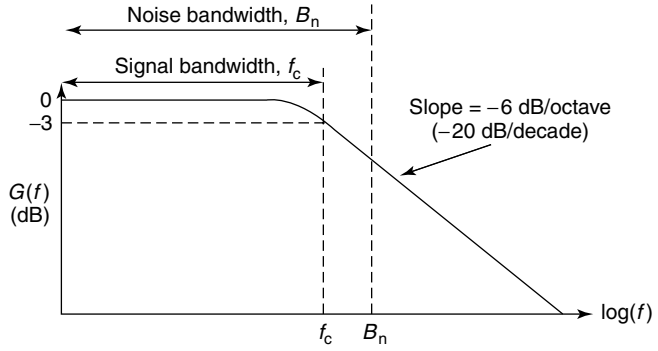

Figure 11. Low-pass filter transfer characteristic.

relationship

$$B_n = \frac{1}{G^2}\int_0^\infty |H(j\omega)|^2 \, df \tag{14}$$

where $H(j\omega)$ is the frequency response function of the system and G is a gain parameter suitably chosen to be a measure of the response of the system to some parameter of the signal. In the case of a low-pass filter such as that shown in Figure 10, G is usually taken to be the zero-frequency (DC) gain, whereas for band-pass responses, G is usually made equal to the maximum gain.

Using the above definition and taking G to be the zero-frequency gain (i.e. unity), it can readily be shown that for the simple RC filter shown in Figure 10 which has a −6 dB/octave roll-off rate

$$B_{no} = \frac{1}{4RC} \text{ Hz} \tag{15}$$

while for a two-stage buffered filter, which has a −12 dB/octave roll-off rate:

$$B_{no} = \frac{1}{8RC} \text{ Hz} \tag{16}$$

The lock-in amplifier's output filter is adjusted using the time constant control, where $TC = RC$. Hence, for example, if the time constant is set to 100 ms and the −12 dB/octave slope is selected, then $B_{no} = 0.1/8$ Hz, or 12.5 mHz. With an input noise bandwidth of say 100 kHz, the resulting SNIR is nearly 70 dB, demonstrating the power of the lock-in technique.

9 EXAMPLES OF LOCK-IN AMPLIFIER APPLICATIONS

9.1 Signal recovery

Figure 12 illustrates a basic optical detection setup using a mechanical light chopper and a lock-in amplifier. The light chopper consists of a motor, a speed control mechanism, and a rotating blade or chopper wheel. In some cases, all three of these components are in one assembly. In other choppers, the control unit may be in a separate housing.

The chopper wheel is a rotating metal disk, which contains one or more sets of equally spaced apertures, which

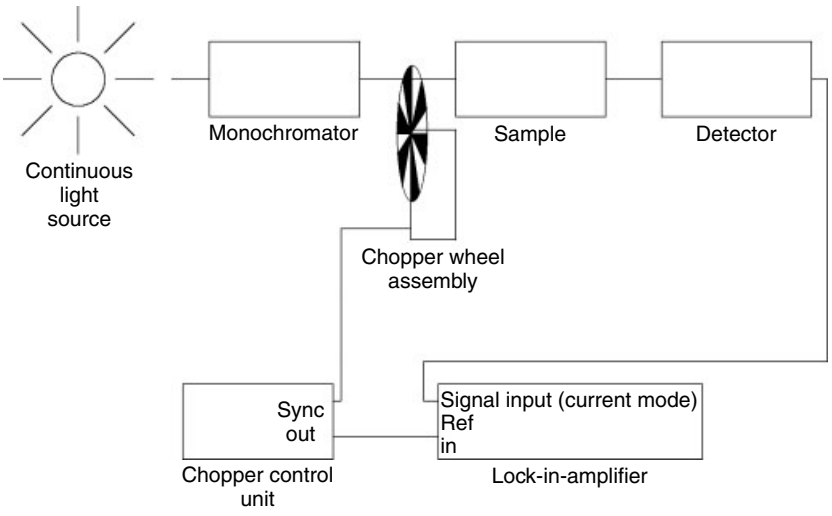

Figure 12. AC measurement system using a lock-in amplifier and mechanical chopper.

allow the light source to pass through or be blocked altogether. The number of apertures and the wheel rotation speed determine the chopping frequency. Since the rotation of the blade causes the optical signal path to be interrupted, the light source that stimulates the experiment is in the form of an AC excitation. One could visualize this excitation as an optical equivalent of a square wave, although this is only true if the aperture size is large compared to the beam diameter. The signal appearing at the detector output may or may not be a good representation of the optical stimulation since factors such as detector response time and cable capacitance must be considered.

In addition to modulating the light source, the chopper also provides a synchronous reference signal capable of driving the reference channel of a lock-in amplifier. This reference output voltage is a square wave, usually in the order of a few volts peak to peak.

The optical signal stimulating the experiment and thus falling on the optical detector generates an electrical current that can be measured by the lock-in. Any discrete frequencies or noise voltages not equal to the reference frequency will be rejected by the lock-in amplifier. The end result is a much lower limit on signals that can be measured. In fact, it is possible that the signal of interest may be completely obscured by noise if one were to view the detector output with an oscilloscope. Again, stray light falling on the detector is usually not a problem as long as the magnitude is insufficient to saturate the detector. However, the user still needs to ensure that stray light does not enter into the experiment via the chopped light path.

9.2 Vector voltmeter measurements

Figure 13 shows a typical application for a dual-phase lock-in where the signals being measured are relatively clean, but advantage is taken of the dual-phase capability to directly determine the wanted values.

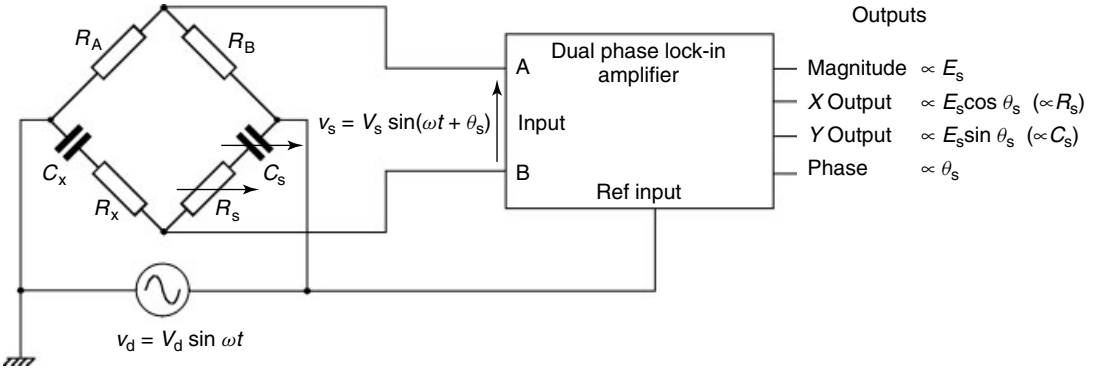

Figure 13. Bridge balancing using a dual-phase lock-in amplifier.

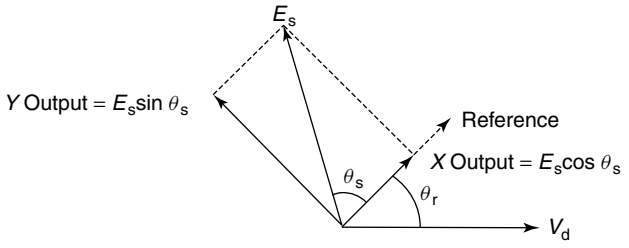

Figure 14. Dual-phase lock-in amplifier – vector relationships.

In this AC bridge application, the phase shift (θ_r) can be set to zero, so that the in-phase (X) signal responds only to the bridge resistance and the quadrature output (Y) to the bridge capacitance. The bridge can then be balanced very simply by separately nulling R_s and C_s. The phase relationships of the various waveforms are shown in Figure 14.

10 ADVANCED TECHNIQUES

The advent of DSP based lock-ins has allowed instruments (such as the *SIGNAL RECOVERY* models 7265 and 7280) to be designed that can simultaneously measure signals at two different frequencies. These operating modes are known as *dual reference* and *dual harmonic* modes.

One application for the dual reference mode is to build a very cost-effective dual-beam measurement system. This technique can eliminate variations in source intensity over several orders of magnitude, which is especially useful in two common situations:

- If the source output is unstable over time, such as with some discharge lamps;
- If the 'source' is the output of a spectrometer with a tungsten–halogen or other lamp as its input, and the spectrometer center wavelength is being scanned as part of the experiment.

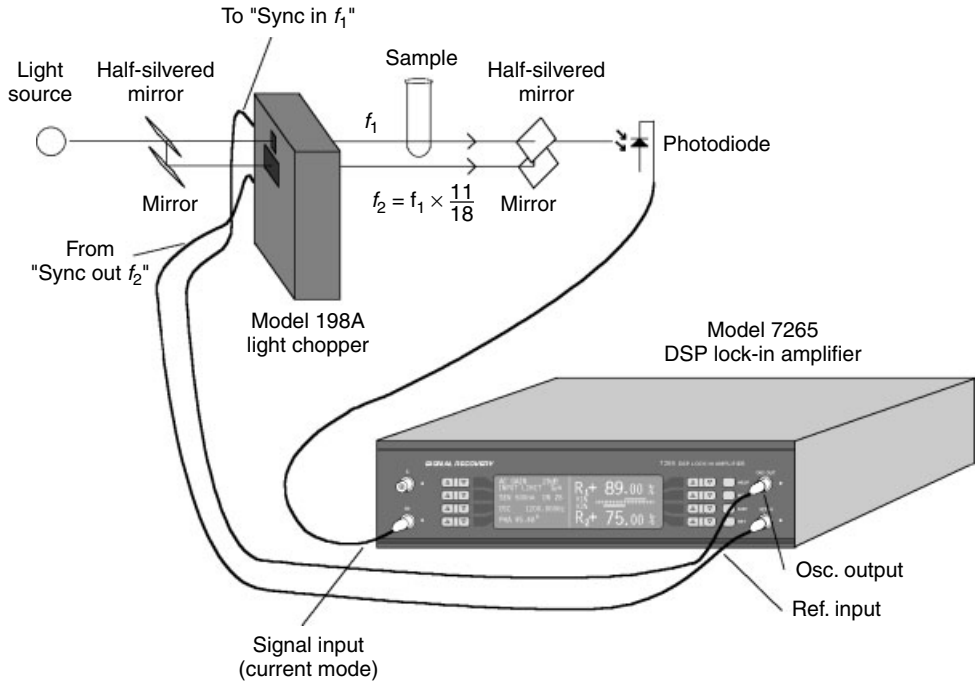

Figure 15. Dual-beam ratiometric system using model 198A light chopper and model 7265 DSP lock-in amplifier. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

A typical experimental arrangement is shown in Figure 15 above. A focused light source is split into two beams using either a half-silvered mirror or beam splitter, with the two beams being aligned so that they pass through the inner and outer apertures of the model 198A. One beam passes through the sample, while the other passes via a reference path that may include ND (neutral density) filters (not shown). Both beams are recombined back onto a single photodiode using a second mirror/beam-splitter combination. Hence, there will be two signals at the detector, one at frequency f_1, which is due to the light that passes through the sample and the second at f_2, due to light traveling via the 'reference' path.

A DSP lock-in amplifier with dual reference mode is set to this mode and with the internal oscillator set to 360 Hz. The oscillator amplitude is set to 2 V rms and the Osc. out connector coupled to the Sync in f_1 input on the 198A. The chopper locks to this input causing the f_1 frequency also to be 360 Hz, and thereby satisfying an instrument restriction in the dual reference mode that one of the signals being detected by the lock-in must be at the internal reference frequency.

The chopper also generates a reference signal at the f_2 frequency, which is coupled back to the lock-in's Ref. in input. Hence, its external reference channel operates at this frequency, which is in this case $360 \times 11/18 = 220$ Hz.

Once the lock-in amplifier's sensitivity and phase controls have been properly adjusted then it indicates in the R2 channel (i.e. the internal reference frequency) the magnitude of the signal due to light through the sample, while the R1 channel (the external frequency) show the magnitude of the signal due to light via the reference path.

The ratio of these two signals is independent over several orders of magnitude to changes in the source intensity, so if the ratio is calculated and displayed using the instrument's user equations menu such variations can be eliminated.

10.1 Advantages

The system described is considerably more cost effective than the traditional approach, which required two lock-in amplifiers. Since the same detector and analog signal channel is used for both signals, differential drift between channels is also eliminated. Note, however, that since the signals at f_1 and f_2 share a common path as far as the main ADC, best results are obtained when the experiment is arranged so that their absolute levels differ by no more than a factor of 100.

1 BOXCAR AVERAGER

The *boxcar averager* (***SIGNAL RECOVERY***, 1), also known as a *boxcar integrator* or *detector,* is a sampling instrument that integrates the applied input signal during a predefined *gate or aperture width* starting at a predefined *trigger, gate,* or *aperture delay* after an applied trigger. Each of these integrated samples of input signal can then be averaged, using either an analog averager or by digitizing each sample and then averaging the resulting digital values.

The boxcar therefore performs signal recovery by three methods. First, the input signal only affects the output during the period in which it is being sampled; at all other times its level is unimportant, other than the need to avoid causing an input overload for which the recovery time might affect a subsequent sample. This is temporal separation of the signal from the noise.

Second, the signal is integrated during the gate width, unlike common sample and hold circuits that simply take a 'snapshot' measurement of the signal level at one point in time. Hence, if there is noise or other interference present at the input at frequencies much higher than the reciprocal of the gate width, then these will be rejected.

Finally, the measured samples are themselves averaged, ensuring that low frequency fluctuation or noise that would cause sample-to-sample variation can also be removed.

In commercial instruments, the output was traditionally recorded using an analog chart recorder, with the Y input being connected to the output from the boxcar's output averager, and the X input being driven by a voltage generated by the boxcar and proportional to the trigger delay. Nowadays, the boxcar's output is usually digitized for recording by a computer and the trigger delay is set using a separate digital delay generator. This makes it possible to use a computer to run the whole experiment and record the resulting data.

Boxcar averagers can recover very fast waveforms and resolve features down to sub nanosecond level. However, they are time inefficient if used for waveform recovery and in such applications have been superseded by signal averagers and storage oscilloscopes. They do, however, remain cost-effective for static gate work.

2 GENERAL PRINCIPLES OF OPERATION OF THE 'BOXCAR' INTEGRATOR

The heart of any boxcar is the *gated integrator* circuit, shown in simplified form in Figure 1. This circuit is simply an *RC* low-pass filter gated by switch S_1, (the sampling gate). As shown, the gated integrator has unity DC signal gain.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

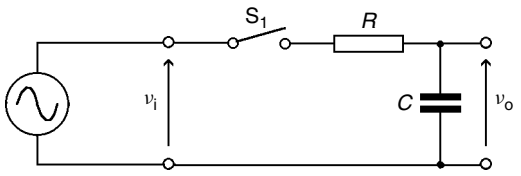

Figure 1. The gated integrator (simplified).

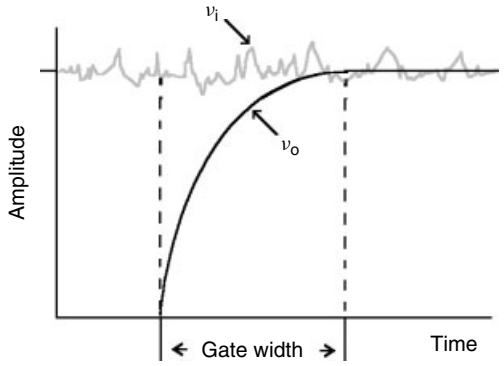

Figure 2. Gated integrator – gate time constant.

When the gate opens (switch S_1 closes) the output voltage v_o starts to rise exponentially toward v_i, as shown in Figure 2 where the gate width is shown as being small in relation to long-term changes in v_i. The gate time constant (set by the product RC) is adjusted so that the v_o is typically within a few percent of the input v_i at the end of the selected gate width. Consequently, high frequency components of the input signal are removed. The equivalent noise bandwidth is simply $B_{no} = 1/4RC$.

The integral of the gate sample is the voltage v_o at the end of the gate width. This can either be stored as an analog voltage or be digitized in order to be processed by the output averager, after which the sampling circuit is reset ready for the next trigger.

The rest of the boxcar consists of the output averager, discussed in another section, and trigger processing and delay circuits. Commercial instruments offer trigger inputs that are similar in design to those used on oscilloscopes, allowing triggering on a variety of waveforms. Following the trigger, a delay circuit allows the position in time start of the gate to be adjusted while a variable pulse generator creates the gate pulse.

The overall maximum trigger rate of the instrument is set by the gate delay, gate width, averager processing and reset times, and is typically up to 80 kHz.

3 STATIC GATE BOXCAR AVERAGING

In the *static gate* boxcar averager, the length of the trigger delay is fixed and the intention is usually to determine the amplitude of some 'spike' or feature of a waveform that is typically much narrower than the repetition period set by the overall trigger rate. Consider the situation shown in Figure 3.

The input signal consists of a repetitive waveform triggered at a 10 kHz rate so that each cycle lasts 100 µs. The trigger delay is set to open the gate just before the feature of interest and the gate width is set to 'bracket' this

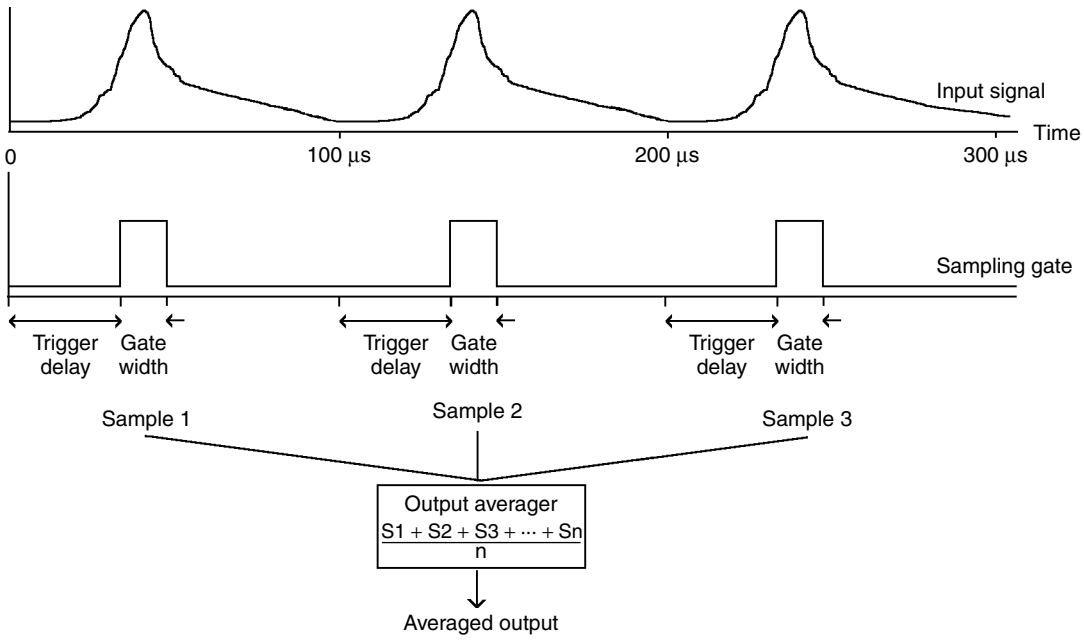

Figure 3. Boxcar averager with linear output averaging.

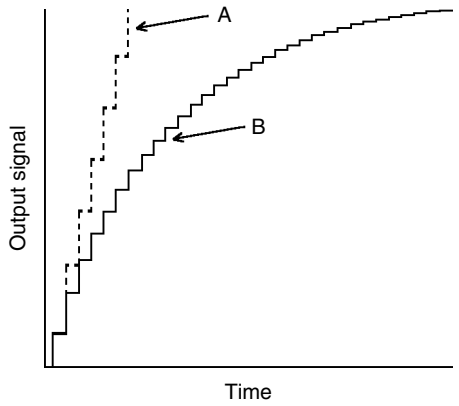

Figure 4. Boxcar output averager modes of operation: curve A – linear averaging, curve B: exponential averaging.

feature. Each sample results in an integral representing the area under the signal curve for the duration of the gate, and these samples are then averaged.

When using a linear output averager, all samples have equal weight and so the output will rise in a linear staircase fashion as shown in Figure 4, curve A. Each step in this curve represents a new sample becoming available, which in turn corresponds to a trigger cycle. In this *linear summation* mode, the desired number of signal samples (n) is selected; after n triggers have occurred, a switch or other method is used to reset the output averager. Since the signal component of the samples will add linearly, but random noise samples will add vectorially, after n samples of a constant-amplitude signal (S) plus white noise (N), and after maximizing the gate width to suit the signal wave shape, the output SNR (signal-to-noise ratio) is given by

$$\begin{aligned}\mathrm{SNR}_{\mathrm{out}} &= \frac{S_1 + S_2 + S_3 + \cdots + S_n}{\sqrt{({N_1}^2 + {N_2}^2 + {N_3}^2 + \cdots + {N_n}^2)}} \\ &= \frac{nS}{\sqrt{(nN^2)}} \frac{S}{N}\sqrt{n} = \mathrm{SNR}_{\mathrm{in}}\sqrt{n} \end{aligned} \quad (1)$$

so that

$$\mathrm{SNIR} = \frac{\mathrm{SNR}_{\mathrm{out}}}{\mathrm{SNR}_{\mathrm{in}}} \left(= \frac{\mathrm{SNR}\ (n\ \mathrm{samples})}{\mathrm{SNR}(1\ \mathrm{sample})} \right) = \sqrt{n} \quad (2)$$

Note that in this operating mode, it is easiest to think in terms of time averaging since the equivalent noise bandwidth of the gated integrator circuit is not constant but will decrease with increasing n.

The linear averager suffers from the disadvantage of needing to be reset after each set of triggers. Although this is not difficult if the output averager is implemented digitally, it is not as easy when using analog techniques. Historically, these were more common and so in such cases the output used *exponential averaging*, which essentially consists of nothing more than a further gated integrator stage, but this time with a time constant much longer than the gate width. The gate at this stage is operated for a short fixed period (typically a few microseconds) to apply the sample voltages out of the input averager to the output averager, with one such gate per trigger cycle.

If the samples from the input averager are similar in amplitude, then the output from the output averager will rise exponentially as shown in Figure 4, curve B. Again, each step corresponds to a new sample becoming available, and hence a trigger cycle.

4 WAVEFORM RECOVERY BOXCAR AVERAGER

Boxcar averagers can also be used for *waveform recovery,* where the intention is to record the waveform of the input signal. In this mode of operation, the trigger delay is not fixed but rather is incremented by a fixed amount on successive groups of n triggers so that it sweeps between *initial delay* and *final delay* values. In this mode, the boxcar output is a replica of the signal waveform and the boxcar can be regarded as a time-translation device that can slowdown and recover fast waveforms.

Figure 5 gives a simplified view of this mode. The gate width is now set to be much shorter than the signal period. The first set of n samples is taken after a trigger delay set to the initial delay setting. This group of samples is then averaged by the output averager and appears as point A on the output plot. The boxcar counts the applied triggers and after the first set of n has been detected, the trigger delay is incremented and the cycle repeats, resulting in point B. The process continues (generating point C and further points) until the trigger delay is equal to the preset final delay value.

The number of points m on the output waveform record is

$$m = \frac{\text{Final delay} - \text{initial delay}}{\text{Delay increment}} \quad (3)$$

It will therefore be seen that, as the delay increment is reduced, the time resolution of the recorded waveform will improve since there are more points. But of course the time to record the waveform will also increase since each point requires n triggers.

5 SIGNAL AVERAGERS – OVERVIEW

The boxcar is a *single-point* averager: it samples each signal occurrence (sweep) only once. A *signal averager* acts

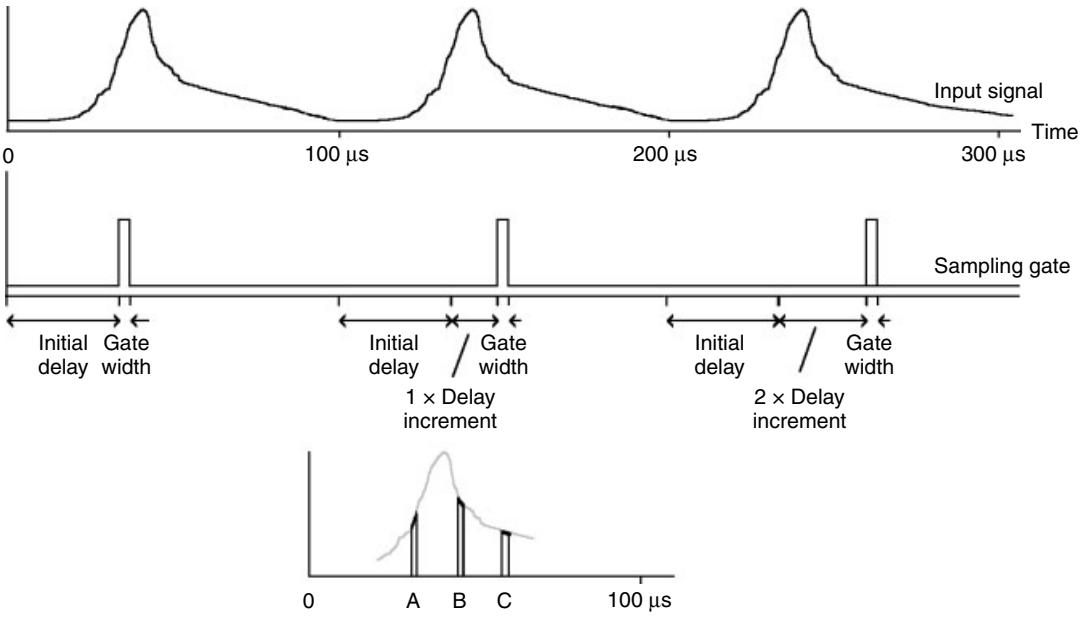

Figure 5. Boxcar averager – waveform recovery.

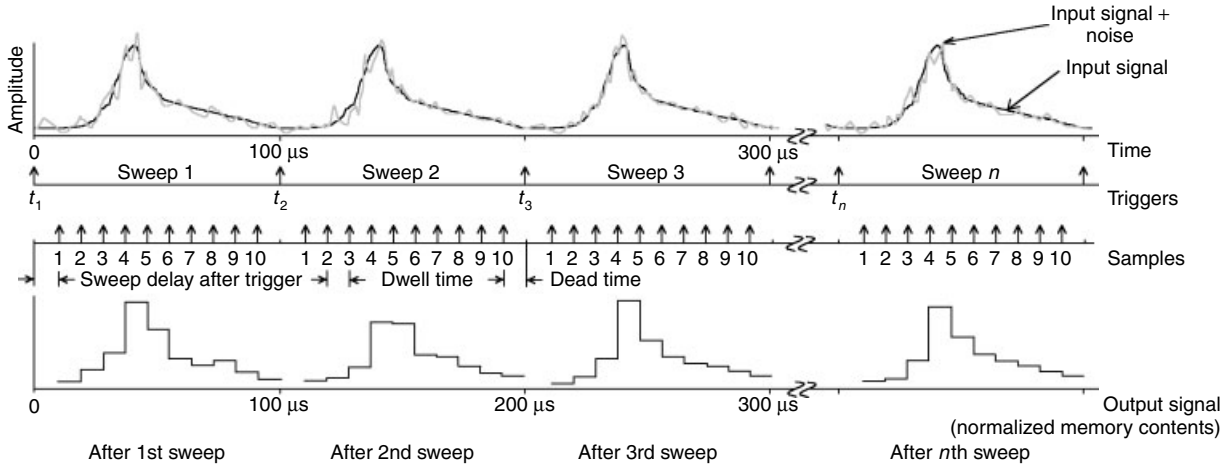

Figure 6. Multipoint signal averager.

much like a large number of boxcars connected in parallel, since it samples many points during each signal sweep. In such signal instruments, the analog storage capacitor of the boxcar is replaced by digital memory; each sample is digitized and the new data is added to the data from previous sweeps already in the memory location corresponding to that sampling point.

Figure 6 illustrates some typical waveforms and timing details for a multipoint signal averager; for simplicity $I = 10$ (i.e. only ten samples/sweep are shown). The total signal duration (T) is given by the product of the number of samples/sweep (I) and the dwell-time (gate width or sampling duration, t_g) of each sample. Note that T is less than the total sweep duration (τ) by the dead time (t_d), and that there is usually a fixed delay time (the *intrinsic delay*) between receipt of a trigger pulse and the beginning of the first sample. Although in most applications a signal averager is triggered at a constant rate ($f = 1/\tau$), it is not necessary that the trigger be periodic. Assume that the averager is set to continue averaging until n input sweeps have been sampled, at which point it will automatically stop.

Suppose the waveform of a noisy signal, $f(t)$, is to be recovered where

$$f(t) = s(t) + n(t) \tag{4}$$

For the ith sample of the kth sweep,

$$f(t) = f(t_k + it_g) = s(t_k + it_g) + n(t_k + it_g) \quad (5)$$

For any particular sample point (i), the input signal can be assumed to remain unchanged with each new value of k (i.e. with each new sweep) and the averaged signal will therefore be simply

$$S(i)_{out} = \sum_{k=1}^{n} s(t_k + it_g) = ns(it_g) \quad (6)$$

For random noise, samples (X_i) will add vectorially, so that the rms value (σ) of the averaged noise will be given by

$$\left(\sum (X_i)^2\right)^{1/2} = \sigma\sqrt{n} \quad (7)$$

The averager output can be described by

$$g(t_k + it_g) = ns(it)_g + \sigma\sqrt{n} \quad (8)$$

so that the output SNR is

$$SNR_{out} = \frac{s_{out}}{N_{out}} = \frac{ns}{\sigma\sqrt{n}} it_g = \frac{s}{\sigma} it_g \sqrt{n} \quad (9)$$

The input SNR is simply

$$SNR_{in} = \frac{s(it_g)}{\sigma} \quad (10)$$

so that

$$SNIR = \frac{SNR_{out}}{SNR_{in}} = \sqrt{n} \quad (11)$$

6 FREQUENCY RESPONSE OF SIGNAL AVERAGERS

In order to consider a signal averager from a frequency domain or filtering point of view, it is necessary to know its transfer function, $H(j\omega)$. This can be determined if the impulse response $h(t)$ is known, since $H(j\omega)$ and $h(t)$ are a Fourier-transform pair.

$h(t)$ can be determined heuristically by the following approach. In a multipoint averager, trigger pulses are used to synchronize the signal sweeps and allow the signal samples to be coherently added (CO-ADDed). Mathematically, this action can be thought of as convolving the input signal, $f(t)$, with a train of n unit impulses (triggers) spaced τ seconds apart. The averager's effective impulse response is, therefore, given by

$$h(t) = \sum_{k=1}^{n} \delta(t - k\tau) \quad (12)$$

By Fourier transforming this expression for $h(t)$, we find that the averager's transfer function is

$$|H(j\omega)| = \left|\frac{\sin(n\omega\tau/2)}{\sin(\omega\tau/2)}\right| \quad (13)$$

Notice (from L'Hopital's rule) that $H(j\omega) = n$ whenever ωt is an integral multiple of 2π. Figures (7) to (10) show the *comb filter* response of (13) for several values of n. Each band-pass response is centered at a harmonic (n/τ) of the sweep/trigger rate. (If the trigger rate is aperiodic, then this comb filter concept becomes meaningless.) Since the peak transmission of each band-pass response is n, the -3 dB points must occur at $n/\sqrt{2}$, so that

$$|H(j\omega)| = \left|\frac{\sin(n\omega\tau/2)}{\sin(\omega\tau/2)}\right| = \frac{n}{\sqrt{2}} \quad (14)$$

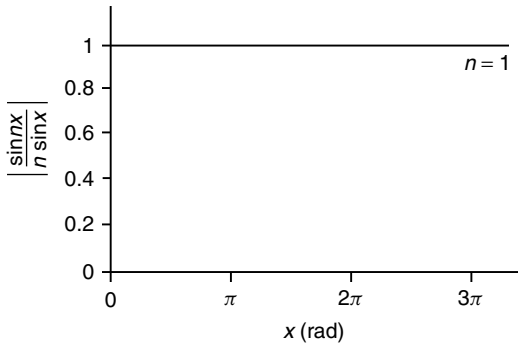

Figure 7. Comb filter response of multipoint signal averager, $n = 1$.

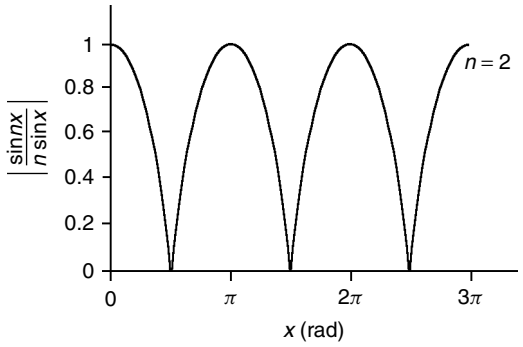

Figure 8. Comb filter response of multipoint signal averager, $n = 2$.

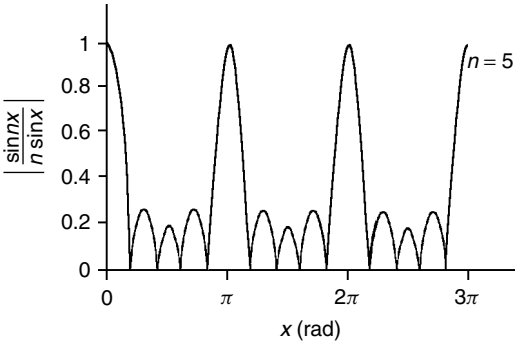

Figure 9. Comb filter response of multipoint signal averager, $n = 5$.

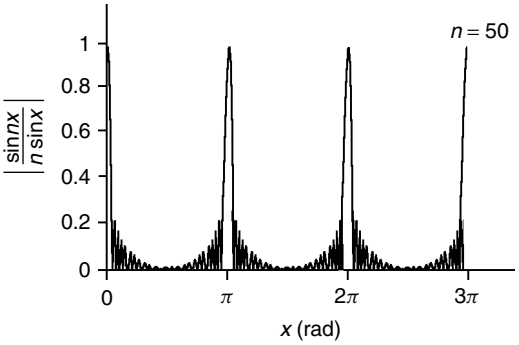

Figure 10. Comb filter response of multipoint signal averager, $n = 50$.

from which the −3-dB bandwidth B for large values of n, is found to be

$$B = \frac{0.886}{n\tau} \tag{15}$$

Large values of n are practicable, particularly at high sweep rates. With a trigger rate $1/\tau$ of 2 kHz and $n = 10^6$, for example, the total measurement time will be $n\tau = 10^6 \times 1/(2 \times 10^3) = 500\,\text{s} \simeq 8.3$ min, and $B = 1.772 \times 10^{-3}$ Hz.

Thus far in this discussion of signal averagers, a *linear summation* mode of averaging has been assumed that is, for the ith memory location, the average after n sweeps is given by

$$A_m = \sum_{k=1}^{n} f(t_k + it_g) = \sum_{k=1}^{n} I_k \tag{16}$$

where $I_k = f(t_k + it_g)$ is the value of the ith sample in the kth sweep.

This algorithm has the advantage of being simple to implement digitally. The output averaged signal, however, continually increases with each new sweep, so that rescaling is required to keep the displayed output at a useful size. A seemingly more convenient algorithm would be to normalize the data in memory after each sweep, that is, implement

$$A_k = \frac{1}{k}\sum_{k=1}^{n} I_k = A_{k-1} + \frac{I_k - A_{k-1}}{k} \tag{17}$$

During each sweep, the data (A_{k-1}) in each memory location are compared with the new sample value I_k and the computed value of $(I_k - A_{k-1})/k$ is added to memory to form the new average value A_k. Because of practical difficulties in implementing a division by k during or after each sweep, the algorithm shown in (17) is often approximated by

$$A_k = A_{k-1} + \frac{I_k - A_{k-1}}{2^J} \tag{18}$$

where J is a positive integer selected automatically such that 2^J is the closest approximation to k. Notice for $k = 6$ for example, that the closest 2^J values are $2^2 = 4$ or $2^3 = 8$. Though this *normalized averaging* mode is very slightly slower than the summation mode in enhancing the signal, we can assume that SNIR $= \sqrt{m}$ for all practical purposes. Note that the discrepancy between k and 2^J increases as larger values of J are used to deal with very noisy signals. In compensation, this averaging mode provides a stable, constant-amplitude display from which the noise appears to shrink with time.

If slowly varying noisy signals are to be recovered and monitored, the algorithm of (18) can also be used for *exponential* averaging if J is made a manually selectable constant. When $J = 0$, then $2^J = 1$ and $A_k = I_k$; with this setting, the input signal may be monitored in real time, since it is digitized and stored without averaging. In general, selecting a value of J will establish an effective time constant, τ_J, where

$$\tau_J = \frac{t_g}{-1n(1 - 2^{-J})} \tag{19}$$

or

$$2^{-J} = 1 - \exp\left(\frac{-t_g}{\tau_J}\right) \tag{20}$$

The larger the value of J selected, the greater the signal enhancement, and the more slowly the averager responds to changes in the input signal. For a large number of sweeps, the SNIR (signal-to-noise improvement ratio) is given by

$$\text{SNIR} \simeq \sqrt{2^{J+1}} \tag{21}$$

7 BLOCK DIAGRAM OF SIGNAL AVERAGER

Figure 11 shows the simplified block diagram of a commercial signal averager. The signal passes to an 8-bit flash ADC (analog digital converter) via a summing amplifier, the purpose of which is described later. The digitized samples are then summed into the averager memory, for which the sampling clock and control block provides suitable timing signals.

At the end of the preset number n of sweeps to averager, the sum data in the averager memory is transferred across to the output memory, allowing the averager memory to be cleared and the cycle to repeat. This allows the data to be transferred to the PC while the next set of sweeps is being acquired, thereby reducing the deadtime after each set of sweeps.

The maximum number of sweeps ($n_{\max}$) that can be digitized by an averager without data overflow, if the input signal is full scale and noise free, is given by 2^{h-c} where h is the memory size (bits) and c (bits) is the resolution of the A/D converter (ADC). For an 8-bit ADC and a memory of N words, each of 24 bits, then

$$n_{\max} = 2^{h-c} = \frac{2^{24}}{2^8} = 2^{16} = 32\,768 \tag{22}$$

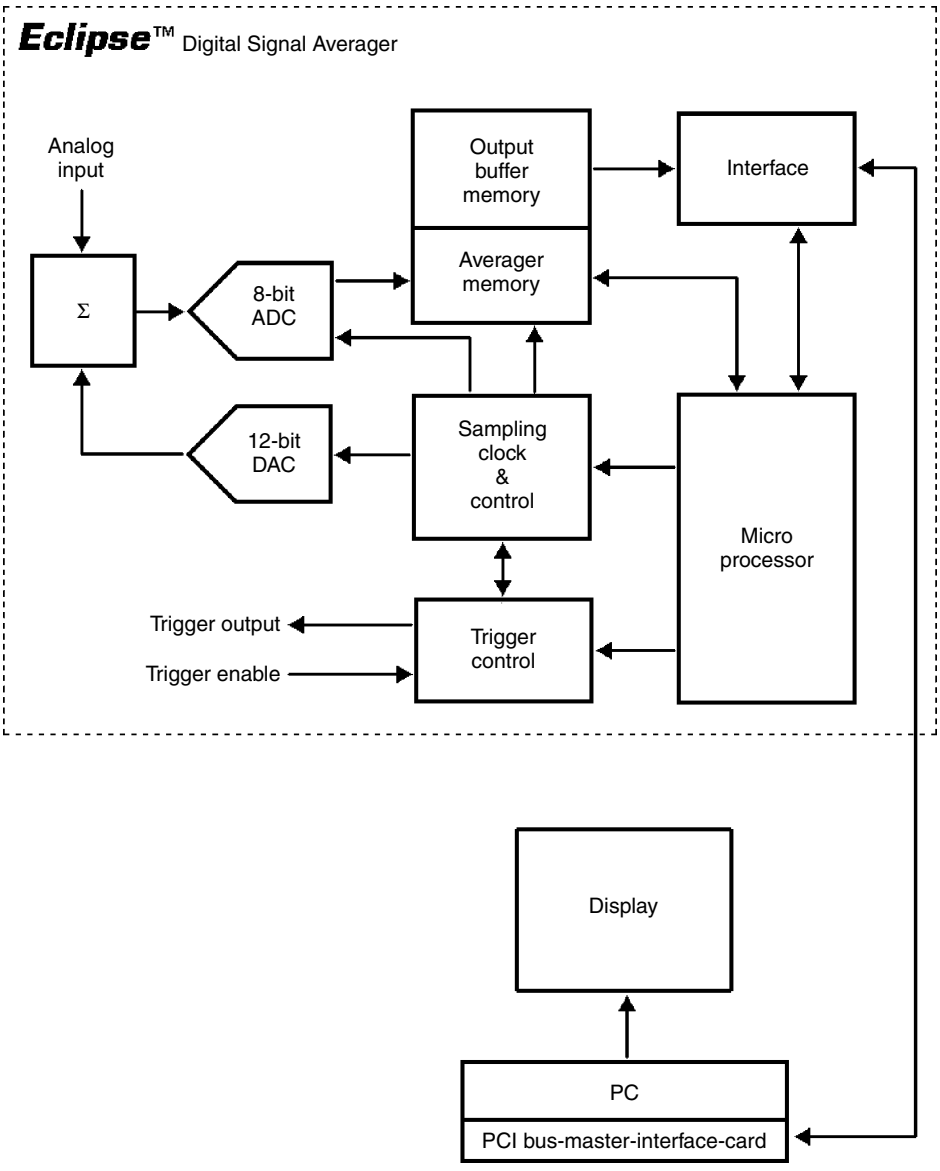

Figure 11. Typical multipoint signal averager. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

Suppose that the input SNR to an averager is 1:10; that is, the RMS noise (σ) is 10 times larger than the peak signal (S). The AC gain before the ADC, must be set such that the noise peaks do not exceed full scale. For Gaussian noise, it is 99.9% probable that the peak noise (N_p) amplitude is less than five times greater than the rms noise amplitude; that is, $N_p/\sigma \leq 5$, so that $N_p/s \leq 50$.

Assume that the input gain is set such that N_p is just equal (say) to the full-scale input level of an 8-bit ADC. Assume also that the resolution of the ADC is $2^8(=256)$, and the memory size $h = 2^{24}$, as before. Of these 8 bits, 6 bits ($=2^6 = 64$) will be required as dynamic reserve (i.e. to handle the input noise), and only 2 bits ($=2^2 = 4$) will be left to quantize the signal (S). In this example, then, the maximum number of sweeps before overflow would be

$$n_{\max} = \frac{2^{24}}{2^2} = 2^{22} \simeq 4.2 \times 10^6 \qquad (23)$$

Under the conditions of this example, the output (vertical) resolution will not be limited to 2 bits. Random noise accompanying the signal will *dither* the ADC; that is, the noise will modulate the quantization levels of the ADC so as to provide a resolution that increases as n increases. Note, however, that without noise and with the same full-scale setting, the averager output would indeed have a 2-bit amplitude resolution. In order to overcome this, the system shown in Figure 11 employs a Precision Enhancer, which is a separate 12-bit DAC, (digital analog converter) the output of which is added to the signal being digitized. The full-scale range of this signal is set to correspond to changes in only the bottom few bits of the main 8-bit ADC.

The 12-bit DAC is driven by a pseudorandom binary signal so that the analog output is effectively a noise source that dithers the true signal over a range of main ADC thresholds. Since the average of this extra noise is zero, it does not affect the averaged output, but it does improve the effective resolution of the main ADC.

It is useful to compare boxcar and signal averagers. Boxcar averagers can recover very fast waveforms and resolve features down to sub nanosecond level. However, they are time inefficient if used for waveform recovery and in such applications have been superseded by signal averagers and storage oscilloscopes. They do, however, remain cost-effective for static gate work.

1 TYPES OF CORRELATION

For the purpose of this article, correlation analysis is a method of detecting any similarity between two time-varying signals.

Autocorrelation consists of the point-by-point multiplication of a waveform by a delayed or time-shifted version of itself, this process being followed by an integration or summation process. Mathematically, the autocorrelation function $R_{xx}(\tau)$ of a time-varying function $f(t)$ is given by

$$R_{xx}(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} f(t) f(t+\tau)\, \mathrm{d}t \qquad (1)$$

where τ is the lag value or time shift between the two versions of $f(t)$.

Cross-correlation involves two waveforms and consists of the multiplication of one waveform $f(t)$ by a time-shifted version of a second waveform $g(t)$, followed by integration or summation. The cross-correlation function $R_{xy}(\tau)$ is given by

$$R_{xy}(\tau) = \lim_{x\to\infty} \frac{1}{2T} \int_{-T}^{T} f(t) g(t+\tau)\, \mathrm{d}t \qquad (2)$$

Note that cross-correlation requires two input signals, as is also true in the case of signal averaging (where a synchronizing input is required in addition to the signal input). Also, as with an averager, a cross-correlator preserves signal phase information. Unlike the averager, however, the cross-correlator output waveform, the correlogram, is affected by the waveform of the second input signal – an undesirable and unnecessary complication for signal-recovery applications since a multipoint averager may be used.

Cross-correlators are normally used in flow or velocity measurements where the time lag is detected to indicate flow rate; they are rarely used for simple signal-recovery purposes. (All that said, this is ignoring the lock-in amplifier and boxcar integrator, both of which can be regarded as a special type of cross-correlator.)

2 LOSS OF PHASE INFORMATION IN CORRELATORS

Phase information is lost in an autocorrelation function, as is also true for its Fourier transform, power spectral density. This lack of phase information means that in some cases, the input signal responsible for a given correlogram must be deduced by intelligent guesswork. For example, as shown in Figure 1, the autocorrelation function for band-limited white Gaussian noise is a spikelike peak at $\tau = 0$, with a width that would decrease as the noise bandwidth increases. A similar correlogram could have resulted from an input consisting of a single narrow pulse; the narrower the pulse width, the narrower the correlogram spike. Thus, the pulse and the band-limited white noise have similar power-density spectra. (The difference between them is

that frequency components of the noise have random phase relationships.)

3 SIMPLIFIED AUTOCORRELATORS

A simplified block diagram of an autocorrelator is shown in Figure 2. The ADC digitizes the input signal once every lag interval or dwell time, t_g, with each such A/D conversion requiring a conversion time, t_c, where $t_c \ll t_g$. The output digital word from the ADC, corresponding to the latest sample, provides one input to the digital multiplier and is also shifted, as word 0, into an n-word shift register. During this shift operation, the last word in the register, word $(n-1)$, is shifted out and discarded and the former word $(n-2)$ becomes the new word $(n-1)$. The control and timing circuits then cause the shift register to step n times, recirculating its contents one full cycle, and requiring a time interval t_r. During t_r, each shift-register word (i.e. $(n-1)$, $(n-2)$, $(n-3)$,. . ., 3, 2, 1, 0) is applied sequentially to the other input of the multiplier, which multiplies each of these words by the word at its other input, word 0. Each multiplier output is added to the contents of the corresponding bin of the N-bin main memory; for instance, word 0 $\times$ word $(n-16)$ bin$(n-16)$, word 0 $\times$ word 0 bin 0. After many such cycles, the contents of bin i (for example) of the main memory, will be the sum of products formed by multiplying each new signal sample by an it_g delayed version of itself. Bin 0, for example, corresponds to the signal multiplied by itself with zero delay.

The minimum time between successive samples is $(t_c + t_r)$. When $t_g \geq (t_c + t_r)$, the correlator is said to be working in a real-time mode. When $t_g \leq (t_c + t_r)$, samples can no longer be taken every t_g seconds and the correlator is said to be in a pseudo-real-time mode. For $t_g \ll (t_c + t_r)$, the correlator is in a batch mode.

4 PROCESS OF AUTOCORRELATION

The process of autocorrelation involves the concept of sliding a waveform past a replica of itself. For random noise, the two waveforms will match at only one point as they slide by each other, that is, at $\tau = 0$, when they are perfectly aligned. In contrast, a square wave sliding by another square wave will find a perfect match once in every period and will give rise to a triangular correlogram. More generally, signals that are periodic in time will produce a correlation function that is periodic in τ. Suppose, for example, that the input to an autocorrelator is $f(t) = A\cos(\omega t)$. Then,

$$R_{xx}(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} A\cos(\omega t) A\cos(\omega t + \tau)\,\mathrm{d}t$$
$$= \frac{1}{2}A^2\cos(\omega\tau) \tag{3}$$

5 CORRELATOR FUNCTION FOR SINE WAVE WITH NOISE

Figure 3 shows the correlation function of a sine wave accompanied by band-limited white noise. Note that the

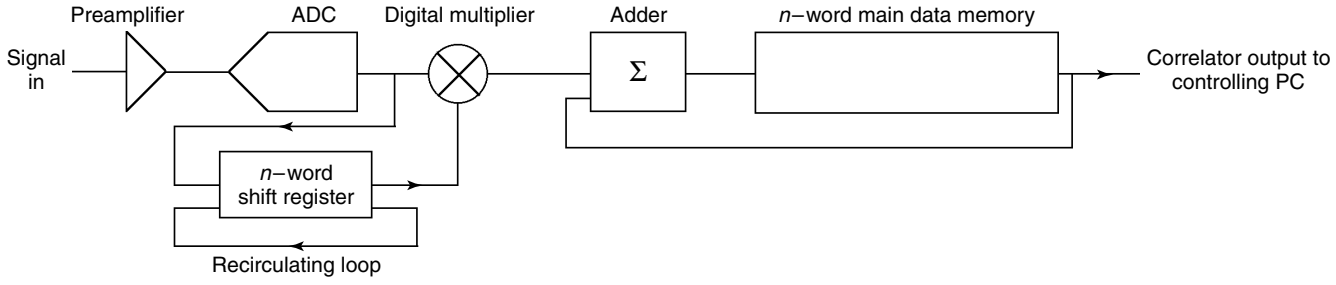

Figure 2. The autocorrelator (simplified). (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

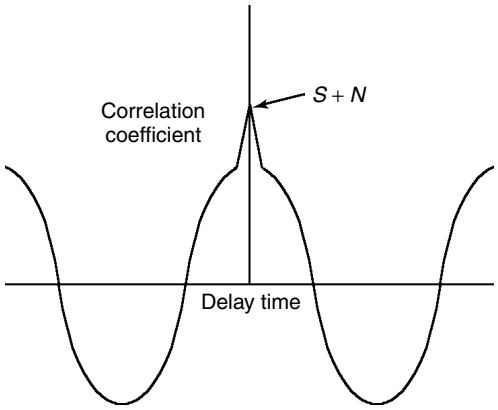

Figure 3. Correlogram of a noise sine wave. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

peak value at $\tau = 0$ in this correlogram is the mean-squared value of the signal plus noise (i.e. $S + N$). The mean-squared value of the sinusoidal signal component is given by the peak value of the sine wave at approximate values where the white noise spike has damped to zero. The SNR of the correlator output can, therefore, be determined since

$$\frac{S}{(S+N)-S} = \frac{S}{N} = SNR \tag{4}$$

Most importantly, notice that the signal and noise components have been separated by virtue of their different positions on the τ-axis. It is this separating ability that makes correlation a powerful signal-recovery technique.

1 THE PHOTOMULTIPLIER TUBE, PMT

Photomultiplier tubes (PMTs) are used to measure the intensity or flux of a beam of visible photons (see Figure 1). With its photocathode removed, the PMT becomes an electron multiplier tube (EMT) that is widely used to detect ions and electrons.

One of the most important advantages of such detectors is that their high gain and low noise allow them to give one output pulse for each detected input particle. Since visible-light measurements are perhaps most commonplace, we consider here as an example a PMT and pulse-counting system of the type shown in Figure 2.

2 QUANTUM EFFICIENCY OF PMT

The probability of each incident photon causing an output pulse from the PMT is essentially equal to the quantum efficiency; ζ: typically, ζ is between 5 to 25%. In addition to the photon-derived pulses (i.e. the signal pulses), there will be spurious noise pulses at the PMT output due to thermionic emission.

Noise pulses caused by thermionic emission from the dynodes will experience less gain and will be smaller in amplitude than pulses due to cathode emission. The PMT output pulses are amplified and presented to a pulse-height discriminator circuit, where the peak amplitude of each pulse is compared to an adjustable threshold or reference voltage.

Ideally, the discriminator will reject all dynode-derived noise pulses and accept all cathode-derived pulses; in practice, the PMT gain is statistical in nature and cathode and dynode-derived pulses have overlapping amplitude distributions. The discriminator will therefore accept most cathode-derived pulses and reject most dynode noise pulses. Each accepted input pulse will cause a standardized output pulse. Such pulse-height discrimination also reduces the effect of PMT gain variations with time and temperature.

3 RATEMETERS

Ratemeters are used to give a continuous analog output voltage that is proportional to the rate of digital pulses being generated by the discriminator. Today, digital counter circuits are more commonly used to accumulate output counts for a preselected measurement time. Such counters allow very long integration times and give a direct digital output suitable for computer logging purposes.

4 SIGNAL-TO-NOISE RATIO (SNR) OF PMT

Suppose the PMT is set up to detect photons emitted from a thermal light source such as a tungsten filament lamp. The

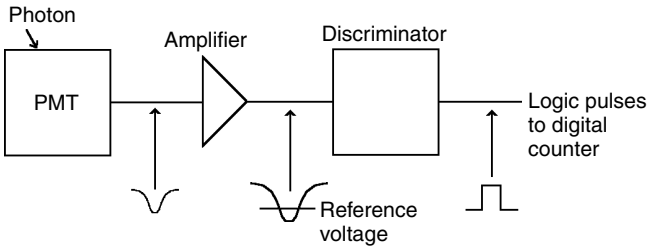

Figure 2. Typical photon counting system. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

time interval between successive photons impinging upon the PMT photocathode is random and governed by a Poisson distribution (see Figure 3, Curve A). The probability P of detecting n photons in time t following the last photon is given by

$$P(n,t) = \frac{(\zeta Rt)^n \mathrm{e}^{-\zeta Rt}}{n!} = \frac{N^n \mathrm{e}^{-N}}{n!} \tag{1}$$

where R is the mean photon rate (photons per second) and $N = \zeta Rt$ is the signal (i.e. the mean number of photon electrons emitted by the PMT photocathode during the time interval t). The noise, or uncertainty, in N is given by the standard deviation σ, where

$$\sigma = \sqrt{(\zeta Rt)} = \sqrt{N} \tag{2}$$

so that

$$\mathrm{SNR} = \frac{N}{\sqrt{N}} = \sqrt{N} = \sqrt{(\zeta Rt)} \tag{3}$$

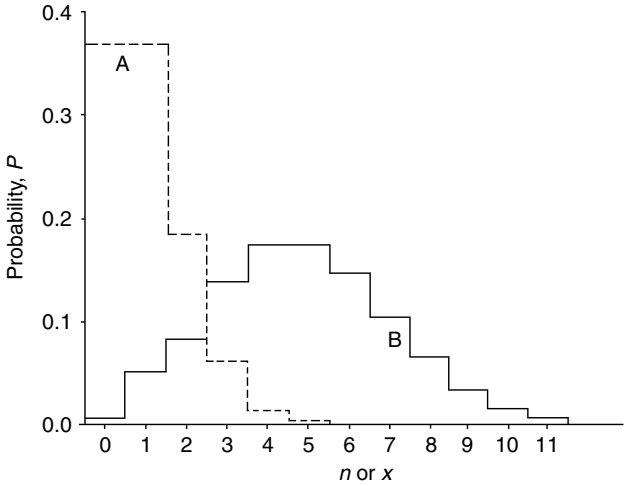

Figure 3. The Poisson distribution. Curve A: Probability of detecting n photons in time $t = (Rt)^n \exp(-Rt/n)$, $R = 10^8$ photons per second, $t = 10\,\mathrm{ns}$ and so $Rt = 1$, $\sigma = \sqrt{Rt}$. Curve B: Probability of gain magnitude $P(x) = M^x \mathrm{e}^{-M}/(x!)$ where $x =$ dynode gain, $M =$ mean dynode gain $= 5$, and $\sigma = \sqrt{M}$. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

5 THERMIONIC EMISSION AND DYNAMIC RESPONSE

Note that, as in all of the techniques examined in this section (with white noise), the SNR is again proportional to the square root of the measurement time (t). If we assume that there is no thermionic (dark) emission of electrons from the photocathode, then the photocathode (signal) current (in amperes) is given by

$$I_{\mathrm{pe}} = \zeta Re \tag{4}$$

where e is the charge of an electron ($\approx 1.6 \times 10^{-19}\,\mathrm{C}$).

The signal-to-noise ratio ($\mathrm{SNR_k}$) of the photocathode current (I_{pe}) is given by

$$\mathrm{SNR_k} = \sqrt{(\zeta Rt)} = \sqrt{\left(\frac{\zeta Rte}{e}\right)} = \sqrt{\left(\frac{I_{\mathrm{pe}}t}{e}\right)} \tag{5}$$

Now the measurement time t has associated with it a frequency range Δf, where

$$t = \frac{1}{2\Delta f},$$

so that

$$\mathrm{SNR_k} = \sqrt{\left(\frac{I_{\mathrm{pe}}}{2e\Delta f}\right)} = \sqrt{\left(\frac{I_{\mathrm{pe}}^2}{2eI_{\mathrm{pe}}\Delta f}\right)} = \frac{I_{\mathrm{pe}}}{\sqrt{(2eI_{\mathrm{pe}}\Delta f)}} \tag{6}$$

If we multiply both the numerator and denominator of (6) by the mean PMT gain A, then

$$\mathrm{SNR_k} = \frac{A I_{\mathrm{pe}}}{A\sqrt{(2eI_{\mathrm{pe}}\Delta f)}} = \frac{I_{\mathrm{a}}}{\sqrt{(2AeI_{\mathrm{a}}\Delta f)}} = \mathrm{SNR_a} \quad (7)$$

where I_{a} is the DC anode current and $\mathrm{SNR_a}$ is the signal-to-noise ratio of the anode current, if thermionic emission and other dynode noise contributions are ignored.

Note that the general expression for the shot noise of a DC current I is given by

$$\text{rms shot noise current} = \sqrt{(2AeI\Delta f)} \quad (8)$$

where A is the gain following the shot noise process. When $A = 1$, the expression simplifies to $\sqrt{(2eI\Delta f)}$. Notice also that shot noise is present in the light beam itself and that the PMT quantum efficiency (ζ) degrades the SNR by a factor of $\sqrt{\zeta}$.

6 DARK CURRENT IN PMT

In practice, with no input photons, the photocathode will emit electrons due to temperature effects. The dynodes will also emit thermionic electrons. The rate of such thermionic emission is reduced by cooling the PMT. Thermionic emission from the photocathode, that is, dark counts, can be further reduced by minimizing the cathode area and by selecting a photocathode material with no more red (long wavelength) spectral response than is necessary.

If the photocathode emits electrons randomly at a dark count rate R_{d}, then the noise components of the cathode current will increase to $\sqrt{(\zeta Rt + R_{\mathrm{d}}t)}$ and the signal-to-noise ratio of the cathode current will degrade to

$$\mathrm{SNR} = \frac{\zeta Rt}{\sqrt{(\zeta Rt + R_{\mathrm{d}}t)}} = \frac{\zeta R\sqrt{t}}{\sqrt{(\zeta R + R_{\mathrm{d}})}} \quad (9)$$

7 PRACTICAL ASSUMPTIONS IN PMT USE

The above expression, (9), will also be the PMT output's SNR if the dynode noise is assumed to be removed completely by pulse-height discrimination. For PMTs equipped with a high-gain first dynode with Poissonian statistics (see Figure 3, Curve B), this is not an unreasonable approximation.

Note that when a PMT is used in a noncounting or DC mode, as is discussed in **Article 180, Bandwidth Reduction of Baseband DC Signals, Volume 3**, all of the output electrons resulting from spurious cathode emission (i.e. dark counts) and dynode emission are integrated by the anode or preamplifier time constant into a DC dark current; the opportunity to remove dynode noise by pulse-height discrimination is lost.

Further Reading 1226

1 AMPLIFICATION IN THE PMT

Each electron emitted by a PMT photocathode will be amplified by the instantaneous value of the PMT gain. For a mean gain of 10^6, for example, each cathode electron will cause an average output charge q of $10^6 e$ C. This charge q will accumulate at the anode during a time t, given by the transit-time spread of the PMT. Typically, t will be about 10 ns so that the resulting anode current pulse ($i_a = dq/dt$) will have a full width (t_w) between half-maximum amplitude points (FWHM) of about 10 ns also. The peak value, I_{pk}, of the anode current pulse may be approximated by assuming the pulse to be rectangular so that in this example,

$$I_{pk} \approx \frac{q}{t_w} = \frac{10^6 e}{10 \times 10^{-9}} = \frac{10^6 \times 1.6 \times 10^{-19}}{10 \times 10^{-9}} = 16\,\mu\text{A} \quad (1)$$

In a photon-counting system, the anode-load resistor (R_a) of the PMT is kept small, usually 50 to 100 Ω. Therefore, the time constant (τ_a) formed by the anode stray capacitance (C_a) will be small compared to t_w and thus will not stretch the anode voltage pulse. Typically, $R_a = 50\,\Omega$ and $C_a = 20$ pF so that $\tau_a = 1\text{ ns} \ll t_w$. The anode voltage pulse will then have the same shape as the anode current pulse and a peak value of

$$E_{pk} = I_{pk} R_a = 16 \times 10^{-6} \times 50 = 0.8\,\text{mV} \quad (2)$$

It should be remembered that such pulse amplitudes depend upon the PMT gain, which in turn depends upon the dynode gains – which are statistical. In the above example, $E_{pk} = 0.8$ mV is the average pulse height to be expected. Actual pulse heights will be distributed above and below this value, and the better the PMT, the narrower this distribution will be. A suitable preamplifier is normally used to amplify the anode pulses to a suitable level for the pulse height discriminator.

2 ADJUSTMENT OF DISCRIMINATION IN THE PMT

Notice that the PMT gain, the preamplifier gain, and the discriminator threshold controls may all be used to adjust the effective discrimination level. Figure 1 shows a typical count-rate variation with PMT high voltage (i.e. PMT gain) at a fixed discriminator threshold level. This is one of the family of curves that could be plotted for different threshold levels; similar curves could be obtained by varying the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

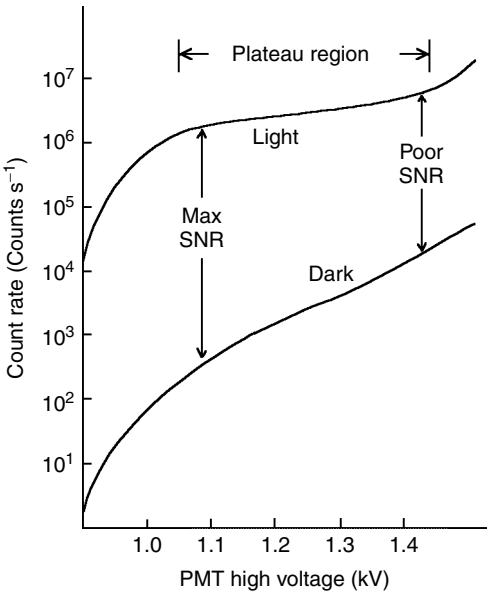

Figure 1. The PMT counting plateau. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

preamplifier gain rather than that of the PMT or by plotting count rate against discriminator threshold.

The upper curve in Figure 1 is plotted by allowing light to fall upon the PMT photocathode and by slowly varying the PMT voltage (which is nonlinearly related to the PMT gain). Notice that the steep slope at low PMT voltages begins to flatten and form a not-quite-horizontal plateau as proper focusing takes place in the PMT. The increasing slope at very high PMT bias voltages is due to increasing instability in the PMT.

The upper curve corresponds to $S + N$, since it is based on both signal and noise pulses. The lower curve was plotted with the PMT in darkness and therefore represents noise (N) pulses only. Note that, typically, the dark-count curve has no plateau; it has been suggested that the lack of a plateau is due to corona effects associated with microscopic protrusions from the dynode surfaces.

Since the count rate is plotted on a logarithmic scale, the vertical distance between the two curves corresponds to

$$\log(S+N) - \log(N) = \log\left(\frac{S+N}{N}\right) = \log\left(1\frac{S}{N}\right) \approx \log\left(\frac{S}{N}\right) \text{ for } \frac{S}{N} \gg 1 \qquad (3)$$

3 SETTING THE PMT HIGH VOLTAGE

A commonly used method for setting the PMT high voltage for a given preamplifier gain and discriminator threshold level is, therefore, to select a point at the beginning of the counting plateau, corresponding to maximum SNR.

4 RATEMETERS AND DIGITAL COUNTERS

Historically, the pulse rate generated by a PMT amplifier-discriminator was measured using an analog ratemeter. Essentially, this consists of a current pulse generator that produces a precise current pulse for each applied trigger as generated by the discriminator. These pulses are integrated using a low pass filter, whose output voltage is therefore proportional to the average value of the discriminator output count rate (R_{sig}). The voltage is displayed on an analog panel meter that is calibrated in counts per unit of time.

Nowadays, digital counters are almost always used as recording device in photon-counting experiments. These simply count the number of applied pulses and can give an output in terms of number of counts or counts per second. Dual counters allow more sophisticated work, such as ratio mode (also known as *source compensation mode*), where the signal count rate is proportional to both the measurand and (say) the intensity of a light source. By monitoring the light source with a separate PMT and amplifier-discriminator to produce a source-dependent count rate R_{sc}, R_{sig} can be normalized by R_{sc} to provide an output count that is independent of source fluctuations.

In the reciprocal mode, the counter measures the time (t, in μs) required for the cumulative signal counts to reach N; the smaller the signal count rate, the longer the elapsed time. If the dark count rate is negligible, then the measurement accuracy is $1/\text{SNR} = 1/\sqrt{(R_{sig}t)}$, and for a constant value of $R_{sig}t\ (= N)$, all measurements will have the same SNR and accuracy.

5 SYNCHRONOUS DETECTION

A synchronous photon-counting system that provides automatic background subtraction is shown in Figure 2. When the chopper blade blocks the input light, the output pulses from the amplifier-discriminator are, by definition, background noises; these pulses (N) are gated into counter B by the timing circuit – which is itself synchronized by the chopper reference signal. When the chopper blade allows light to reach the PMT, the discriminator output consists of signal-plus-background pulses ($S + N$), and these pulses are gated into counter A.

After each measurement interval, an arithmetic circuit provides two outputs:

$$A - B = (S+N) - N = S = \text{signal} \qquad (4)$$

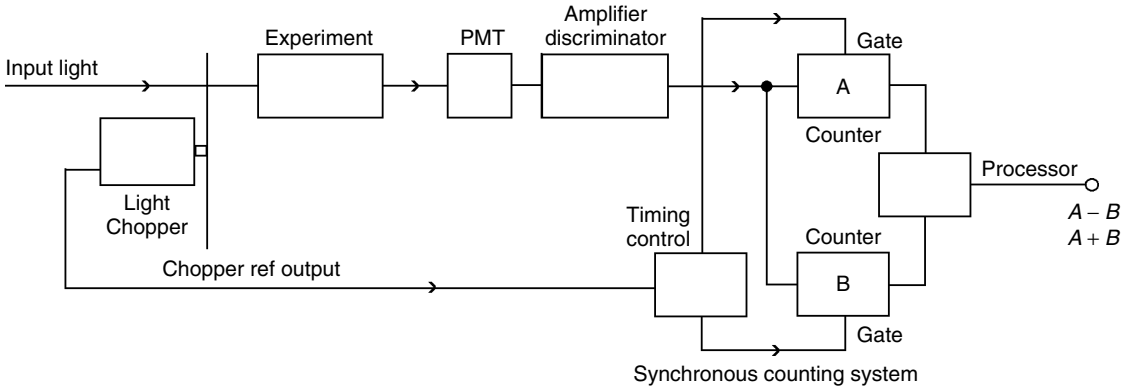

Figure 2. Photon counter with background subtraction. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

and

$$A + B = (S + N) + N = \text{total counts} \tag{5}$$

where A and B are the numbers of counts in counters A and B respectively. For Poissonian noise,

$$\text{SNR} = \frac{\text{signal}}{\sqrt{\text{total counts}}} = \frac{A - B}{\sqrt{A + B}} \tag{6}$$

Suppose, for example, that $A = 10^6$ counts and $B = 9.99 \times 10^5$ counts, then $S = A - B = 10^3$ counts and $\sqrt{(A + B)} = 1.41 \times 10^3$, so that

$$\text{SNR} = \frac{A - B}{\sqrt{A + B}} = \frac{10^3}{1.41 \times 10^3} = 0.71$$

and (in)accuracy

$$\frac{1}{\text{SNR}} = \frac{1}{0.71} = 141\%$$

or, expressed in words, the measurement is worthless! The $A + B$ output is important since it allows the measurement accuracy to be estimated in this way.

6 PULSE PILEUP

The dynamic range of photon-counting measurements is limited at low light levels by PMT dark count and at high light levels by pulse pileup in the PMT or electronics. As the mean rate (R) of photons arriving at a PMT photocathode increases, so does the probability of two or more photons arriving with too short an interval between them to be resolved by the PMT.

The time resolution of a PMT is effectively equal to its output pulse width t_w, and each output pulse from a PMT, therefore, occurs whenever an electron is emitted after a time greater than t_w following the previous electron. The probability of this happening is the same as that for zero photoelectron events in a time t_w (dark counts at high light levels can be neglected). As shown in Figure 3 of **Article 184, Photon Counting, Volume 3** and from (1) in that article,

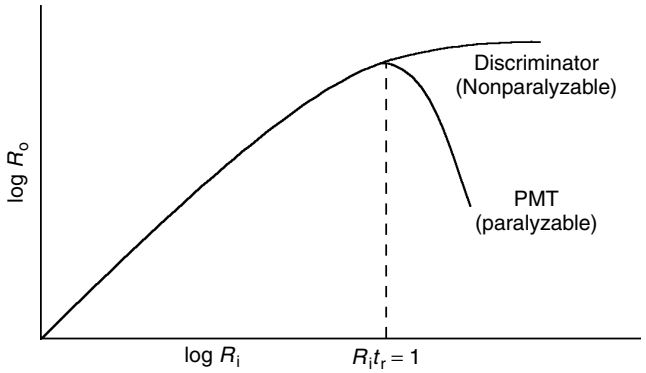

Figure 3. Counting error due to pulse pileup. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK Advanced Measurement Technology.)

$$P(0, t_w) = \exp(-\zeta R t_w) \tag{7}$$

and the output count rate, R_o, is given by

$$R_o = P(0, t_w) R_i = \zeta R \exp(-\zeta R t_w) = R_i \exp(-R_i t_w) \tag{8}$$

The resulting PMT pulse pileup error is given by

$$\varepsilon_{pmt} = \frac{R_i - R_o}{R_i} = \frac{R_i - R_i \exp(-R_i t_w)}{R_i} = 1 - \exp(-\zeta R t_w) \tag{9}$$

7 PARALYZABLE DETECTORS

The PMT is a paralyzable detector; that is, when the input count rate exceeds a certain value ($R_i = 1/t_w$), the output count rate will begin to decrease for an increasing input count rate and will become zero when the PMT is completely paralyzed (saturated) (See Figure 3).

Discriminators and counters, on the other hand, are usually nonparalyzable. Suppose a discriminator, for example, has a pulse-pair resolution or dead time t_d. That is, each time it accepts an input pulse, it cannot accept a new pulse until after a time t_d. Then, for a measurement time t, an input pulse rate of R_i, and an output rate R_o; the total number of output pulses, N_o, is given by

$$N_o = R_o t \tag{10}$$

and the

$$\text{total dead time} = N_o t_d = R_o t t_d \text{s} \tag{11}$$

so that

$$\text{total live time} = t - R_o t t_d \tag{12}$$

The total number of input pulses accepted is therefore given by

$$N_o = R_o t = R_i(t - R_o t t_d) \tag{13}$$

so that

$$R_o = \frac{R_i}{1 + R_i t_d} \tag{14}$$

8 DEAD TIME IN PMTs

A fast discriminator and counter have a dead time, t_d, of about 10 ns – similar to the time resolution, t_w, of a reasonably fast PMT. Note, however, that any PMT pileup will act as a prefilter to the discriminator; that is, such pileup will decrease the input count rate to the discriminator. PMT pileup usually provides the upper limit to the system dynamic range. Photon-counting systems cannot be used in pulsed light measurements where the peak photon rate (during the light pulse) will cause unacceptably high pulse pileup errors.

1 SIGNAL RECOVERY FAMILY

Many of the signal recovery considerations discussed in this section in **Part 12, Elements: F – Signals and Noise, Volume 3**, such as instrument selection, are summarized in Figure 1.

Note that this figure includes several instruments not mentioned in the preceding articles of this section, including the multichannel scaler (MCS) and multichannel analyzer (MCA).

The choice of signal recovery instrument is often limited to that which is available so that, for example, a combination of an MCS and voltage-to-frequency converter (VFC) can be used in place of a digital signal averager. Similarly, a boxcar averager in swept gate (waveform recovery) mode can be a substitute for a high performance digital signal averager.

2 MULTICHANNEL SCALERS AND MULTICHANNEL AVERAGERS

An MCS consists of a digital counter, whose output is recorded by a bank of digital memory, in much the same way that the output of the analog-to-digital converter (ADC) is processed in a digital signal averager.

During each sweep, the counter records the number of input pulses during each dwell time and adds that number to the cumulative count in the corresponding memory address. By using a VFC in front of an MCS, analog signals can be time-averaged, and the VFC/MCS combination is essentially an alternative approach to using a sampled ADC as in a digital signal averager.

An MCA performs pulse-height analysis by using the amplitude of each pulse to determine an address location. The memory at that address is then incremented by one count, and the cycle repeats for many pulses.

In other words, each input pulse with amplitude between 63.85 and 63.95% (say) of full-scale, will add one count to the memory address No. 639. In this way, a pulse-height distribution or spectrum is built up.

Another common use of an MCA is to precede it by a time-to-amplitude converter (TAC), so that each input pulse to be digitized corresponds to a time interval. Low-level measurements of short fluorescent lifetimes, for example, may be made in this manner.

3 USING SEVERAL INSTRUMENTS TOGETHER

In some cases, two or more signal recovery instruments may be used at the same time. For example, the output of a lock-in amplifier can be digitally averaged in order to reduce $1/f$ noise problems. Similarly, a boxcar averager followed by digital signal averager can offer the picosecond or nanosecond time resolution of the boxcar, but without the need to scan so slowly that the system being measured may change during a scan (sweep).

© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

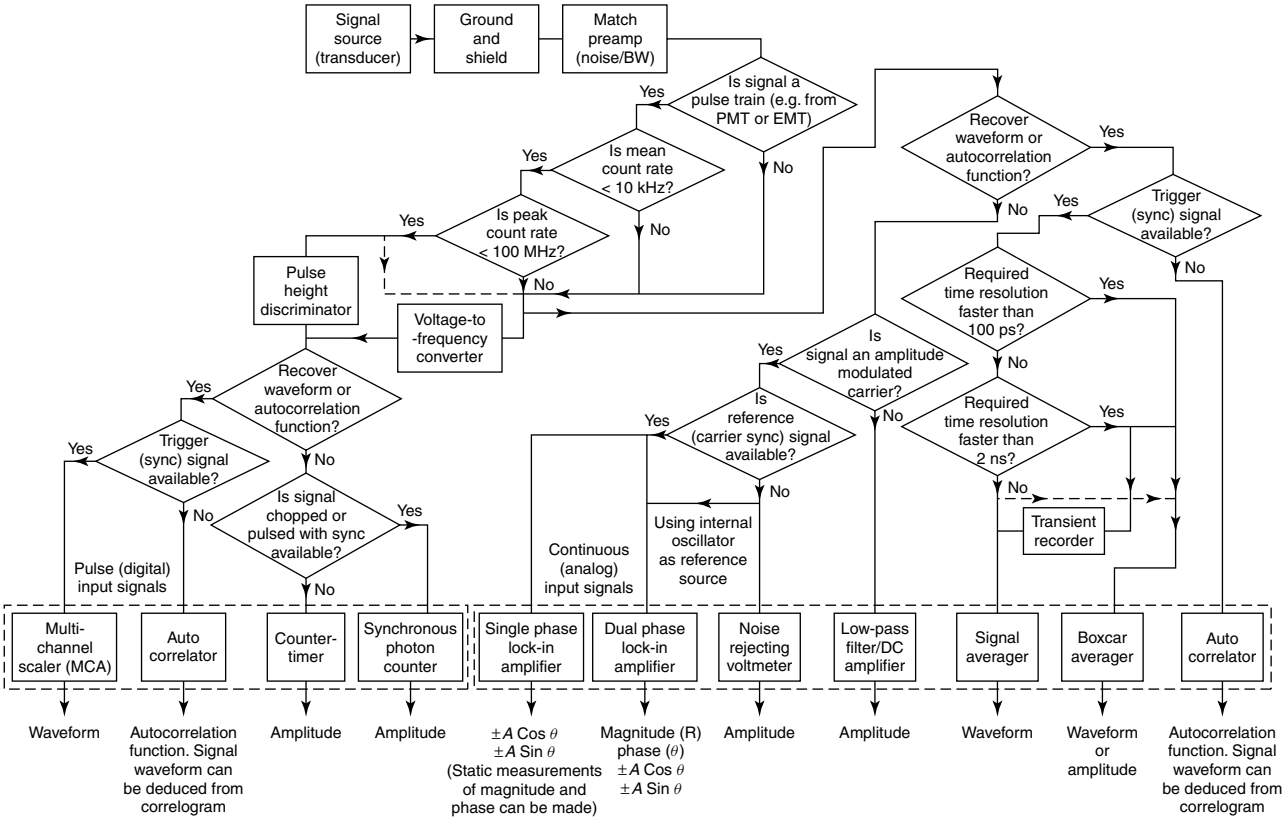

Figure 1. Signal recovery flowchart. (Reproduced by permission of SIGNAL RECOVERY, a part of AMETEK advanced measurement technology.)

Two lock-in amplifiers can be used for tandem demodulation experiments, where the signal being measured consists of an amplitude-modulated carrier of frequency f_1 with a modulation of frequency f_2. The first lock-in amplifier is run at a reference frequency f_1 and, assuming the output time-constant is short enough to allow it to pass, generates an analog output signal that is at f_2. This is then coupled to a second lock-in, running at f_2, which therefore measures the modulation amplitude.

4 TIME TAKEN VERSUS SIGNAL RECOVERY SENSITIVITY

The object in signal recovery is not to maximize the signal-to-noise improvement ratio (SNIR) alone but to minimize the measurement time required to reach a particular output signal-to-noise ratio (SNR). Similarly, in selecting a preamplifier, the real object is to minimize noise, not the noise figure. The noise and/or bandwidth of the signal source or transducer should, therefore, always be first minimized before using other signal recovery techniques to further improve the SNR. As a general rule, increasing the discrimination needed for a given SNR increases the time required to achieve it. Furthermore, care must be taken to ensure that the signal is stable during the extraction time.

1 SURVEY OF FLOWMETERS AND BENEFITS OF THEIR USE

In the United Kingdom alone there are around 15 million flowmeters in use, employing as many as 120 different operating principles. These meters have to operate at temperatures between −260 and +800 °C and at pressures from vacuum to 800 bar. Flowmeter diameters range from less than 1 mm to several meters, and the fluids are as diverse as water, natural gas, hot nitric acid, cryogenic liquids, and complex mixtures of liquids and gases. Flowmeters are essential for buying or selling fluids, for taxation, for process control, for evaluation of the performance of pumps, turbines or fans, and for many other purposes. Some flowmeters need to operate at the lowest possible level of uncertainty (e.g. large gas meters); some only need to be repeatable (e.g. some meters used for process control).

The benefits of using flowmeters are varied: they may be used to obtain fairness in purchase, sale, or taxation, or to give the required quality in a manufacturing process, or to ensure in water distribution systems that reservoirs are appropriately sized and that there are no leaks. Picking the best meter for a particular application is therefore a difficult task and one that the inexperienced plant designer or engineer can find very confusing. This is especially true when the plant designer is not familiar with flow measurement, or when the instrument engineer familiar with the technology is not involved early in the design process.

2 FLOWMETER TYPES

To assist in the selection of a flowmeter, a classification guide was produced within BS 7405 (British Standards Institution 1991). It is of use in helping to clarify what types of meter are available and hence to assist in selection. BS 7405 divides flowmeters into 10 groups, as shown in Table 1. The groups are loosely based on each flowmeter's operating principles rather than on their applications. The basic principles of each of these types of flowmeters is described in **Article 189, Basic Principles of Flow Measurement, Volume 3**.

3 AN OVERVIEW OF DIFFERENT TYPES OF FLOWMETERS

3.1 Conventional differential-pressure flowmeters

The orifice plate is by far the most widely used type of flowmeter; consequently, more is known about its behavior than about the behavior of any other flowmeter. It has good standards, which have recently been revised (International Organization for Standardization 2003a,b). It is affected by flow profile and hence needs a sufficient straight installation length. The upstream straight length can be reduced by

Table 1. Classification of flowmeters.

Group	Meter type	Description
1	Conventional differential pressure	Sharp-edged concentric orifice plates, Venturi tubes, and flow nozzles.
2	Other differential pressure	All other differential-pressure devices, including those that can only loosely be termed differential pressure, including sonic nozzles and variable area meters.
3	Positive displacement	All PD meters, sliding vane, gear, piston types, etc.
4	Rotary turbine	Rotary turbine meters, of which the most common is the axial-bladed turbine meter.
5	Fluid oscillatory	Meters in which the operating principle is based on fluidic oscillations, normally generated by the meter itself, e.g. vortex meters, fluidic meters.
6	Electromagnetic	Meters in which an electromagnetic principle is used directly to sense the flow.
7	Ultrasonic	Meters in which ultrasonic sensors directly measure the flow, e.g. time of flight and Doppler meters. This excludes meters in which ultrasonic methods are used to detect another principle.
8	Direct and indirect mass	Mass flowmeters of both the direct and indirect type are included. This would probably include Coriolis meters used as volume meters.
9	Thermal	Meters using thermal heat loss or gain to measure the flow rate. Thermal types include hot-wire anemometers.
10	Miscellaneous	All those meters that cannot easily be classified into any of the other groups, and so this group contains such types as the laser Doppler anemometer, and tracer, cross-correlation and velocity-area techniques.

use of a flow conditioner. The orifice plate will work for liquids and gases and perform in the range 0.5 to 1%. Its main attraction is that this performance can be achieved by careful manufacture and measurement without calibration in a flowing fluid. Its discharge coefficient is a function of Reynolds number, and, if calibration is required to reduce the uncertainty, it is not necessary to use the same fluid for calibration and for use. If the upstream sharp edge is even marginally rounded, the measurement is significantly affected.

Nozzles and Venturi tubes perform in a similar manner, but when used uncalibrated, they generally give a larger uncertainty. Venturi tubes give much less pressure loss than orifice plates or nozzles. Where possible, single-phase flow differential–pressure devices should use multiple tappings or annular chambers, and not a pair of single pressure tappings.

Further information on this important class of flowmeter can be found in **Article 188, Differential Pressure (DP) Flowmeters, Volume 3**.

3.2 Other differential-pressure methods (including sonic nozzles)

The variable area meter is a cheap and simple meter for both gas and liquid applications at about 2% accuracy. It can be very good for process-control and indication applications.

Many other differential-pressure devices are available such as V-cones and laminar-flow elements. Each has particular advantages. Even instrumenting a valve or pipe restriction may provide the measurement required.

For gas, the sonic or critical-flow nozzle provides a good calibration reference and also a good measurement device for mass flow. It has a very high pressure drop and hence is not used for applications in which pressure loss is important.

3.3 Positive-displacement flowmeters

Positive-displacement (PD) meters provide highly accurate and repeatable measurement of most *clean* fluids. They can be heavy and bulky in larger sizes and hence expensive. They are ideal for batch measurement at high accuracy and are extensively used for fiscal and custody transfer work. PD meters are generally unaffected by changes in flow profile generated by pipe installation. They are often the only meter that is capable of being used with high-viscosity fluids, but they can block the flow if they seize up. A variant is the metering pump that pumps and measures at the same time.

3.4 Turbine flowmeters

Turbine meters are used for many high accuracy applications in both gas and liquid. They have a restricted range with viscosities greater than 30 cSt. They are very repeatable but sensitive to viscosity, flow profile, and pulsations. Wear to the bearings has a significant effect on the meter's performance. Fast response and good repeatability ensure a wide range of applications from fiscal measurement of

hydrocarbon liquids and gases through to process control. For fiscal oil-flow measurement they are often used with a dedicated meter prover.

3.5 Oscillatory flowmeters

Vortex meters are the most common type of oscillatory meter. They provide good process control and are used in both liquid and gas applications. They are affected by flow profile and pulsations in the flow line. Vortex meters can be characterized by Reynolds number: this feature makes the nature of the fluid less important and calibration possible in a different fluid from the one in the application. They have no moving parts. Pulsations at a frequency close to that of the shed vortices lead to large errors.

In very small sizes, fluidic meters find some specialist niche applications. Special designs for domestic gas and water meters have been produced and are in service.

3.6 Electromagnetic flowmeters

Restricted to conductive fluids, electromagnetic meters are used extensively for water-flow measurement. Their very wide rangeability (up to 1000 : 1) and apparent long life without significant drift makes them the first choice for water distribution systems. Electromagnetic flowmeters are relatively unaffected by flow disturbances.

3.7 Ultrasonic flowmeters

In its various forms, the ultrasonic meter is the meter that is being most rapidly improved at present. Currently, multipath meters provide fiscal, custody transfer or allocation measurements in both oil and gas. Single-path clamp-on meters often provide the only solution to nonintrusive measurement but cannot be expected to give better than 2 to 5% uncertainty. Owing to their principle of operation, ultrasonic flowmeters can be affected by acoustic noise generated by valves or pipe fittings.

3.8 Mass flowmeters

Coriolis meters provide direct mass measurement of most liquids. The inclusion of density measurement means that volume also is measured. They also measure gas but perform best when the pressure (density) is high. Achieving better than 0.5% uncertainty, this type of meter is starting to compete with the turbine meter and the positive-displacement meter for liquid applications in both 'easy' and difficult fluids. Long calibration intervals are claimed assuming verification of zero drift can be achieved in situ. No evidence has been shown that Coriolis meters are affected by flow-profile effects. When using Coriolis meters, it is vital to avoid the vibration of the meter by providing firm clamping and to avoid flow pulsations. Valves must be installed to allow zero setting.

3.9 Thermal flowmeters

Thermal meters can be divided into two main types: the thermal meters used to measure low gas flow rates and the insertion hot-wire anemometers usually used for research purposes.

Generally, capillary thermal mass flowmeters are not affected by skewed or swirling flows. In-line thermal mass flowmeters (ITMF), however, are sensitive to both skew and swirl and the manufacturer's recommendations for minimum distances upstream and downstream of sources of disturbance should be observed. ITMF meters are not sensitive to pipework vibrations, but, like all insertion meters, the insertion version should be firmly fixed to the pipe wall to prevent resonance.

3.10 Miscellaneous

It is possible using various techniques (pitot tubes, insertion electromagnetic meters, hot-wire anemometers, laser Doppler anemometers) to measure the velocity at different points across the pipe and then to integrate the measurements to give the flow rate; such techniques are called *velocity-area methods*.

Tracers can be added to the flowing fluid, and the measured velocity of the tracer between two points can be used to give the flow rate of the fluid.

Meter provers, syringes, and automatic weighing dispensers are some other devices that can be considered for specialist applications.

4 INSTALLATION ISSUES

Most flowmeters are designed to operate in ideal conditions. In practice, it is rarely possible to achieve these conditions and the way in which the meter is installed may generate a measurement error. Common sources of installation error include

- upstream and downstream disturbances to the flow caused by bends, valves or other fittings;
- flow pulsations;

- acoustic noise sources and vibration;
- particles or bubbles in the flow.

Flow disturbances are most important as they affect most types of flowmeters to a greater or a lesser degree. Other potential installation problems have been highlighted in Section 3 on a meter-by-meter basis. A high proportion of meters are installed incorrectly because they were an afterthought in the project design. It is good project design to involve the metering engineer early in the design process, as it can be very difficult and costly to modify the design later to allow for the correct installation of the meter.

Pipework fixtures disturb the flow by

- changing the distribution of flow in the pipe (distortion of the axial velocity profile);
- causing the flow in the pipe to swirl;
- changing the turbulence of the flow in the pipe.

Meters may be affected by one or more of these factors. In most cases, the percentage error generated by flow disturbances tends to be only slightly affected by Reynolds number or flow rate.

In general, disturbing elements that are in the same plane generate distorted axial velocity profiles without bulk rotation of the flow. If, for example, the fluid passes through a single bend, the flow will be skewed to one side of the pipe generating higher velocities near one wall. Contractions and expansions cause a flattened and a peaked velocity profile respectively. Rough pipework changes the axial velocity profile. Distortions of the axial profile usually become sufficiently small to give negligible effect on flow measurement within about 45 pipe diameters from the disturbance. In many cases, a much shorter length will be required.

Swirl, in the sense of bulk rotation of the flow, can be more persistent than distortion of the axial velocity profile. It can persist for 150 pipe diameters. When the pipe fittings are such that the flow changes direction twice in quick succession and in two different planes, swirl is often generated. The most typical situation in which swirl occurs is two 90° bends in planes at right angles to each other.

In nearly all cases of interest to engineers, the flow in pipes includes random turbulent fluctuations. Passing fluid through pipework fixtures effectively stirs up the flow, usually causing increased turbulence.

Work on the effect of upstream fittings has been carried out on all types of flowmeters. The most comprehensive program of work has been carried out on orifice plates. The fruit of this work is seen in ISO 5167-2 (International Organization for Standardization 2003a), which contains a table of straight lengths required downstream of particular fittings.

There are two problems with tables of straight length requirements such as the one in ISO 5167-2 (International Organization for Standardization 2003a): the user's fitting may not be included in the table, and the required length may be longer than that which is available. One solution to both problems is to use a flow conditioner. Instead of requiring the use of particular flow conditioners ISO 5167-1 (International Organization for Standardization 2003b) contains a compliance test so that, if a flow conditioner provides sufficiently small shifts in discharge coefficient downstream of certain flow disturbers (giving major distortion of the axial profile and strong swirl) and in good flow conditions, then it can be used with the same type of flowmeter downstream of any upstream fitting. The ranges of distances, expressed in terms of numbers of pipe diameters, between the flow conditioner and the flowmeter and between the upstream fitting and the flow conditioner, which are used in the tests, determine the acceptable ranges of distances when the flowmeter is used. The compliance test includes tests at two Reynolds numbers and in two pipe sizes. In the case of an orifice plate, the total upstream length from fitting to orifice plate can be reduced to 17 diameters by use of a Zanker Flow Conditioner Plate.

Standards and manufacturers' recommendations usually specify only a short length of straight pipe downstream of the meter as being necessary. Ten diameters will normally be sufficient and in some cases a much shorter length is necessary.

For information on testing and calibration of flowmeters, *see* **Article 190, Calibration and Standards in Flow Measurement, Volume 3**.

Further information on the selection and application of flowmeters can be found in Baker (2000), Miller (1996) and Spitzer (2001).

1 PRINCIPLES OF OPERATION OF DP FLOWMETERS

Differential pressure (DP) flowmeters partially obstruct the flow and hence operate by creating a difference in static pressure between the upstream and downstream side of the device. If a converging section of pipe, Figure 1, typical of the entry cone of a Venturi tube, is considered and Bernoulli's Equation for incompressible flow is applied between two planes, then

$$p_1 + \tfrac{1}{2}\rho U_1^2 = p_2 + \tfrac{1}{2}\rho U_2^2 \tag{1}$$

where p, ρ, and U are the pressure, density, and mean velocity respectively and the subscripted 1 and 2 represent the upstream and downstream (throat) planes.

From conservation of mass for incompressible flow

$$q_m = \rho A_1 U_1 = \rho A_2 U_2 \tag{2}$$

where q_m is the mass flow rate and A is the area of each plane. The area ratio, m, and the diameter ratio, β, are defined by

$$\frac{A_2}{A_1} = m = \left(\frac{d}{D}\right)^2 = \beta^2 \tag{3}$$

where d and D are the throat and upstream pipe diameters.

From these relations, it can be shown that

$$q_m = \frac{1}{\sqrt{1-\beta^4}} \frac{\pi d^2}{4} \sqrt{(2\rho(p_1 - p_2))} \tag{4}$$

The expression $[1/\sqrt{(1-\beta^4)}]$ is known as the velocity of approach factor and has usually been denoted by E. $p_1 - p_2$ is the differential pressure, Δp.

Hence,

$$q_m = \frac{1}{\sqrt{1-\beta^4}} \frac{\pi d^2}{4} \sqrt{2\rho\Delta p} \tag{5}$$

assuming no losses occur and the moving fluid completely fills the pipe.

In reality, some loss will occur and the equation is multiplied by the discharge coefficient C to take this into account.

Thus,

$$q_m = \frac{C}{\sqrt{1-\beta^4}} \frac{\pi d^2}{4} \sqrt{2\rho\Delta p} \tag{6}$$

The product $[C/\sqrt{(1-\beta^4)}]$ is sometimes referred to as the *flow coefficient* of the meter and represented by α.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

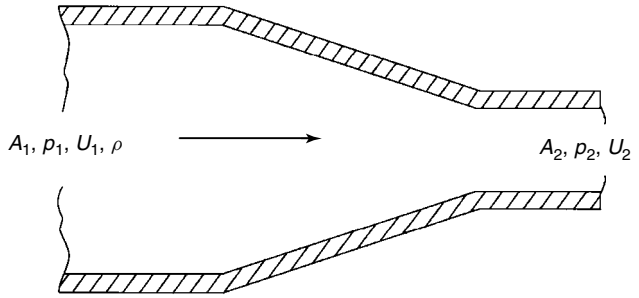

Figure 1. Converging flow.

In nozzles and Venturi tubes, the flow follows the boundary of the tube closely and the value of C is usually close to unity. However, in the case of an orifice plate, the flow continues to converge downstream of the plate forming a vena contracta. Bernoulli's Equation can be applied between an upstream plane and the vena contracta, but the area of the vena contracta cannot practically be measured and is thus not known accurately; therefore, in (6) the area of the orifice bore is used. This leads to a value of C of approximately 0.6, which, in effect, includes a coefficient of contraction.

If the fluid being metered is compressible, there will be a change in density when the pressure of the fluid falls from p_1 to p_2 on passing through the device. As the pressure changes quickly, it is assumed that no heat transfer occurs and because no work is done by or on the fluid, the expansion is isentropic. In nozzles and Venturi tubes, Bernoulli's Equation is applied, and an expansibility factor, ε, is calculated:

$$q_m = \frac{C}{\sqrt{1-\beta^4}}\varepsilon\frac{\pi d^2}{4}\sqrt{2\rho_1\Delta p} \tag{7}$$

where

$$\varepsilon = \left(\left(\frac{\kappa\tau^{2/\kappa}}{\kappa-1}\right)\left(\frac{1-\beta^4}{1-\beta^4\tau^{2/\kappa}}\right)\left(\frac{1-\tau^{(\kappa-1)/\kappa}}{1-\tau}\right)\right)^{1/2} \tag{8}$$

ρ_1 is the density at the upstream tapping, τ is the pressure ratio, p_2/p_1, and κ is the isentropic exponent. Because of the assumptions on which this equation is based, it has an uncertainty, which increases with $\Delta p/p_1$.

The theoretical values of ε do not apply to orifice plates because the effective area ratio is not readily obtained and the flowing jet can also expand laterally within the orifice. Hence, empirical values are used, and for all three recognized tapping arrangements (7) is used together with the equation

$$\varepsilon = 1 - (0.351 + 0.256\beta^4 + 0.93\beta^8)\left\{1 - \left(\frac{p_2}{p_1}\right)^{1/\kappa}\right\} \tag{9}$$

2 HARDWARE AND SOFTWARE OF DP FLOWMETERS

The chief types of differential pressure meters are

orifice plate	low-loss device (e.g. Dall tube)
nozzle and Venturi nozzle	inlet flowmeter
Venturi tube	

DP flowmeters may be installed either 'in-line', that is, with pipework both upstream and downstream of it, or at the inlet to a length of pipe. It is estimated that at least 40% of industrial flowmeters in use at present are differential pressure devices, with the orifice plate being the most popular. The orifice plate may be installed in an orifice fitting to enable the orifice plate to be changed easily, or it may be installed between flanges. Processing methods for data vary from the simple to the use of flow computers.

3 PERFORMANCE OVERVIEW OF DP FLOWMETERS

The main advantages of DP flowmeters are that

1. they are simple to make, containing no moving parts,
2. their performance is well understood,
3. they are cheap – especially in larger pipes when compared with other meters,
4. they can be used in any orientation,
5. they can be used for most gases and liquids,
6. they have generally good standards, based on years of research, and
7. some types do not generally require calibration.

A typical orifice plate designed and manufactured according to a recognized standard will measure flow with an uncertainty around 1% (or a little lower) in good conditions depending on its area ratio. Uncertainty can be reduced by calibration. Because of the square root relationship between differential pressure and flow rate, the relative uncertainty of the flow rate measurement increases at low flow rates, and the rangeability of a differential pressure meter is limited normally to 3 : 1 and to about 8 : 1 at most. The use of modern 'smart' pressure transmitters is increasing the range of the meter.

In some situations where brief interruption of the flow is permissible, a greatly extended flow range can be obtained by the use of multiple orifice plates. Interruption of the flow will not be necessary if the multiple meter runs downstream of a header are used or a suitable orifice fitting is employed.

4 DESIGN ISSUES OF DP FLOWMETERS

4.1 Orifice plate

There are many forms of orifice plates in the sense that various profiles of the actual orifice are used and alternative positions of pressure tappings are permitted by ISO 5167-2 and ISO TR 15377. The normal profile used in orifice plates is the square edge, Figure 2. The downstream edge of a square-edged plate is beveled, unless the plate is thin.

Three alternative positions of the pressure tappings are permitted corner, flange, and D and $D/2$, *see* Figure 3. Their choice is largely a matter of local custom and engineering convenience, although experience indicates that D and $D/2$ tappings are generally less sensitive to disturbed flow than flange or corner tappings. In industry, especially in the United States, flange tappings are commonly used.

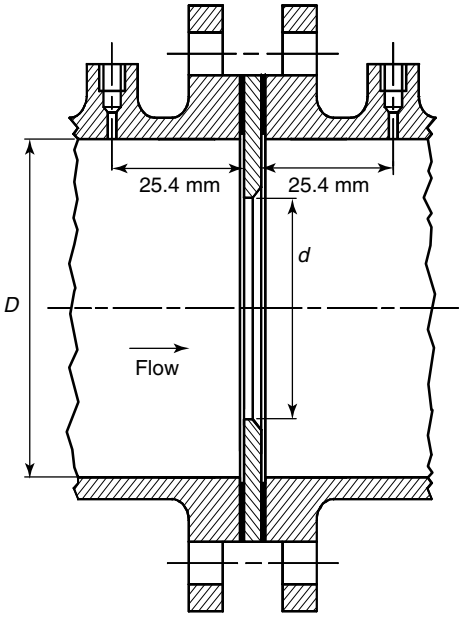

Figure 2. Orifice plate with flange tappings.

To measure pressure, it is generally better to use a piezometer ring or annular groove than a single tapping. A triple-tee arrangement (Figure 4) has been shown to be the most satisfactory, especially where flow disturbances exist (Blake, 1976).

The outstanding advantage of a square-edged orifice plate is that, if designed and manufactured according to ISO 5167-2, the coefficient can be predicted by an internationally accepted equation based on a wide range of good data, and this removes the need for calibration. No other type of flowmeter has quite this capability.

A very large international program of work led to the creation of a database of orifice plate discharge coefficients: the diameter ratios range from 0.1 to 0.75, orifice Reynolds numbers from 1700–7×10^7, and pipe diameters from 50 to 600 mm. As a result of this work, the Stolz Equation for the discharge coefficient in ISO 5167-1:1991 was replaced by the Reader-Harris/Gallagher (1998) Equation first in ISO 5167-1:1991/Amd 1:1998 and then in ISO 5167-2:2003. The Reader-Harris/Gallagher (1998) Equation is as follows:

$$C = 0.5961 + 0.0261\beta^2 - 0.216\beta^8 + 0.000521\left(\frac{10^6\beta}{Re_D}\right)^{0.7} + (0.0188 + 0.0063A)\beta^{3.5}\left(\frac{10^6}{Re_D}\right)^{0.3} + (0.043 + 0.080e^{-10L_1} - 0.123e^{-7L_1})(1 - 0.11A)\frac{\beta^4}{1-\beta^4} - 0.031(M_2' - 0.8M_2'^{1.1})\beta^{1.3} \quad (10a)$$

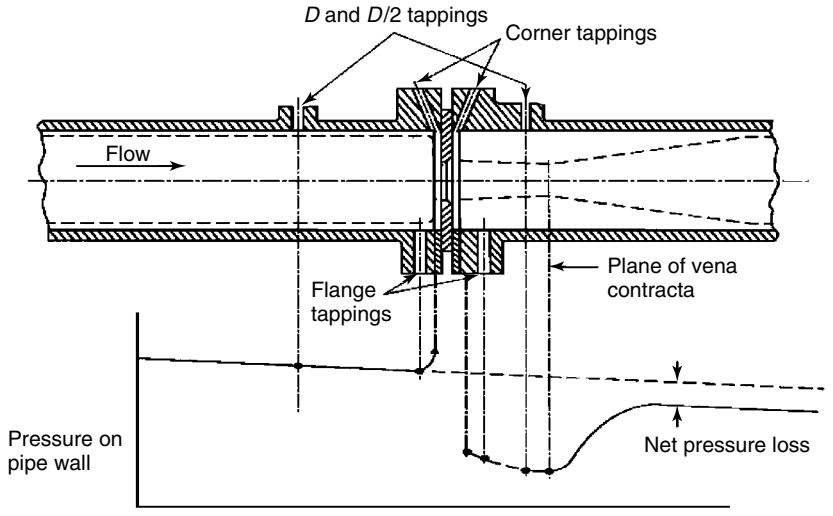

Figure 3. Tapping locations and pressure profile upstream and downstream of an orifice plate.

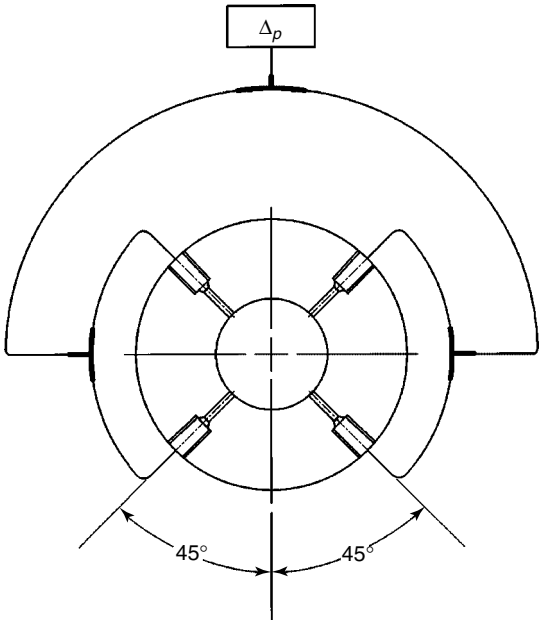

Figure 4. Triple-tee arrangement.

Where $D < 71.12$ mm (2.8 inch) the following term should be added to the above Equation:

$$+0.011(0.75 - \beta)\left(2.8 - \frac{D}{25.4}\right)(D : \text{mm}) \qquad (10b)$$

In this Equation,

Re_D is the Reynolds number related to D;
$L_1 = l_1/D$ is the quotient of the distance of the upstream tapping from the upstream face of the plate and the pipe diameter;
$L'_2 = l'_2/D$ is the quotient of the distance of the downstream tapping from the downstream face of the plate and the pipe diameter;

$$M'_2 = \frac{2L'_2}{1 - \beta}; \qquad (11)$$

$$A = \left(\frac{19000\beta}{Re_D}\right)^{0.8}$$

The limits of use in terms of Reynolds numbers and pipe roughness are given in ISO 5167-2. A similar but not identical equation is included in API 14.3 Part 1.

Square-edged orifice plates and nozzles may be used in pipes smaller than 50-mm diameter: this is covered by ISO TR 15377, which also includes conical-entrance, quarter-circle and eccentric orifice plates. Conical-entrance and quarter-circle plates are used especially for viscous flow. For special purposes, eccentric or even noncircular orifice plates are used; for example, in metering suspended solids, a chord-type orifice plate can be used.

Further guidance on the use of pressure differential devices is given in other standards (*see* Section 9).

4.2 Venturi tubes

The profile of the classical Venturi tube is shown in Figure 5. Although the included angle of the conical divergent section can be between 7 and 15°, it is recommended that an angle of 7 to 8° be chosen where possible. Various forms of construction are employed, depending upon size, but all are considerably more expensive than the orifice plate. When the outlet diameter of the divergent section is less than the upstream pipe diameter, a Venturi tube is called *truncated*. The divergent portion can be truncated by about one-third of its length without greatly affecting the pressure loss in the device.

The discharge coefficient of a Venturi tube with a machined convergent is typically 0.995. Because it has pressure tappings in the throat, a Venturi tube is much more affected by burrs on the tappings than an orifice plate.

There is an increasing desire to use Venturi tubes in gas flows and especially in wet gas. However, on undertaking the calibrations it has been found that on many occasions discharge coefficients significantly greater than 1 have been found (e.g. $C \approx 1.02$). This problem has been described by Jamieson *et al*. (1996). Part of the cause of this problem is static hole error. A full understanding of the problem is a matter of current research (*see* Reader-Harris *et al*., 2001).

4.3 Nozzles

The nozzle (see ISO 5167-3) has a curved entry and cylindrical throat, but no divergent outlet section (Figure 6). Therefore, the discharge coefficient is similar to that of a Venturi tube. However, the pressure loss is the same as that of an orifice plate for the same flow rate in the same size of pipe at the same differential pressure.

There are two types of standard nozzles, the ISA 1932 nozzle and the long-radius nozzle. The profile of the ISA

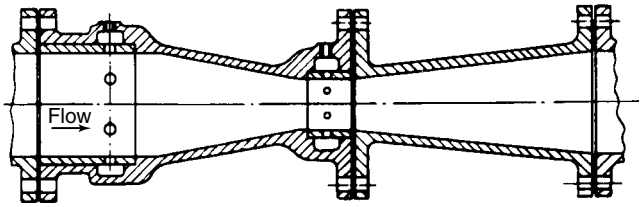

Figure 5. Venturi tube. (*Source*: Extracts from British Standards reproduced with the permission of BSI under licence number 2002SK/0147.)

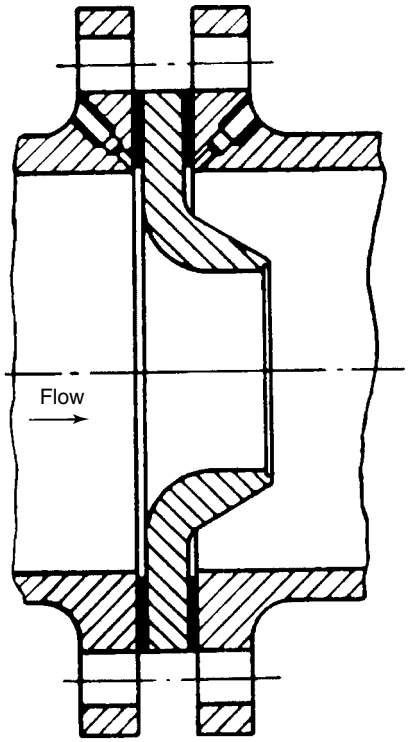

Figure 6. Nozzle mounted between pipe. (*Source*: Extracts from British Standards reproduced with the permission of BSI under licence number 2002SK/0147.)

1932 nozzle depends on whether the throat diameter d is less or greater than two-thirds the pipe diameter D. Corner pressure tappings are usually used with this nozzle, which may be mounted between pipe flanges or in a carrier.

Two standard designs of long-radius nozzles are used according to the value of the diameter ratio β. The upstream pressure tapping is about one pipe diameter from the inlet face. The downstream tapping is half a pipe diameter from the inlet face unless the nozzle is less than $D/2$ in length in which case it must be no further downstream than the nozzle outlet.

Long-radius nozzles with throat tappings have been standardized in ASME PTC-6. This standard is commonly used in the electrical power generation industry.

In order to reduce the pressure loss caused by a nozzle it can be fitted with a divergent section similar to that used for a Venturi, hence becoming a Venturi nozzle. The upstream face is identical with an ISA 1932 nozzle. Upstream corner and throat pressure tappings are used, Figure 7.

4.4 Low-loss meters

Given the importance of energy conservation there is every incentive to develop devices with a low pressure loss, and yet to retain the basic advantages of differential pressure meters.

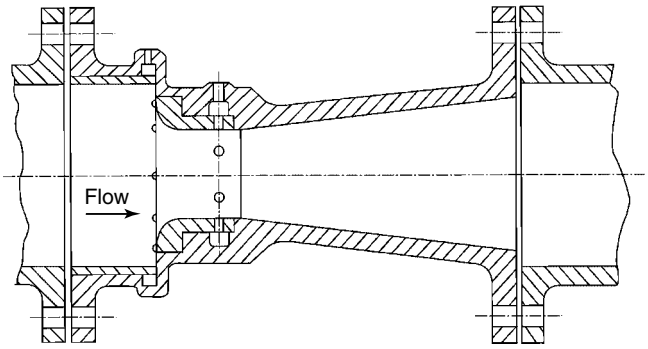

Figure 7. Venturi nozzle (with truncated divergent section). (*Source*: Extracts from British Standards reproduced with the permission of BSI under licence number 2002SK/0147.)

Many variations of low-loss meters have been invented, but only a few have been exploited commercially. The main problem perhaps is that to be competitive with conventional pressure differential devices, an immense amount of test data would need to be accumulated to match the installation experience on the latter.

One of the earliest such developments was probably the Dall tube (Dall, 1960), Figure 8. It comprises two cones, each with a substantial included angle, between which is a circumferential slot. The abrupt change of boundary contour results in flow curvature, which increases the differential pressure produced. The sudden reduction in section immediately downstream of the upstream pressure tapping gives a local pressure increase, which also augments the differential pressure produced by this device.

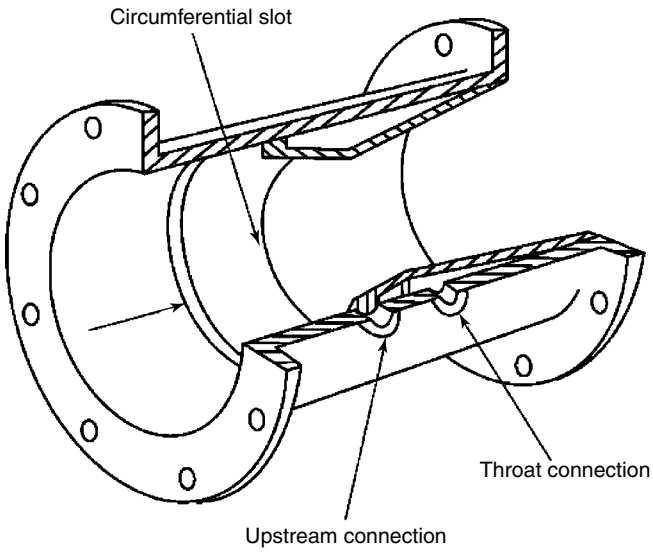

Figure 8. Dall tube.

Other low-loss devices are the Dall orifice, virtually a shortened version of the Dall tube intended for insertion between flanges, the Epiflo device (Lewis, 1975), which features a cylindrical ring protruding upstream and a conical diffuser downstream to obtain maximum pressure recovery, and the Gentile Flow Tube (Gentile, 1950). The Gentile Flow Tube is about $1.5D$ long and has two groups of pressure sensing holes, one group pointing upstream, the other downstream, and can measure flow in either direction since it is symmetrical.

4.5 Inlet flowmeters

Four devices are commonly used as a flowmeter at the inlet to a pipe: the nozzle, bellmouth entry, conical inlet, and Borda inlet. Such flowmeters are most commonly used for airflow measurements; although there is no reason in theory why they should not be used with liquid flows, there are, in practice, few situations in which they are appropriate.

In every case, the 'upstream' pressure is simply that in the reservoir (normally the atmosphere) from which the air is drawn into the pipe. Details of the dimensions and construction of the devices are given in Figure 9.

The use of *nozzles* at an inlet is described in Jaumotte and Nagel (1976). Alternatively, an ISA or a Venturi nozzle can be used in accordance with ISO TR 15377.

The design of *bellmouth entries* is not standardized, but any long-radius curved inlet will act as a good flowmeter provided that the walls are smooth, and will have a discharge coefficient of about 0.99.

The *conical inlet* has been standardized (BS 848) and has been shown (Whitaker, 1968) to have a discharge coefficient of about 0.96, although this value can vary by $\pm 2\%$ even with carefully made devices.

The *Borda inlet* has the advantages that it is easy and cheap to make, and generates about four times the differential pressure produced by a conical or a bellmouth entry with the same throat diameter (the diameter of the 'throat' being that of the downstream pipe). It does, however, have

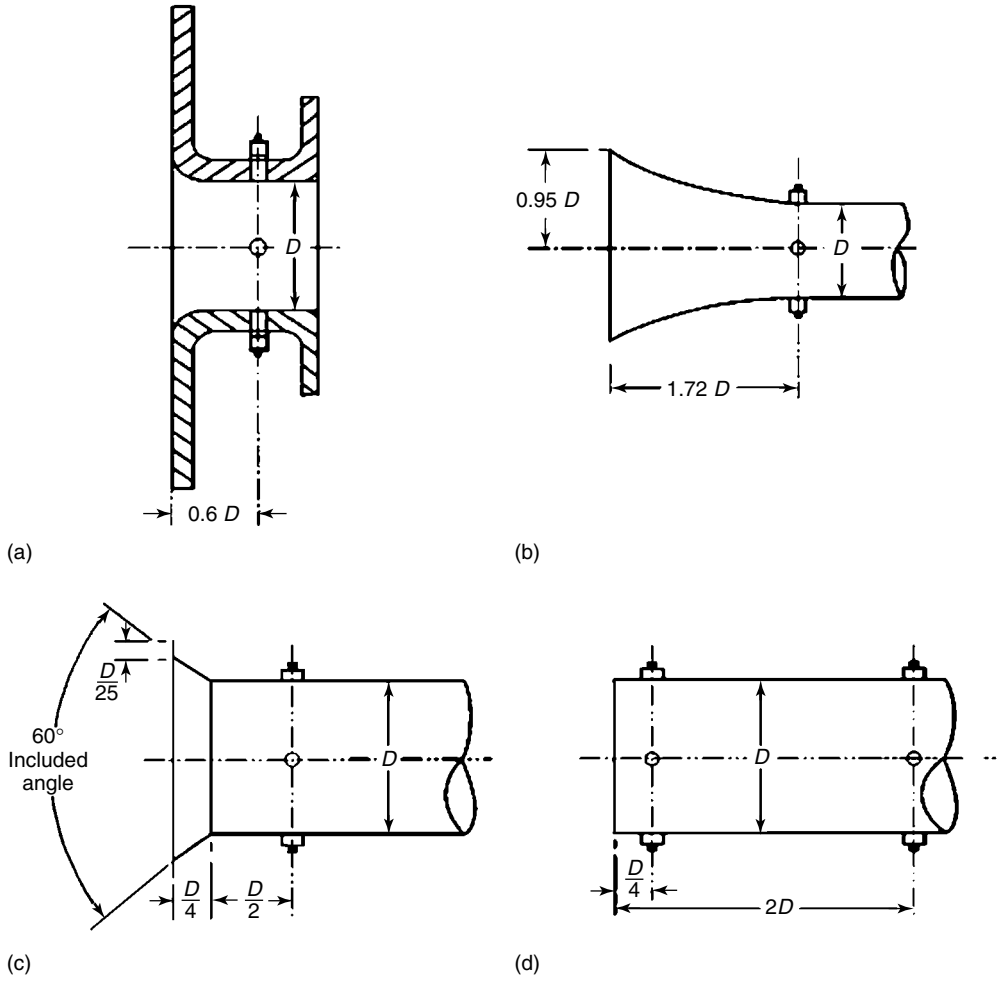

Figure 9. Inlet flowmeters: (a) inlet nozzle, (b) bellmouth entry, (c) conical inlet, and (d) Borda inlet.

a higher head loss – about 0.5 times the velocity head. The discharge coefficient is approximately 0.5, and details of the design and use of Borda inlets are given in Kinghorn and McHugh (1978).

When using inlet flowmeters, care has to be taken that the area from which the air is drawn is free from draughts or crosswinds, since otherwise significant errors can occur (Kinghorn, McHugh and Crawford, 1975).

4.6 V-Cone flowmeter

A modern patented differential flowmeter that has found significant use is the McCrometer V-Cone flowmeter (Figure 10). Its advantages include the fact that it requires a shorter straight length upstream than an orifice plate (Ifft, 1995).

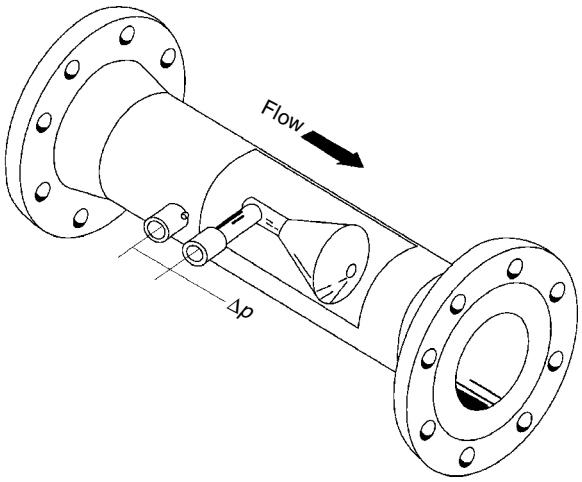

Figure 10. V-Cone flowmeter.

4.7 The spring-resisted, differential pressure, variable-area flowmeter

Because of the square law relationship between differential pressure and flow rate, one option to extend the range of differential pressure flowmeters is the spring-resisted, differential pressure, variable-area flowmeter, Figure 11. The cone takes up a position of equilibrium under the combined effects of the flow, the spring, and the area of the orifice. By suitable design of the profile to match the choice of spring, the differential pressure can be made a linear (or even some other) function of flow rate.

5 SELECTION OF DP FLOWMETERS

An orifice plate is probably the least expensive differential pressure flowmeter, and it has the great advantage that it is normally sufficient to manufacture it in accordance with ISO 5167-2 without calibrating it in a flowing fluid. If the flow rate changes after installation, then it may be possible to change the plate for one of a different diameter ratio very simply and inexpensively.

One advantage of a nozzle over an orifice plate is that there is no sharp edge to erode, but it is more expensive to manufacture and more difficult to install and to remove from the pipe.

If it is important to minimize the length required upstream of the meter, Venturi tubes will have an advantage over orifice plates.

The pressure loss in a system is shown in Figure 12. Therefore, if it is important to reduce the pressure loss a Venturi tube or, for even lower loss, a low-loss meter such as the Dall tube will be desirable.

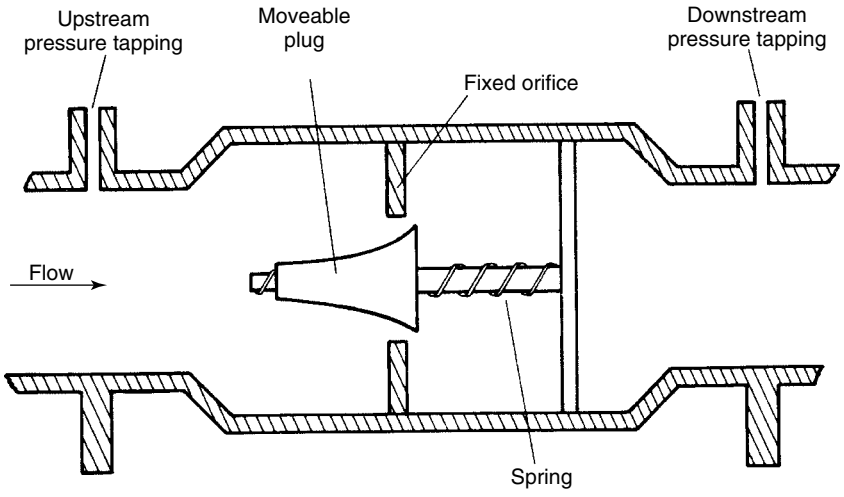

Figure 11. Variable-area differential pressure meter.

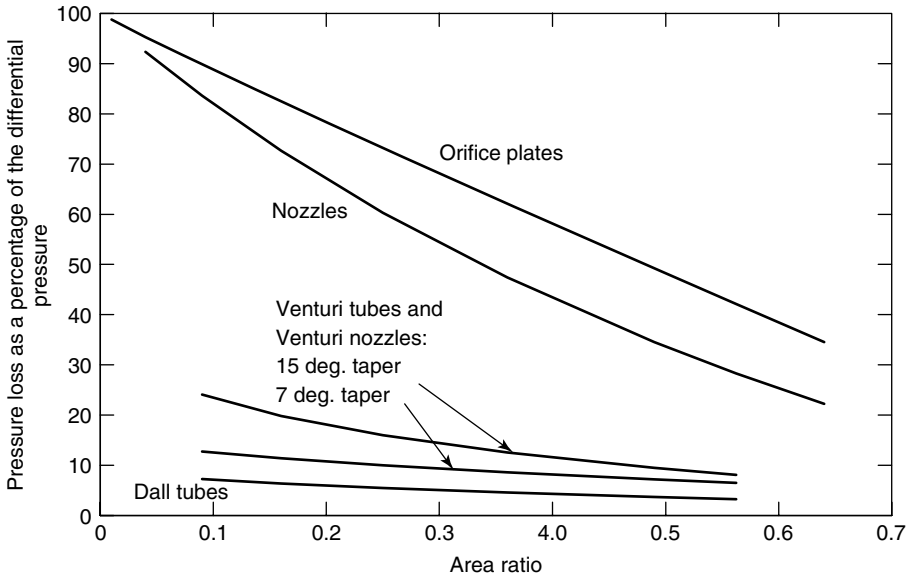

Figure 12. Pressure loss as a percentage of the differential pressure.

Throat-tapped devices may have an unexpected performance at high Reynolds number; so it is desirable to calibrate them or to use an orifice plate.

In wet gas, Venturi tubes may have advantages because of their shape.

6 INSTALLATION ISSUES OF DP FLOWMETERS

DP flowmeters are significantly affected by upstream installation. The standards state the lengths of straight pipe required between specified upstream fittings and the flowmeters. Generally, the lengths increase with diameter ratio. In recent years, in addition to the work on the orifice plate discharge coefficient, there has also been a significant amount of work on installation effects on orifice plates: data have been collected on the effect of single 90° bends, two 90° bends in the same plane (S-configuration) and in perpendicular planes, single 45° bends, two 45° bends in the same plane (S-configuration), a tee, reducers, expanders, a gate valve, and headers. A large part of the data is in Studzinski *et al*. (1997). These data have helped to determine the required upstream lengths in ISO 5167-2. The straight lengths required upstream of a Venturi tube have also been recently reevaluated (Reader-Harris, Brunton and Sattary, 1997). The lengths are much shorter than those required upstream of an orifice plate, but longer than those in ISO 5167-1:1991. Revised lengths have been included in ISO 5167-4:2003.

In many cases, it is possible to use a flow conditioner to reduce the required upstream straight length. ISO 5167-1:2003 contains a compliance test for flow conditioners: this provides that if in good flow conditions, in strong asymmetry and in strong swirl, a flow conditioner gives a sufficiently small shift in discharge coefficient from a baseline in a long straight pipe, then the flow conditioner can be used with any upstream fitting, given the same lengths upstream and downstream of the flow conditioner as in the compliance test.

Rough pipe and steps in the upstream pipe diameter also affect the discharge coefficient and again the standards contain limits which have been revised in the case of orifice plates in the light of recent data.

7 LIMITATIONS OF DP FLOWMETERS

The main disadvantages of DP flowmeters are

1. rangeability (turndown, dynamic range) – *see* **Article 57, Static Considerations of General Instrumentation, Volume 1** – is less than for most other types of flowmeter,
2. significant pressure loss may occur,
3. output signal is nonlinear with flow,
4. coefficient and accuracy may be affected by pipe layout or nature of flow, and
5. they may suffer from aging effects, that is, the buildup of deposits or erosion of sharp edges.

8 ERRORS IN DP FLOWMETERS

Errors in DP flowmeters can be due to poor manufacture and consequent failure to meet the standard and thus to obtain the predicted discharge coefficient, to poor installation, and to the effects of aging. The effects of some errors are described in ISO TR 12767; the effect of pulsation is described in ISO TR 3313.

As time goes by, gradual changes to DP flowmeters may occur, which eventually cause significant errors to be introduced unless remedial measures are taken. The sharp edge of an orifice plate may be eroded away causing the discharge coefficient to rise. The convergent section and throat of a nozzle or Venturi tube may roughen resulting in a lower discharge coefficient. Unfortunately, no general rules for the rate of deterioration are available; each installation must be assessed according to its own set of circumstances and renewals or recalibrations made as appropriate.

9 STANDARDS RELEVANT TO DP FLOWMETERS

9.1 ISO standards

ISO TR 3313:1998. Measurement of fluid flow in closed conduits – guidelines on the effects of flow pulsations on flow measurement instruments.

ISO TR 9464:1998. Guide to the use of ISO 5167-1:1991.

ISO TR 12767:1998. Measurement of fluid by means of pressure differential devices – guidelines to the effect of departure from the specifications and operating conditions given in ISO 5167-1.

ISO TR 15377:1998. Measurement of fluid flow by means of pressure differential devices – guidelines for specification of nozzles and orifice plates beyond the scope of ISO 5167-1.

ISO 5167-1:2003. Measurement of fluid flow by means of pressure differential devices inserted in circular cross-section conduits running full – Part 1: General principles and requirements.

ISO 5167-2:2003. Measurement of fluid flow by means of pressure differential devices inserted in circular cross-section conduits running full – Part 2: Orifice plates.

ISO 5167-3:2003. Measurement of fluid flow by means of pressure differential devices inserted in circular cross-section conduits running full – Part 3: Nozzles and Venturi nozzles.

ISO 5167-4:2003. Measurement of fluid flow by means of pressure differential devices inserted in circular cross-section conduits running full – Part 4: Venturi tubes.

9.2 British standards

BS 848: Part 1:1980. Fans for general purposes. Part 1: Methods of testing performance.

9.3 API standards

API 14.3 Part 1:1990. Manual of Petroleum Measurement Standards, Chapter 14 – Natural Gas Fluids Measurement, Section 3 – Concentric Square-Edged Orifice Meters, Part 1 – General Equations and Uncertainty Guidelines.

9.4 ASME standards

ASME PTC-6:1996. Performance Test Code 6 on Steam Turbines.

10 TESTING OF DP FLOWMETERS

Orifice plates are rarely individually calibrated. Nozzles and Venturi tubes may be calibrated. Other DP flowmeters probably require calibration. It is necessary to have the same Reynolds number for the calibration as for the use of the meter. It is not necessary to have the same fluid. It is possible to calibrate in water a device for use in low-pressure air. Calibrations for use in gas generally assume that the expansibility factor equation is correct and determine the discharge coefficient. For some DP flowmeters, it may be necessary to determine the expansibility factor equation first.

General texts on flow have material on DP flow metering (Liptak, 1993; Miller, 1996; Spitzer, 2001; Baker, 2000).

1 INTRODUCTION

Flow measurement is something that nearly everyone has experience of. Everyday examples include the metering of household utilities such as water and gas. Similarly, flowmeters are used in nearly every sector of industry, from petroleum through to food manufacture and processing. It is therefore not surprising that today the total world flowmeter market is worth over $3000 million and expected to continue growing steadily in the future.

However, what is surprising, given the undoubted importance of flow measurement to the economy, is the accuracy and technology of the most commonly used flowmeters that are poor and relatively old fashioned in comparison to instruments used to measure other measurands such as pressure and temperature. For example, the orifice plate flowmeter, which is still one of the most frequently used flowmeters in the process industry, only has a typical accuracy of $\pm 2\%$, and was first used commercially in the late-1800s. The conservative nature of the flow measurement industry means that traditional techniques such as the orifice plate, Venturimeter, and variable area flowmeter still dominate, while ultrasonic flowmeters, which were first demonstrated in the 1950s, are still considered by many to be 'new' devices. This article will consider the principles of operation of the most commonly used commercially available methods of flow measurement. For recent research developments in flow measurement, see the journal Flow Measurement and Instrumentation.

2 BASIC TERMINOLOGY

The term flow measurement is a general term, and before selecting a flowmeter, it is important to be sure what type of flow measurement is actually required. For a fluid flowing through a pipe, flow measurement may mean any one of six different types of measurements.

1. Point velocity measurement – the fluid's velocity at a fixed point across the pipe's cross section ($\mathrm{m\,s^{-1}}$)
2. Mean flow velocity measurement – average fluid velocity across the cross section of the pipe ($\mathrm{m\,s^{-1}}$)
3. Volumetric flowrate measurement – the rate of change in the volume of fluid passing through the pipe with time ($\mathrm{m^3\,s^{-1}}$)
4. Total volume measurement – the total volume of fluid that has passed through the pipe ($\mathrm{m^3}$)
5. Mass flowrate measurement – the rate of change in the mass of the fluid passing through the pipe with time ($\mathrm{kg\,s^{-1}}$)
6. Total mass measurement – the total mass of fluid passing through the pipe ($\mathrm{kg\,s^{-1}}$).

Although the most common type of flow measurement is that of a fluid through a closed conduit or pipe, open channel flow measurements are also regularly needed in

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

applications such as sewage and water treatment. For further information on open channel flow measurement techniques, see Grant (2001).

3 CHARACTERISTICS OF FLUID FLOW

The fluid being metered is usually a liquid or gas and is known as *single-phase flow*. However, there is an increasing need for the flowrate of multiphase mixtures to be measured (See Section 6).

There are a number of important principles relating to the characteristic of flow in a pipe that should be understood before a flowmeter can be selected and used with confidence. These are the meaning of Reynolds number and the importance of the flow's velocity profile (Mulley, 2004).

The Reynolds number *Re* is the ratio of the inertia forces in the flow ($\rho \bar{v} D$) to the viscous forces in the flow (η), and it can be used to determine whether a fluid flow is laminar or turbulent in nature. Reynolds number can be calculated using

$$Re = \frac{\rho \bar{v} D}{\eta} \tag{1}$$

where ρ is the density of the fluid, $\bar{v}$ is the mean velocity of the fluid, D is the pipe diameter, and η is the dynamic viscosity of the fluid. If *Re* is less than 2000, viscous forces in the flow dominate and the flow will be laminar. If *Re* is greater than 4000, inertia forces in the flow dominate and the flow will be turbulent. If *Re* is between 2000 and 4000, the flow is transitional and either mode can be present. The Reynolds number is mainly calculated using properties of the fluid and does not take into account factors such as pipe roughness, bends, and valves, which also affect the flow characteristic. However, the Reynolds number is a good guide to the type of flow that might be expected in most situations.

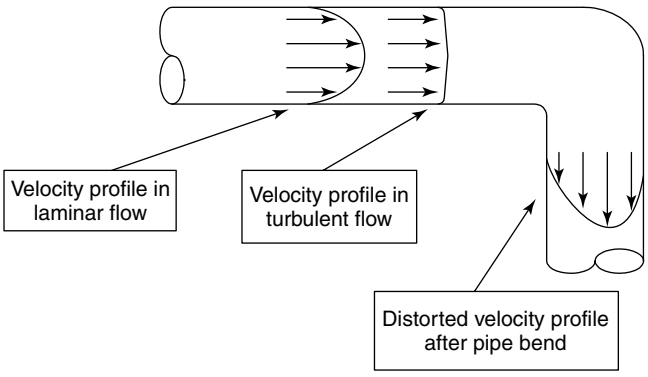

Figure 1. Flow velocity profiles in laminar and turbulent flow.

The fluid velocity across a pipe's cross section is not constant and depends on the type of flow present (Figure 1). In laminar flow, the velocity at the center of the pipe is twice the average velocity across the pipe cross section, and the flow profile is unaffected by the roughness of the pipe wall. In turbulent flow, pipe wall effects are less and the flow's velocity profile is flatter, with the velocity at the center being about 1.2 times the mean velocity. The exact flow profile in a turbulent flow depends on pipe wall roughness and Reynolds number. In industrial applications, laminar flows are rarely encountered unless very viscous fluids are being metered. The pipe Reynolds number should always be calculated since some flowmeters are not suitable for use in both laminar and turbulent flow conditions.

A flow's velocity profile will only be symmetrical at the end of a very long pipe. Bends and obstructions such as valves will cause the profile to become distorted or asymmetric. Since the calibration of many flowmeters is sensitive to the velocity profile of the flow passing through the meter, in order to have confidence in the performance of a flowmeter, the velocity profile of the flow passing through the flowmeter should be stable and known.

4 FLOWMETER CLASSIFICATION

Although there at least 80 different types of commercially available flowmeter, they may all be classified into 10 main groups (British Standards Institution, 1991) – Differential pressure, Variable Area, Positive Displacement, Turbine, Oscillatory, Electromagnetic, Ultrasonic, Mass, Thermal, and Miscellaneous (*see* **Article 187, Flowmeter Selection and Application, Volume 3**).

Traditional flow measurement technologies are represented by the differential pressure, variable area, positive displacement, and turbine categories. Newer techniques are represented by the electromagnetic, ultrasonic, oscillatory, and mass categories. Although differential pressure flowmeters are still the most commonly used method of flow measurement, especially in the process industrial sector, in general, traditional methods are being increasingly replaced by newer techniques. These techniques are now often preferred because, in most cases, they do not obstruct the flow and yet match many of the traditional flowmeters in terms of accuracy and reliability.

The following sections will consider the principles of operation, advantages, and limitations of the most popular types of flowmeters. For information on the selection and application of these flowmeters, *see* **Article 187, Flowmeter Selection and Application, Volume 3**. For further information on flowmeters, see one of the many textbooks

on flow measurement such as Baker (2000), Miller (1996), Spitzer (2001), and Webster (2000).

5 BASIC PRINCIPLES OF SINGLE-PHASE FLOWMETERS

5.1 The differential pressure flowmeter

Over 40% of all liquid, gas, and steam flow measurements made in industry are still accomplished using the common types of differential pressure flowmeter, that is, the orifice plate, Venturi tube, and nozzle. The operation of these flowmeters is based on the observation made by Bernoulli that if an annular restriction is placed in a pipeline, then the velocity of the fluid through the restriction is increased. The increase in velocity at the restriction causes the static pressure to decrease at this section and a pressure difference to be created across the element. The difference between the pressure upstream and pressure downstream of this obstruction is related to the rate of fluid flowing through the restriction and therefore, of course, through the pipe. A differential pressure flowmeter consists of two basic elements – an obstruction to cause a pressure drop in the flow (a differential producer) and a method of measuring the pressure drop across this obstruction (a differential pressure transducer).

One of the major advantages of the orifice plate, Venturi tube, or nozzle is that the measurement uncertainty can be predicted without the need for calibration if it is manufactured and installed in accordance with one of the international standards covering these devices. In addition, this type of differential pressure flowmeter is simple, has no moving parts, and is therefore reliable. The main disadvantages of these devices are their limited range (typically 3:1), the permanent pressure drop they produce in the pipeline (which can result in higher pumping costs), and their sensitivity to installation effects (which can be minimized using straight lengths of pipe before and after the flowmeter). The combined advantages of this type of flowmeter are still quite hard to beat, and although it has limitations, these have been well investigated and can be compensated for in most circumstances. Unless very high accuracy is required, or unless the application makes a nonintrusive device essential, the differential flowmeter should be considered. Despite the predictions of its demise, there is little doubt that the differential pressure flowmeter will remain a common method of flow measurement for many years to come. For further information on this important class of flowmeter, *see* **Article 188, Differential Pressure (DP) Flowmeters, Volume 3**.

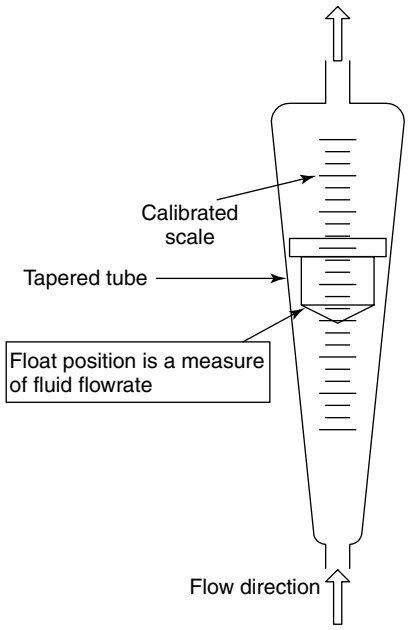

Figure 2. Tapered tube and float variable area flowmeter.

5.2 The variable area flowmeter

Variable area flowmeters are also based on using an obstruction in the flow to create a differential pressure, except, in this case, the differential pressure is constant and the area of the obstruction varies as the flowrate being measured changes. Probably the best-known type of variable area flowmeter is the taper tube and float flowmeter known almost universally as a *rotameter* (Figure 2). This type of flowmeter consists of a vertical tapered tube into which a float or bob is fitted. The fluid being metered enters the tube at the bottom and forces the float up the tube, which also increases the cross-sectional area available around the float for the fluid to pass through. Increasing the flowrate will move the float further up the tube, and so the position at which the float comes to rest is a direct function of flowrate.

Rotameters are extremely simple and reliable, and have an output, which changes linearly with flowrate (unlike differential pressure flowmeters) and a typical range of 10:1 (compared to 3:1 for differential pressure flowmeters). Accuracy is typically $\pm 2\%$ of full scale, but will depend on range and cost of the device. In addition, the flowmeter's calibration is insensitive to changes in the velocity profile of the flow. If the tube can be made of glass or clear plastic then a visual indication of flowrate is directly available and the flowmeter requires no external power supply in order to function. As a result, such flowmeters are commonly found in many process and laboratory applications where gases or liquids need to be metered. If high temperature,

high pressure or corrosive fluids need to be metered then the rotameter's tube can be made of metal. In such cases, a mechanism for detecting and displaying the position of the float is required.

A major limitation of the rotameter is that it can usually only be used vertically and so causes installation difficulties if the pipeline being metered is horizontal. Some manufacturers produce spring-loaded rotameters, which can be used in any position; however, in general, these have poorer accuracy than standard rotameters. Other limitations are that the calibration of the meter is dependent on the viscosity and density of the fluid being metered, and producing an electrical output signal suitable for transmission requires extra complexity. However, the use of optical or magnetic limit switches to enable the flowmeter to be used in high or low flow alarm applications is common.

5.3 The positive displacement flowmeter

Positive displacement flowmeters are based on a simple measurement principle. The flow being measured is 'displaced' or moved from the inlet side of the flowmeter to the outlet side using a series of compartments of known volume. The number of compartments of fluid that have been transferred are counted to determine the total volume that has passed through the flowmeter, and if time is also measured then volumetric flowrate can be measured. There are many designs of positive displacement flowmeter commercially available. For liquids, the most common designs are piston, sliding vane, oval gear, birotor, trirotor, and disc types of flowmeter, while for gases, roots, bellows (or diaphragm), or CVM flowmeters are popular. Despite this wide range of design, all are based on the same principle and all are predominantly mechanical devices.

The advantages of positive displacement flowmeters are that they are capable of high accuracy measurement (typically $\pm 0.5\%$ of reading for liquids and $\pm 1\%$ of reading for gases) over a wide range of flowrates. They can be used to meter fluids with a wide range of viscosity and density. In addition, unlike most other flowmeters, they are insensitive to changes in flow velocity profile and so do not require long lengths of straight pipe work before and after the flowmeter.

Figure 3 shows the principle of the oval gear flowmeter and illustrates the limitations of positive displacement flowmeters. They are relatively complex mechanical devices with moving parts, which of course wear with time. Their measurement accuracy depends both on the initial quality of manufacture and a regular maintenance schedule once in use. Fluids being metered should also be free of solid particles so as to reduce wear of the seals and

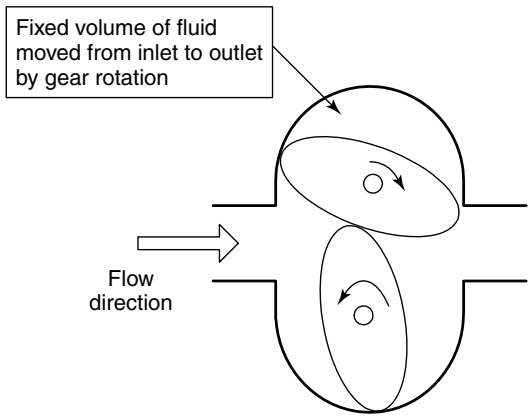

Figure 3. The oval gear positive displacement flowmeter.

the need for excessive maintenance. Positive displacement flowmeters can also be heavy and expensive for larger pipe sizes, and some designs can result in a complete blockage of the pipeline if the flowmeter seizes up.

5.4 The turbine flowmeter

Like the positive displacement flowmeter, turbine (or vane) flowmeters are mechanical devices capable of achieving high measurement accuracy. The principle of operation of this type of flowmeter is that a multibladed rotor is placed in the flow and rotates as fluid passes through it. The rotor's speed of rotation is detected using a sensor (rf, magnetic, and mechanical types being the most common) and is proportional to the velocity of the fluid flowing through the meter. These flowmeters measure the average velocity of fluid in a pipeline, and since the pipe diameter is known, volumetric flowrate can be determined.

Despite the fact that the turbine flowmeter is a mechanical device that may appear to be old fashioned when compared to many of the other technologies available, it is still one of the most accurate and repeatable flowmeters available today. Measurement accuracy of better than $\pm 0.1\%$ of reading for liquids, and better than $\pm 0.25\%$ of reading for gases, are possible using this type of flowmeter. For this reason, the turbine flowmeter is one of the most commonly used instruments in custody transfer applications. These flowmeters have a linear output and a range of at least 10:1, with 100:1 possible in some applications.

The main limitation of the turbine flowmeter is the fact that key mechanical components such as the rotor bearings will wear with use and, in doing so, degrade the instrument's repeatability and alter its calibration. Regular maintenance and recalibration is therefore necessary with this type of flowmeter. Care should also be taken to ensure that the fluid being metered is clean since solid particles in

the flow will cause more rapid bearing wear. The flowmeter's calibration is also sensitive to changes in fluid viscosity and upstream flow velocity profile.

Other types of flowmeters that use the turbine principle include the Pelton wheel and propeller meter, although they have poorer measurement accuracy than axial designs.

5.5 Oscillatory flowmeters

The vortex shedding flowmeter, now more commonly known as the *vortex flowmeter*, is the most common type of oscillatory flowmeter. This flowmeter relies on the phenomena of vortex shedding, which was first experimentally studied by Strouhal in 1878. Figure 4 shows the principle of the vortex flowmeter. A nonstreamlined obstruction known as a *shedder bar* or *bluff body* is placed across the middle of the flow stream. As the fluid stream in the pipe hits this obstacle, it must separate to pass around it, with fluid layers nearer the surface of the bar moving slower than those further away. As a result, when these fluid layers recombine after passing the bar, vortices are generated and shed alternately from either side of the shedder bar. The frequency of generated vortices is related to the upstream velocity of the fluid and the width of the shedder bar and is defined by the K factor of the flowmeter. For a given geometry of shedder bar, the K factor of a flowmeter is relatively constant over a wide range of pipe Reynolds number, and so, in these circumstances, the volumetric flowrate of the fluid is linearly related to the vortex shedding frequency.

The frequency of generated vortices is usually detected using sensors integrated into the sides of the shedder bar. Pressure, capacitance, thermal, and ultrasonic are the most common types of sensors used for this purpose.

The vortex flowmeter is capable of accurate measurement of liquid or gas (typically $\pm 1\%$ of reading) over a minimum flow range of 30:1. The flowmeter can also be used over a wide range of fluid temperatures and so is commonly used for metering process fluids at the extreme ends of the temperature range such as liquid nitrogen and steam. The instrument's calibration is also insensitive to changes in fluid density, and so a meter's calibration holds for any fluid as long as the flowmeter is used within the Reynolds number range specified by the manufacturer. The vortex flowmeter has a simple and reliable construction and so can be used with flows containing small amounts of particles, although more extreme multiphase flows such as slurries will cause rapid wear of the shedder bar and so a change in calibration. The relatively small obstruction that the shedder bar causes results in a permanent pressure loss of about half that of an orifice plate over the same range of flowrate.

The main limitation of the vortex flowmeter is that it can only be used in turbulent flow conditions. It is therefore not usually suitable for use in large pipe diameters, or in applications where the flow velocity is low or the fluid viscosity high. Most manufacturers set a minimum Reynolds number of typically 10 000 at which the specified flowmeter performance can be achieved. While many flowmeters will continue operating at Reynolds numbers less than this, the generated vortex stream becomes less stable and so accuracy is reduced. At a Reynolds of less than around 3000, vortices will not be generated at all and so the flowmeter will stop operating. The vortex flowmeter is also sensitive to changes in upstream flow velocity profile and other disturbances such as swirl and so should be installed with a sufficient straight length of pipe upstream and downstream of the measurement point. The flowmeter should not be used in applications where pipe vibration or local sources of electrical interference are high since this will corrupt the vortex signal being detected and possibly generate false readings under no-flow conditions.

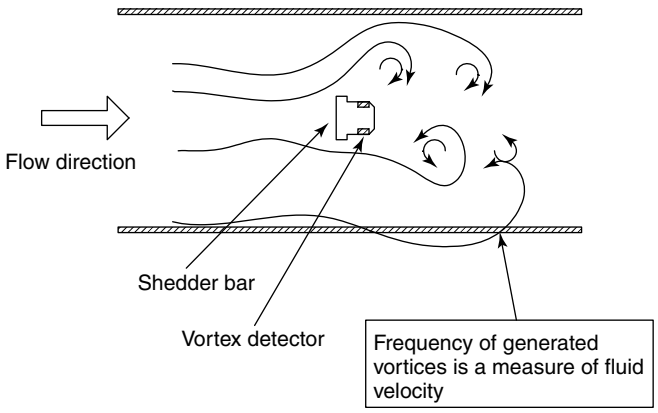

Figure 4. Principle of the vortex shedding flowmeter.

5.6 The electromagnetic flowmeter

The operation of the electromagnetic flowmeter is based on Faraday's law of induction that is when a conductor is moving perpendicular to a magnetic field, the voltage induced across the conduction is proportional to its velocity. In the case of the electromagnetic flowmeter, the conductor is the fluid being metered, while the induced voltage is measured using electrodes in the pipe wall. Since in most applications, the pipe wall of the flowmeter is made from a conductive material such as stainless steel, an inner nonconducting liner is required to insulate the electrodes and prevent the generated voltage signal from being dissipated into the pipe wall. Coils on the outside of the pipe are used to generate a magnetic field across the fluid, with simpler AC coil excitation methods, which suffer from zero drift problems, being

increasingly replaced by pulsed DC excitation techniques, which do not.

The electromagnetic flowmeter has a number of advantages over traditional flow measurement techniques and some characteristics of an ideal flowmeter. The flowmeter has no moving parts, does not obstruct the pipe at all, is available in a very wide range of pipe sizes, and may be used to measure bidirectional flows. A measurement accuracy of typically $\pm 0.5\%$ of reading over a range of at least 10:1 is possible. The flowmeter's accuracy is also unaffected by changes in fluid viscosity and density and may be used to meter difficult mixtures such as slurries and paper pulp.

The major limitation of the electromagnetic flowmeter is that it can only be used with fluids with a conductivity of typically greater than $5\,\mu S\,cm^{-1}$, although special designs are available for use with liquids with conductivities as low as $0.1\,\mu S\,cm^{-1}$. The flowmeter is therefore not suitable for use with gases, steam, or nonconducting liquids such as oil. The flowmeter's calibration is also sensitive to changes in flow velocity profile, although it requires a shorter straight length of pipe upstream of the meter than the orifice plate or turbine meter. Although electromagnetic flowmeters do not require significant maintenance, care must be taken during operation to ensure that the liner does not become damaged and that significant deposits do not build up on the electrodes since these can cause changes in the calibration or, in some cases, cause the flowmeter to stop functioning altogether. Even if these effects are minimized, electromagnetic flowmeters will require periodic recalibration using either traditional techniques or an electronic calibrator now available as an accessory from most manufacturers.

5.7 The ultrasonic flowmeter

The dream of producing a universal noninvasive flowmeter has been the catalyst for the many different ultrasonic flowmeter configurations, which have been investigated over the last 40 years (Lynnworth, 1989). However, most ultrasonic flowmeters commercially available today can be placed into one of two categories; Doppler and transit-time.

The ultrasonic Doppler flowmeter is based on the Doppler shift principle. Ultrasound at a frequency of typically 1 MHz is transmitted at an angle into the moving fluid being monitored. Some of this energy will be reflected back by acoustic discontinuities such as particles, bubbles, or turbulent eddies. The difference in frequency between the transmitted and received signals (the Doppler frequency shift) is directly proportional to the velocity of the flow.

The ultrasonic transducers, which are used to transmit and receive the ultrasound, are usually located in a single housing, which can be fixed onto the outside of the pipe, and so a simple clamp-on flowmeter, which is easy to install and is completely noninvasive, is possible.

The reflected ultrasound does not consist of a single frequency but a spread of frequencies resulting from reflections from a range of different-sized discontinuities, which may also be travelling at different velocities through the detection area. For liquids, the frequency of the transmitted ultrasound may lie in the range from 500 kHz up to a few MHz. At 500 kHz, discontinuities must have a diameter of approximately $50\,\mu m$ in order to reflect ultrasound back to the receiver. Increasing the operating frequency will allow the detection of smaller particles but at the cost of reducing the penetration of the transmitted signal into the fluid. The flowmeter is also sensitive to changes in flow velocity profile and the spatial distribution of discontinuities in the flow. As a result, the accuracy of Doppler flowmeters is poor, typically $\pm 5\%$ of full scale. However, this can be improved by calibrating the flowmeter online. Since there is a large acoustic mismatch between steel and air, clamp-on Doppler flowmeters cannot be used for metering gas flows or, of course, totally clean liquids where there are insufficient reflecting particles or bubbles to produce a reliable Doppler signal.

Figure 5 illustrates the basic principle of the ultrasonic transit-time flowmeter. Two ultrasonic transducers are mounted on either side of the pipe so that ultrasound can be transmitted across the fluid flowing in the pipe. The difference in the time taken for a pulse of ultrasound to travel between transducer 1 and 2 (with the flow) and transducer 2 and 1 (against the flow) is given by

$$\Delta T = \frac{2lv\cos\theta}{c^2 - v^2\cos^2\theta} \tag{2}$$

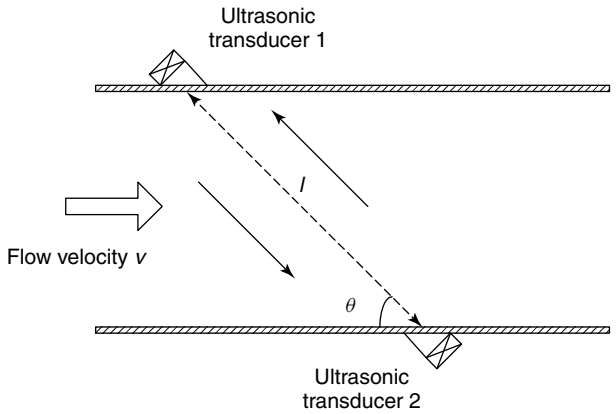

Figure 5. Principle of the transit-time ultrasonic flowmeter.

Since the velocity of sound in the fluid c is much greater than the velocity of the fluid v,

$$\Delta T \approx \frac{2lv\cos\theta}{c^2} \tag{3}$$

Therefore, if the velocity of sound in the fluid is constant, then there is a linear relationship between ΔT and v.

Although this method is elegant and straightforward in principle, in practice, there are difficulties since ΔT can be small and the change in ΔT that occurs with changing fluid velocity can be even smaller (typically fractions of μs per meter). In addition, as 3 shows, if the temperature of the fluid changes, c will change. Measurement of, and correction for, changes in the fluid temperature are usually needed. Transit-time flowmeters therefore require complex signal conditioning and processing.

The flow velocity v that is calculated using (3) is the average velocity along the transmission path between the two transducers, and so the flowmeter's calibration will be very dependent on the flow velocity profile. The problem of flow regime dependency can be significantly reduced by using a configuration of several parallel ultrasonic beams and averaging the measured mean velocity along each beam to calculate the overall fluid velocity. This is analogous to numerical integration, and a wide of range of multibeam configurations have been proposed, each with their own advantages.

Single path ultrasonic transit-time flowmeters have a typical accuracy of ±2% of reading over a range of at least 100:1. Although this type of flowmeter can be used with liquids or gases, clamp-on designs can only be used with liquids. Multibeam flowmeters have an improved accuracy but are more expensive. However, they are finding increased use in high value applications like the custody transfer of natural gas. Unlike most other flowmeters, the cost of transit-time flowmeters does not increase significantly with pipe diameter. Transit-time flowmeters are intended for use with clean fluids, although most can still operate if there are a small amount of impurities present in the flow.

See **Article 118, Ultrasonic Sensors, Volume 2**; **Article 119, Ultrasonic Instrumentation Principles, Volume 2**; and **Article 120, Ultrasonic Instrumentation Design, Volume 2** for information on ultrasonic sensors, and ultrasonic instrumentation principles and design.

5.8 The mass flowmeter

The most common type of mass flowmeter used today is the Coriolis flowmeter. As the name suggests, the principle of operation makes use of the Coriolis effect, which was discovered by Gustave Coriolis in 1835. The fluid being metered passes through a vibrating tube, and as a result of the Coriolis force acting on it, the fluid will accelerate as it moves towards the point of maximum vibration and decelerate as it moves away. This will result in flexure of the tube, the amount of flexure being directly proportional to the mass flowrate of the fluid.

The first commercial Coriolis flowmeter used a U-shaped tube but now many different configurations exist, including dual loops and straight through designs. Each design has its own advantages, with factors such as accuracy, repeatability, and pressure drop varying from design to design.

Whichever design is used, the Coriolis flowmeter is a high accuracy instrument, which may be used to meter gas or liquid with an accuracy of typically ±0.25% of reading. Measurement range varies with design but 100:1 is possible for U-tube designs and 50:1 for straight tube designs. Since the flowmeter measures mass directly, changes in density, viscosity, pressure, and temperature does not affect the calibration of the flowmeter. The flowmeter is also not affected by changes in flow velocity profile or other flow disturbances such as swirl. The flowmeter does not obstruct the flow at all and can be used to meter flow in both directions. However, the pressure drop across U-tube designs can be a limitation with viscous fluids.

The major disadvantage of the Coriolis flowmeter is its cost, which is high in comparison to most other flowmeters. This cost may be justified in applications where the product cost is high or where mass flowrate of the fluid is required. The cost and weight of the Coriolis flowmeter increases significantly with increasing pipe diameter and, as a result, are usually limited to pipe diameters of less than 100 mm.

Unlike most of the flowmeters discussed so far, the Coriolis flowmeter can meter some difficult two-phase flows. For example, reliable measurements of the mass flowrate of liquid/gas mixtures are possible if the gas component is small and well distributed, and therefore, the mixture is acting like a pseudohomogeneous fluid. The percentage of gas that can be tolerated by the flowmeter will depend on the viscosity of the liquid component. The less viscous the liquid, the more likely the gas is to separate out and cause problems. Liquid/solid flows (slurries) may also be metered, although the user has to compromise between avoiding particle dropout and avoiding excessive fluid velocities, which would result in accelerated wear of the flow tube.

Details of less commonly used types of mass flowmeters such as those based on thermal principles can be found in Baker (2000).

6 MULTIPHASE FLOW MEASUREMENT

There is a growing demand in areas such as the petroleum and food industries to be able to measure two-phase flows such as liquid with entrained gas or liquid with solids. Yet, the measurement of such flows nearly always presents difficulties to the process engineer.

For example, an ideal flowmeter would be able to directly measure the volumetric flowrate of a liquid, whether it is all liquid or contains a second phase of gas. Unfortunately, most of the flowmeters described above can usually only be used to meter two-phase flows when the second component is small. A review of the performance of conventional flowmeters in two-phase flows can be found in NEL (1997).

The alternative to direct flow measurement is to use an inferential method. An inferential method for liquid/gas flow would require the velocity of the gas and the liquid phases (v_g and v_l) and cross-sectional fraction of the gas phase (α) to be independently measured in order to calculate the volumetric flowrate of the mixture Q_m:

$$Q_m = v_l A(1-\alpha) + v_g A\alpha \tag{4}$$

The overall uncertainty of the flowrate measurement would depend on the accuracy with which the independent measurements can be made. The velocity of the liquid and gas phases cannot be assumed to be the same, and the way the gas is distributed in the liquid (the flow regime) will change depending on factors such as gas content, individual phase velocity, and pressure. Even in a simple case such as this, it is clear that multiphase flow measurement is by no means straightforward. For this reason, commercial multiphase flowmeters are generally expensive and target at very specific applications.

The most common two-phase flows are liquid/gas (e.g. gas in water), liquid/liquid (e.g. water in oil), gas/solid (pneumatically conveyed solids), and liquid/solids or slurries (e.g. coal in oil). Each presents its own measurement problems, and it is not feasible to discuss all possible metering combinations for these types of flow in a overview article such as this. For further details of two-phase flow measurement techniques, see Rajan, Ridley and Rafa (1993), while the important area of three-phase flow measurement is considered in a paper by Thorn, Johansen and Hammer (1997).

1 GENERAL PRINCIPLES

Calibration is defined as follows: 'The set of operations that establish, under specified conditions, the relationship between values of quantities indicated by a measuring instrument or measuring system and the corresponding values realized by standards.'

It is important to recognize at the outset the definition of a 'calibration' and to note that the 'comparison' applies only to the conditions at the time of the calibration. The purpose of calibration is to increase the confidence in the reading obtained from the flowmeter in service.

Standards for flow measurement are based on a comparison of the quantity of fluid passed, or passing, through the flowmeter with the quantity measured by the standard. Standards can be based on the measurement of mass or volume. The required mass or volume quantity can be calculated from the measured quantity from a knowledge of the fluid density at the test flowmeter. Standards may be static or dynamic, and this choice is made on the basis of the output and end use of the flowmeter. Some flowmeters are used to measure quantity and have a fast response time; others are designed to measure flow rate and have a slow response time. Calibration of a flowmeter should cover a significant flow-rate range for the flowmeter and establish a performance across that range.

A 'standard' for flow calibration should replicate as closely as practicable the conditions under which the flowmeter will be used. Full replication is impossible, and the key to success is to be as close as practicable, and to recognize the nature and performance of the flowmeter type being tested. The factors that should be addressed are the fluid viscosity, the installation effects due to bends and fittings, temperature, and pressure. The standard should also have a defined traceability and uncertainty chosen to match the expectation of the final measurement.

The choice of standard must also recognize the dynamic performance of the flowmeter and the nature and resolution of the output. As a calibration is a comparison, the quantity measured by the standard must match the quantity measured by the flowmeter and this must take cognizance of the resolution of the flowmeter. A flowmeter used to measure very large quantities of fluid over a long period of time may not have a resolution suitable for measuring the smaller quantities measured by a standard.

The result of a flowmeter calibration will normally provide two related figures: one related to the flow rate and the other as a performance indicator. Flow rate will be expressed as mass per unit time, volume per unit time, Reynolds number, or some other flow rate–related measure. The performance indicator relates the expected performance of the meter to the measured performance. Examples of performance indicators are K-factor, error, and meter factor.

2 GRAVIMETRIC CALIBRATION OF LIQUID FLOWMETERS

A flowmeter can be calibrated gravimetrically by weighing the quantity of liquid collected in a vessel. The vessel is weighed and the weight (in air) of the fluid collected is noted.

As the quantity of fluid has to be expressed as mass, the weight has to be corrected for the effect of air buoyancy. As a weighing machine is calibrated using weights with a conventional density of $8000\,\mathrm{kg\,m^{-3}}$, and the fluid collected will have a significantly different density, the upthrust of the air on the tank will have a significant effect. This amounts to around 0.1% for water. This correction is given in (1).

$$M = W \times \left\{1 + \rho_{\mathrm{air}} \times \left[\frac{1}{\rho_{\mathrm{f}}} - \frac{1}{\rho_{\mathrm{w}}}\right]\right\} \qquad (1)$$

where M is the mass, W is the measured weight, ρ_{air} is the density of air, ρ_{f} is the density of the fluid, and ρ_{w} is the density of the calibration weights (by convention, $8000\,\mathrm{kg\,m^{-3}}$).

To determine the volume, the mass is divided by the density determined at the flowmeter. Density can be measured using a densitometer but is more often calculated from a knowledge of the fluid properties and measurements of temperature and pressure at the test meter.

2.1 Standing-start-and-finish method

This method is generally preferred for flowmeters that are used for measuring the quantity of liquids, especially flowmeters for batch quantities (Figure 1).

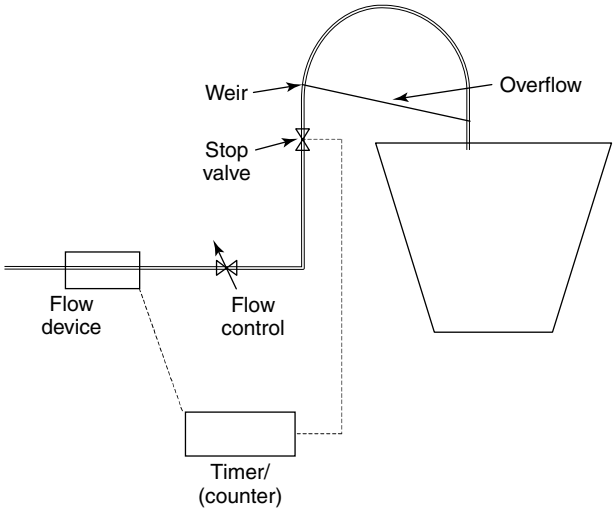

Figure 1. Standing-start-and-finish method for the gravimetric calibration of liquid flowmeters.

The required flow rate is established into the tank. The flow is then stopped using a fast-acting valve, the container drained, and the drain valve closed. The flow is restarted, the container filled, and the flow stopped. The weight of liquid is noted along with the time taken to fill the tank. The reading from the flowmeter is also noted. Temperature and pressure of the liquid at the flowmeter are also noted during the fill.

2.2 Flying-start-and-finish method

This is sometimes called the *diverter method*. In this method, the flow through the flowmeter is not stopped but the flow is diverted between a return to the supply and the collection tank (Figure 2). A switch on the diverter mechanism starts and stops a timer to time the filling of the collection measure and counter to totalize pulses from the test device.

In this method, the key to accurate measurement is a clean separation between fluid entering the tank and fluid returning to the supply.

Flying-start-and-finish methods are used primarily for flowmeters with slow response times and where flow rate is the primary measurement rather than quantity passed. Flowmeters with visual displays cannot be calibrated by this method.

The main source of uncertainty for both gravimetric calibration methods lies in the timing error. In the case of the standing-start method, this is caused by the response time of the flowmeter and the changing flow at each end of the test. For the diverter methods, this is introduced by not triggering at the hydraulic center of the liquid jet.

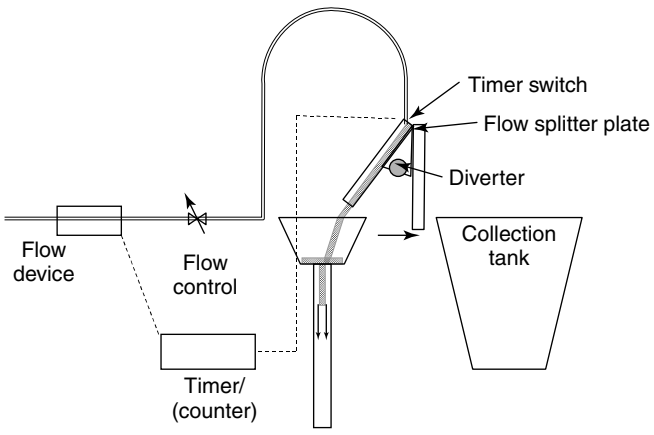

Figure 2. Flying-start-and-finish method for the gravimetric calibration of liquid flowmeters.

3 VOLUMETRIC CALIBRATION OF LIQUID FLOWMETERS

The measurement of the quantity of liquid collected may be carried out volumetrically, that is, by collecting a known volume of liquid in a container. In the volumetric method, the standard vessel takes the form of a container with calibrated volume. Normally, this would be a pipette with conical ends to facilitate drainage and to reduce the risk of air entrapment. The neck of the pipette is normally fitted with a sight glass and a scale marked in volumetric units. A typical volumetric tank is shown in Figure 3.

The tank volume must be determined by calibration against weighed water contained in the vessel, or by using smaller volumetric measures that are themselves traceable to national standards by weighing methods.

Volumetric systems are normally used with standing-start-and-finish methods owing to the difficulty of diverting flow into the tank and controlling the finish of the fill. Drainage time (after the tank is empty) is vitally important, as liquid clingage to the wall can be significant. Each tank has a calibrated drain time and this must be maintained.

Reference volume tanks and pipe provers have their volume defined at a stated reference temperature (and pressure). Normal reference temperatures are 15 °C or 20 °C. For all volumetric methods, corrections due to the expansion and contraction of both the standard and the device being calibrated have to be accounted for along with the expansion and contraction of the fluid between the standard and the flowmeter. This applies to both thermal and pressure expansion.

Pipe provers provide a dynamic volumetric calibration standard method for calibration. They provide a sealed system providing high-accuracy calibrations in situ as well as in laboratories. 'Proving' is used extensively in the oil industry and is generally synonymous with calibration.

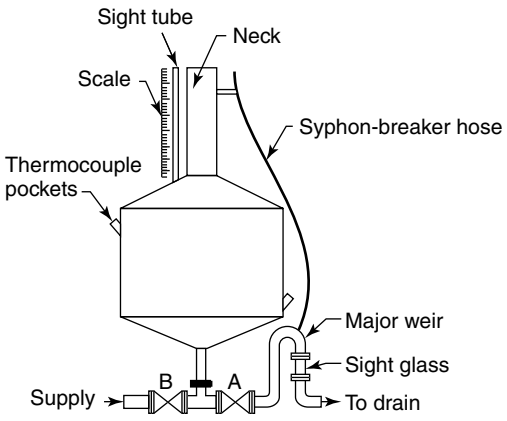

Figure 3. A volumetric tank.

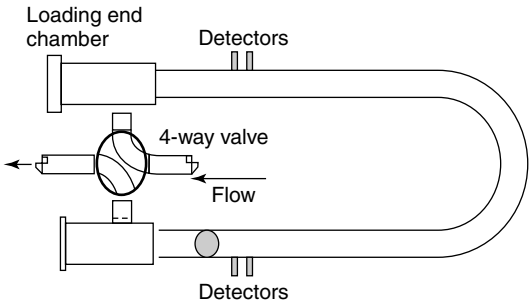

Figure 4. A bidirectional prover.

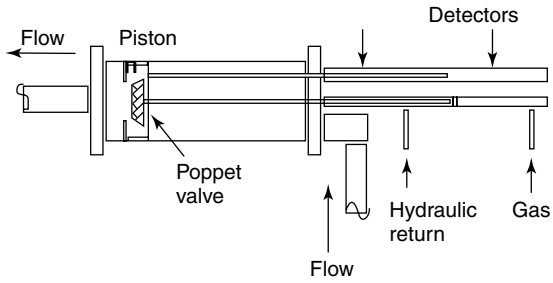

Figure 5. A small volume prover.

A length of pipe is fitted with switches such that the volume between the switches is known. If a displacer, or 'pig', is introduced to the flow, the time it takes to travel between the switches will give a measure of the flow rate. If the switches are used to gate a pulse counter, totalizing pulses from a flowmeter, a measure of the flowmeter factor (pulse per liter) can be found.

A variety of designs are available, and one of the most common, the bidirectional prover, is illustrated in Figure 4.

A four-way valve, of very high integrity, changes the flow path without breaking the flow. The sphere is held in special end chambers. These are designed to launch the sphere and absorb the shock of capture. One chamber also provides a means of removing the sphere. Note from Figure 4 that two switches are provided at each end. This provides better integrity of the measurement by giving redundancy and a means of checking results by developing four separate volumes.

A small volume prover is a pipe prover where the length, diameter, or volume is smaller than that required to obtain 10 000 pulses from the flowmeter. A proprietary device is illustrated in Figure 5, where a precision pipe and a piston along with optical detectors are used. Flowmeter resolution is effectively increased using pulse interpolation.

4 CALIBRATION OF GAS FLOWMETERS

In general, all the methods for the calibration of gas flowmeters have analogies with liquid methods. The main

difference between the calibration of a gas and a liquid flowmeter is the compressibility of the gas and the fact that the gas has to be contained in a closed container. As gas is compressible, the volume measured at the standard and the volume measured at the test device have to be corrected to a common or to a 'standard' condition.

Volume standards generally take the form of displacement devices much akin to flowmeter provers. Three common examples are discussed.

A common standard used extensively for lower pressure calibrations is the 'bell prover' (see Figure 6). In this device, air is displaced into a calibrated bell, which rises or lowers as the bell is filled. A bath of oil or water acts as the seal.

Piston provers for gas are based on a very light and low-friction piston displacing gas from a smooth cylinder. The piston may be driven by the gas or from a mechanical mechanism. The example of the mercury-seal piston prover is illustrated in Figure 7.

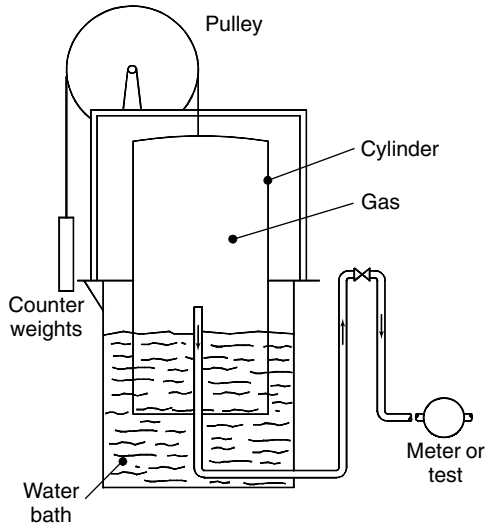

Figure 6. A bell prover.

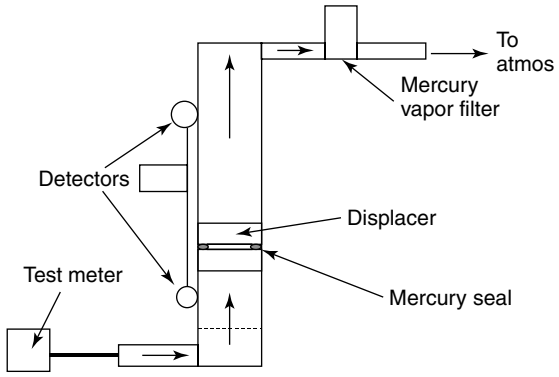

Figure 7. A mercury-seal piston prover.

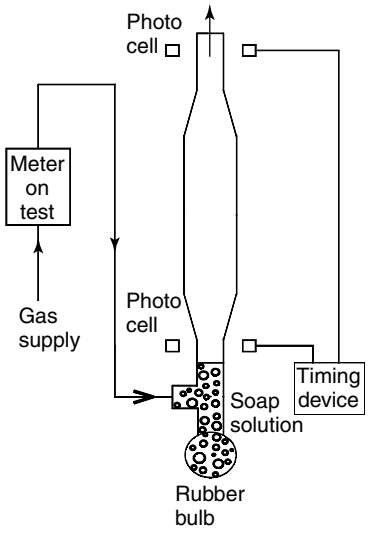

Figure 8. A soap-film burette.

Another device for the measurement of very low-pressure gas is the soap-film burette where the piston is replaced by a soap film (Figure 8).

Gas flowmeters can also be calibrated using mass as the reference quantity. This can be done gravimetrically by weighing high-pressure gas collected from, or delivered to, a test meter. Alternatively, the mass can be calculated using PVT (pressure/volume/temperature) calculations if a fixed volume is used.

Critical flow nozzles provide an extremely stable calibration device. In this device, when the velocity of gas reaches the speed of sound in the throat of the nozzle, the mass flow will be a function of the upstream pressure and the properties of the gas only. This allows measurement of mass flow to 0.3% using a standard nozzle and down to 0.1% if the nozzle has been calibrated. The equation is given by (2).

$$\frac{\mathrm{d}m}{\mathrm{d}t} = C_\mathrm{d} C^* A_\mathrm{t} P_\mathrm{o} \frac{1}{\sqrt{RT_\mathrm{o}}} \tag{2}$$

where C_d is the discharge coefficient, C^* is the critical flow factor, A_t is area of the nozzle throat. P_o and T_o are the upstream pressure and temperature.

5 MIXED OR MULTIPHASE FLOWMETERS

Multiphase flowmeter applications are commonly used for two main applications.

The first application is for mixtures of oil, gas, and water, particularly in the offshore production of hydrocarbons. Meters can be calibrated at a dedicated laboratory such

as NEL in the United Kingdom. Flows of oil, water, and gas are separately metered and combined upstream of the meter. They are then separated and recirculated. The multiphase flowmeter reading is compared with the single-phase measurements. In the field, flowmeters are 'calibrated' or assessed against a 'test separator'. The metered multiphase flow is introduced to a separator and the single-phase measurements from the separator are measured over long time periods.

The second application of multiphase meter is to meter 'wet' gas. This type of meter can also be calibrated in a specialist laboratory, such as NEL, by injecting measured quantities of liquid to a measured gas flow. In the field, dilution tracer techniques can be used to estimate the flow rate of the liquid phase, hence giving a measure of the correction to be applied to the primary gas meter previously calibrated in dry gas.

6 IN SITU OR FIELD CALIBRATION

In an ideal world, all flowmeters would be calibrated in situ, hence avoiding differences in fluid and installation changing the calibration of the flowmeter. In practice, this cannot be done with low uncertainty as the field installations and the possible standards are not suitable.

In the oil industry and for fiscal installations, it is common to have flowmeter provers permanently installed and valve arrangements in place to allow calibration of a bank of flowmeters to be carried out at any time. In other applications, mobile flowmeter provers or even volume tanks can be taken to the installation. This concept is used for high-accuracy systems and for lower-uncertainty systems such as petrol dispensers.

Where a portable volume standard is impractical, reference flowmeters can be installed in series. The various effects of installation and fluid conditions have to be recognized. This applies also to differences between the in situ use and the laboratory calibration of the meter. A different type of reference flowmeter that can be used is the clamp-on ultrasonic meter. In this type, the sensors are strapped to the outside of the pipe wall and the flowmeter measures the velocity of the fluid. If the pipe diameter is known, the flow rate is calculated. Although improved greatly in recent years, uncertainties of better than 1% cannot be expected and 5 to 10% is not uncommon.

Insertion meters can be used to 'verify' the calibration of in situ meters. An insertion meter can be a pitot tube, an electromagnetic sensor, a turbine type sensor, or a thermal sensor fitted to the end of a probe, which can be inserted into the pipe through a fitting on the wall. The point velocity of the fluid is measured, and hence the bulk flow rate calculated. 1 to 10% uncertainties can be expected.

A final technique is to use tracer fluids injected into the fluid to measure the flow. Two methods are used. In the first, a radioactive tracer with a very short half-life is injected as a pulse into the flow. The tracer is injected some distance upstream of a detector strapped to the pipe wall. A second detector is located a measured distance downstream. The time taken for the tracer to travel between the detectors gives a measure of the flow. In the second technique, a chemical tracer is continuously injected at a measured rate into the flow. A sample is withdrawn from the flow some distance downstream and the concentration of the chemical is analyzed. The concentration gives a measure of the flow.

Further information on the calibration of flowmeters can be found in Baker (2000) and Spitzer (2001).

1 DISPLACEMENT AND ANGLE SENSOR CLASSIFICATION

There is a large range of displacement sensors that operate on different physical principles. Some of the basic principles may be capacitance and capacitive effects, magnetism and magnetic effects, optics and its properties, piezoelectric materials and their properties, conductivity of electric conductors, radio and microwave techniques, mechanical means, and so on. Also, within each range many sensors may be available in various sizes and shapes to suit different application requirements. In general, displacement sensors can be classified as

1. *Capacitive displacement sensors*

   Variable plate-distance capacitive sensors
   Variable-dielectric capacitive displacement sensors
   Variable plate-area capacitive displacement sensors
   Differential capacitive sensors.

2. *Magnetic displacement sensors*

   Linear variable-reluctance displacement sensors
   Single-coil linear variable-reluctance sensors
   Variable-differential reluctance sensors
   Linear variable-inductive sensors
   Variable-coupling sensors
   Eddy current displacement sensors
   Linear variable-differential transformers.

3. *Piezoelectric and piezoresistive displacement sensors*

   Resistive displacement sensors
   Strain gauge sensors
   Piezoresistive displacement sensors.

4. *Optical displacement sensors*

   Optical fibers
   Interferometric sensors
   Time-of-flight and frequency shift sensors
   Encoders and digital displacement sensors.

5. *Radio Frequency (RF) and microwave displacement sensors*

   RF position sensing
   Microwave sensors
   Global Positioning System (GPS) systems.

6. *Acoustic and ultrasonic displacement sensors*
7. *Angular displacement sensors*

   Tachogenerators
   Microsyn
   Synchros

Rotary variable-differential transformers.

2 KEY PARAMETERS IN SELECTION OF METHOD

The key parameter associated with these measurements is the magnitude of displacement. The nature of the process that results in the displacement is also significant in determining the type of instrument to be selected. From the basic principles, the displacement is closely associated with acceleration and velocity. Double integration of acceleration and single integration of velocity yield the displacement of an object. Therefore, some devices that resemble acceleration and velocity sensors can easily be modified for displacement measurements.

There will usually be available a variety of suitable sensors that could be used for a particular application, as shown in Figure 1. For a particular application, if a choice is available, the selection may be based on factors such as cost, speed in readings, accuracy and precision, availability, and so on. For example, capacitive displacement sensors may satisfy the requirements of applications in which high linearity and wide ranges from a few centimeters to a couple of nanometers in a cost effective manner whereas similar characteristics with greater accuracy may be obtained by optical methods but at a greater expense.

Capacitive and magnetic displacement sensors enjoy a wide range of industrial applications. In capacitive sensors, precision signal processing allows sensing of capacitance changes down to a few femtofarads. There are a number of different capacitive sensors – *see* **Article 193, Specialty Displacement and Angle Sensors, Volume 3**. For example, the variable plate-distance capacitive sensors are often used for measuring small incremental displacements without making contact with the object. Variable-dielectric capacitive displacement sensors are mostly used in the form of two concentric cylinders for measuring the level of nonconducting fluids in tanks. These types of sensors are used as rotating capacitors for angular displacement measurements.

Similar to capacitive displacement sensors, the magnetic displacement sensors come in various shapes and sizes. They have a diverse range of applications. Linear variable-reluctance displacement sensors are used in acceleration measurements or they can be configured for sensing displacements and velocities. Whereas, eddy current displacement sensors are mainly the probe type for sensing the presence of electrically conductive targets, variable-reluctance magnetic sensors are used in specialized applications such as pressure measurements. Variable-differential reluctance sensors respond to static and dynamic displacements.

In the linear variable-differential transformer (LVDT), there is no physical contact between the core and the coil

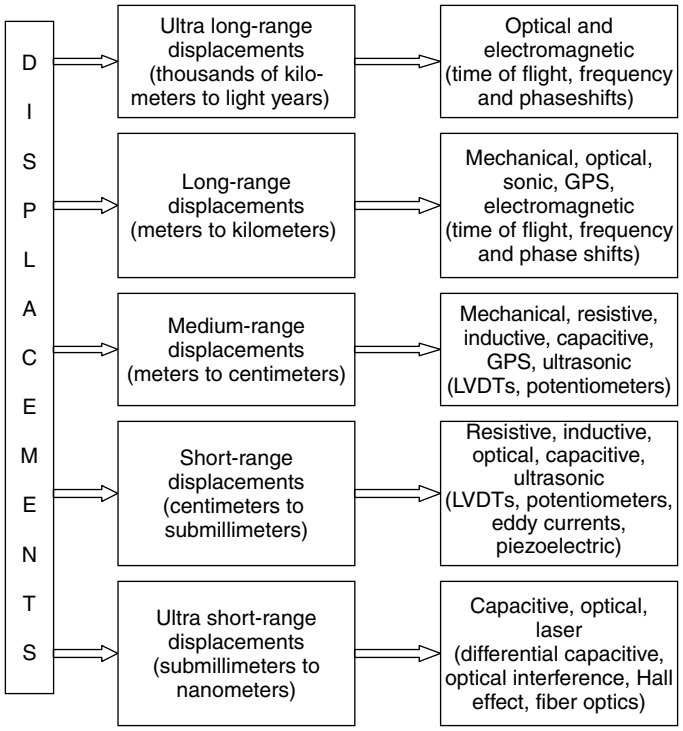

Figure 1. Most commonly applied displacement measurement techniques.

form; thus, there is no friction or wear. Hence, they find a variety of applications in which continuous displacement measurements need to be made, such as in jet engines or in measuring roll positions in the thickness of materials in hot-slab steel mills. After some mechanical modifications of LVDTs, force and pressure measurements can also be made.

A typical commercial LVDT sensor is illustrated in Figure 2. This particular sensor is suitable for high-temperature applications.

The piezoelectric displacement sensors are useful for general-purpose motion and for vibration measurements from low- to medium-frequency displacements. They are often manufactured in the form of piezoelectric ceramic cartridges giving inexpensive but highly reliable displacement measurements.

Piezoresistive displacement sensors are used in vibration measurements at low frequencies (e.g. below 1 Hz).

Optical methods are commonly used in displacement sensing, particularly where high precision and small displacements are involved.

An example of commercial fiber-optic distance measurement devices is illustrated in Figure 3. The resolution of this device is 2.5 μm.

The laser interferometric sensors operate on precise wavelength monochromatic light and are the most accurate in this family of sensors. An accuracy better than 1.0×10^{-9} m can be obtained. Encoders are used mainly for linear and rotary displacement sensing. Some of the encoders are manufactured to give resolution better than 1 μm.

For angle measurements, Microsyns are extensively used in applications involving gyroscopes. By using Microsyns, very small motions can be detected, giving output sensitivity as low as 0.01° of change in angles. The output of the device can be made as high as 5 V/1° of rotation. Synchros are primarily used in angle measurements and are commonly applied in control engineering as parts of servomechanisms, machine tools, antennas, and the like. In most rotary linear variable-differential transformers, the rotor mass is very small, usually less than 5 g. The motion in the radial direction produces a small output signal that can affect the overall sensitivity.

3 SELECTION DISPLACEMENT MEASURING METHODS

Displacement measurement techniques employ various transduction media, including sound waves, magnetic fields, electric fields, light, RF and microwave, and mechanical means. Selection of an appropriate method depends on the application characteristics, range, and other requirements. As mentioned earlier, the magnitude of the displacement is one of the important parameters; the selection of an appropriate displacement sensor to suit this requirement is essential. Some examples are as follows:

A simple way of sensing distance is the use of a linear potentiometer. The moving object is connected to the slider of the potentiometer so that each position along the axis corresponds to movement of the object. These position sensors can give a precision of 0.1%. Alternative methods are capacitive, induction, or other magnetic sensors. For very small distances, strain gauges can be used. Fiber-optic methods and laser interferometers are applicable when very precise changes within micrometer range must be sensed. They find applications in high-precision measurements such as numerically controlled machine tools. They basically compare the changes in optical path length to the wavelength of light. One particular advantage of the laser interferometer is that its output can readily be converted to digital form, since it is based on counting of the wave peaks.

In general, capacitive, magnetic, resistive, and piezoelectric sensors are suitable for subcentimeter measurements. Capacitive sensors are particularly suitable in applications such as automotive, in robotic systems as miniature control elements, in medical applications for tissue deformation, in implant micromotion, in materials science, in civil engineering, in structural deflections, and so on.

In robotic grasp applications, electro-optical techniques are often used. These sensors are relatively small in size, and are known to have a large range of operation. In this particular application, relatively new ultrasonic and capacitive sensors are used.

Figure 4. A typical optical distance sensor. (Courtesy of MTI Instruments Inc., http://www.mtiinstruments.com/.)

Optical methods, RF, GPS, ultrasonic, and microwave techniques are selected for sensing large displacements. In optical, RF, ultrasonic, and microwave techniques, time of flight, phase shift, and frequency change methods are employed by means of comparing the transmitted signals with the returned signals.

A typical commercial optical sensor is illustrated in Figure 4. This device measures distance, displacement, vibration, or thickness without contact for distances of up to 152.4 mm.

A linear digital encoder gives an output, which is a binary number that is proportional to the distance of the encoder relative to a fixed point. Digital encoders provide a set of binary digital signals directly, they require slides with precision printing, good light sources and detectors.

4 SELECTION STRATEGY FOR ANGLE MEASURING METHODS

In the angle-measuring methods, the sensing and measurement of rotational movement is absolutely necessary in many industrial applications since almost all industrial machines include rotations. The simplest form of sensing angular velocity is by using the AC or DC generators commonly known as *the tachogenerators*.

In some applications, signals are generated for each revolution of the wheel or the shaft optically or by means of piezoelectric or magnetic pulsing arrangements. These pulses enable the determination of the angular velocities as well as positions of shafts or wheels.

Angular methods for displacement measurements can be grouped to be small or large angular measurements. Small displacements are measured by the use of capacitive, strain gauge, or piezo sensors. For larger displacements, potentiometric, or inductive techniques are more appropriate. The rotary digital encoders also find wide applications.

Resistive angle and displacement sensors (also known as potentiometers or pots) are commonly used. In potentiometers, an electrically conductive wiper slides against a fixed resistive element according to the angle of displacement of an external shaft. The pot operates on the voltage division principle; therefore, the analog voltage output can directly be used as the indication of angle or it can be digitized.

An alternative resistive angle measurement is the magnetoresistive potentiometer available for linear and rotary applications. In this case, a nonconducting, permanent magnet wiper rides above a pair of magnetoresistive elements.

Microsyn transducers are used extensively in applications involving gyroscopes. By this method, very small angles can be detected, giving measurements as low as 0.01° of change in angles. The sensitivity of this device can be made as high as 5 V per degree of rotation.

5 EXCITATION METHODS AND THEIR CHOICE

Excitation requirements vary from sensor to sensor. Resistive angle and displacement sensors are known to operate on the simplest excitation method by means of supplying a stable DC voltage source across the terminals. Nevertheless, the outputs of these sensors can be highly nonlinear owing to the loading effects that may require some form of linearization. Some of these linearization techniques include terminal-based linearity, absolute linearity, and zero-based linearity – *see* **Article 58, Description of Accuracy, Linearity, and Drift, Volume 1**. Potentiometers are available with linearities ranging from 0.1 to 1%.

A stable AC excitation is essential for magnetic sensors. For example, an inductive linear-variable sensor uses a bridge that is excited typically with 5 to 25 V AC source with a range of frequency of 50 Hz to 5 kHz. They usually deliver a DC output after internal processing of the phase sensitive system.

Another example is the linear variable-differential transformers or the LVDT that requires a stable AC supply with frequency of 50 Hz to 20 kHz. The typical recommended excitation voltage for an LVDT is 4 to 6 V AC with a nominal frequency of 5 kHz.

In the case of capacitive sensors, the frequency responses can be several kHz (typically 7 kHz). These sensors are used as part of a bridge network to process the output signals. In many situations, the signals obtained from the sensors are amplified by using suitable charge amplifiers. Modern IC (integrated circuit) sensors can operate with 2.5 V power supplies.

Excitation of optic, RF, and microwave sensors can be complex. They need highly stable voltage and current sources. For example, a balanced constant-current excitation uses a pair of matched constant-current sources to excite the sensor. This technique provides immunity from noise pickup. Manufacturers usually supply extensive information on excitation requirements of these sensors.

6 RELATIVE MERITS OF RESISTIVE, MAGNETIC, CAPACITIVE, AND OPTICAL SENSING

The relative merits of angle and displacement sensors can be explained in terms of their uses and characteristics. The main merits are as follows:

Inductive and capacitive sensors operate on magnetic and electric field principles respectively and they are suitable for small displacement and angle measurements such as the proximity determinations.

The LVDT works by moving a slug of high permeability material inside part of a transformer. An AC signal is applied to one side of the transformer, the voltage on the other side (across a resistor) is proportional to the displacement. They are suitable for small displacement measurements where friction is not allowed and precision is necessary.

Potentiometers are simply resistors that give a voltage output in response to displacements. They are suitable for small angle and displacement measurements.

Laser, microwave, or acoustic methods use different techniques such as the time of flight or frequency variations. They are generally used for large displacement measurements.

Optical and laser techniques use interferometric and optical gratings methods. They are a highly accurate measurement system but relatively more expensive.

1 BASICS OF THE STRAIN VARIABLE

An object is said to be strained when any of its length dimensions is altered by a small fraction from its nominal length. It can occur in tension or compression.

Strain ε is defined as a change in length ΔL, occurring in the length interval L when a force F is applied, the sense being positive for tensile strain and negative for compressive strain, Figure 1(a).

Being a ratio of two lengths, strain is a dimensionless number. To convey a more meaningful value, it is sometimes preferable to also state the units used as a ratio, such as μm/m. It can also be stated as a percentage but that can lead to confusion where the value has tolerance associated with the stated value. The term *microstrain* is often used, being a strain of 10^{-6}.

Strain is a three-dimensional property and hence is a vector quantity requiring three measurements to uniquely define its magnitude and direction. To ease measurement difficulty, they can often be devised to use a measurement in a known line or in a plane; it is rarely practical to make all three measurements at exactly the same point.

Several sources of strain can arise at the measuring point on an object under test. These are as follows:

- *Real or true strain* is the strain that is actually arising in the component. It is not necessarily produced only by mechanical force but can also occur because of temperature-induced forces.
- *Indicated strain* is the result at the output of the complete strain-gauge measuring system. Again, it is not necessarily the strain measurement that is needed because of instrumentation error.
- *Apparent strain* is the algebraic difference between real and indicated strain.
- *Mechanical strain* is the strain induced by mechanical forces, the measurement that is normally needed. Usually, it is the difference between real and thermal strain.
- *Thermal or temperature-induced strain* is caused solely by temperature, causing length change to the object according to its thermal coefficient of length, see Section 6.

Various delineated stresses exist, Figure 1(b):

Normal stress is a single component measurand occurring in pure tension or compression.

Bending stress arises when a rod is bent, causing the longitudinal fibers to elongate or compress as some function from a defined datum axis. The actual nature of the stress and the related strain is identical with normal stress.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

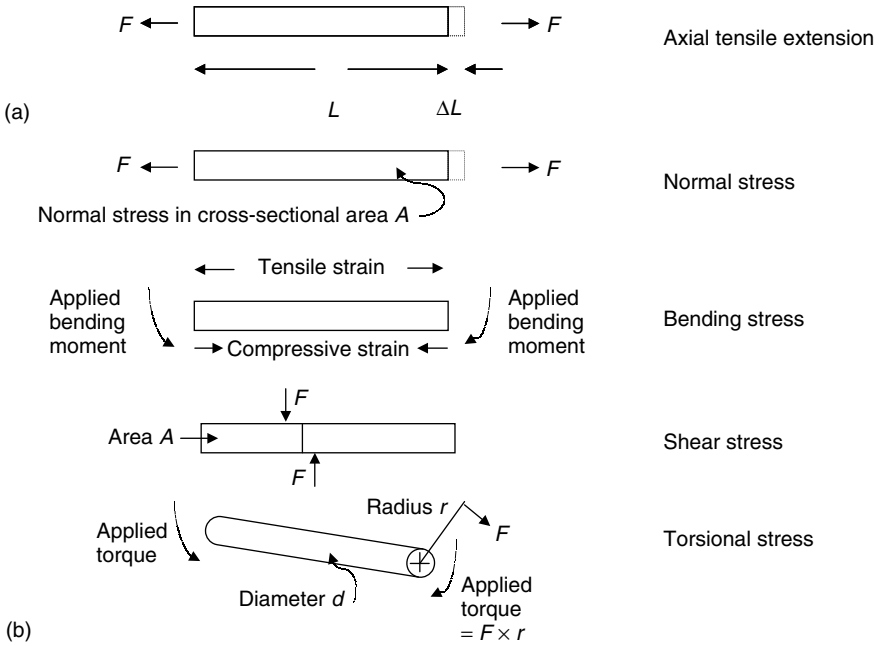

Figure 1. Types of stress and strain (a) definition of strain; (b) types of strain.

Shear stress is stress produced by strain invoked by forces acting to shear a bar along its axis of unbalanced forces.

Torsional stress is the stress arising when the subject is subjected to a rotational, twisting action.

Changes to shape because of the various stress situations all acting together produce complex stresses. Appreciation of these kinds of complex situations requires an advanced understanding of the strength of materials, which is not given here.

Finally, on this primer on the strain situation, correct application of strain gauges requires knowledge of material properties and calculation of the strength of materials data (Dally and Riley, 1991).

The following knowledge on strength of materials should suffice to appreciate how to apply strain gauges. Useful texts are Measurement Group Inc. (1988), Window (1992), and Khan and Wang (2000).

2 PROPERTIES OF MATERIALS

The elasticity of a material is characterized by its elastic or Young's modulus E where

$$E = \frac{\text{normal stress}}{\text{strain}} = \frac{\sigma}{\varepsilon} = P \times \frac{L}{A} \times \Delta L \qquad (1)$$

where P is the applied force, A the area of cross section of interest, and L the gauge interval over which the length change ΔL occurs.

This relationship only holds in the elastic, or Hooke's law region, of a material – *see* **Article 85, Elastic Regime of Design – Design Principles, Volume 2**. Stress levels can, therefore, be calculated from strain measurements. Direct sensing of stress is actually not easy to achieve.

Where the strain measured represents shear stress, the appropriate modulus to use for conversion into stress levels is the shear modulus G:

$$G = \frac{F}{\gamma} \qquad (2)$$

where F is the shear force applied and γ the angular shear distortion.

It can be shown that

$$G = \frac{E}{2(1+\mu)} \qquad (3)$$

where E is Young's modulus and μ is another material property constant known as *Poisson's ratio*.

Thus, appropriately placed strain gauges can measure the angular shear distortion γ, allowing computation of the existing force F at the point of measurement. From this, the stress level at that point can be deduced. Poisson's ratio μ is a measure of the amount to which a material will expand or contract in its longitudinal direction when compressed or tensioned transversely in that direction.

These considerations enable calculation of stresses from strain measurements in the ideal situation. Errors can arise

Table 1. Temperature coefficient of length for common construction materials.

Material	Temperature coefficient of length, α, $10^{-6}\,K^{-1}$
Ferritic steel	11
Austenitic steel	16
Aluminum	23
Titanium	9
Plastic	65
Molybdenum	5.4
Quartz	0

from many influence sources – *see* **Article 16, Reduction of Influence Factors, Volume 1** – the most prevalent being the effect of temperature.

All materials change dimension according to their coefficient of thermal expansion (TEMPCO), Table 1. While there exists some materials with very low values (such as fused silica, invar, carbon fiber), the materials used for construction (such as steels, concrete, glass, plastics, brick, wood, aluminum) have high values such that normal operating conditions produced significant strains in materials that will produce error on strain measurement if not catered for.

As an indication, steel expands at typically 16 parts per million per degree Centigrade. An ambient temperature change of, say, 30 °C will alter the size by 360 ppm, which, in a typical strain-gauge length of 5 mm, will produce a spurious absolute strain of 2.5 μm. Thus, temperature alone can generate strain without any external force being applied. Precision gauging needs to allow for this, especially where the object under test is subjected to a large temperature excursion, such as, for example, the temperature rise in the case of turbine blades in a jet engine.

Closely allied to this effect is the little known, but important, thermoelastic coefficient. This shows how Young's modulus varies with temperature. Steels, for example, become more elastic as their temperature increases, meaning that less stress is needed for the object to obtain a given strain excursion.

At times, another effect can arise if the material under test has significant magnetostriction. This is mentioned because steels with a nickel component (to make it stainless) might be considered for forming the test section (called a *load cell*). In such cases, it will experience a change in length if placed in a large DC magnetic field. For example, a load cell used to weigh the aluminum billets forming on an electrode in an electrolytic refinery process will exhibit this error significantly as the large through electrical current will generate large magnetic fields.

The third error source in strain-gauge measurements to watch for is the thermoelectric effect – *see* **Article 196, Thermocouple Temperature Sensors, Volume 3**. This arises when two dissimilar materials are subjected to a temperature differential along their length; it generates a small electric current due to the thermocouple (t/c) effect. Even a different batch of the same metal can sometimes exhibit a sufficient t/c effect such that small DC currents are generated in strain-gauge circuits that appear to be a strain. Wiring up sensitive strain-gauge circuits needs to allow for any t/c effect to ensure that it is small enough to be ignored.

With this background, it is now possible to appreciate the practical use of strain gauges.

3 INSTALLATION AND CALIBRATION OF STRAIN GAUGES

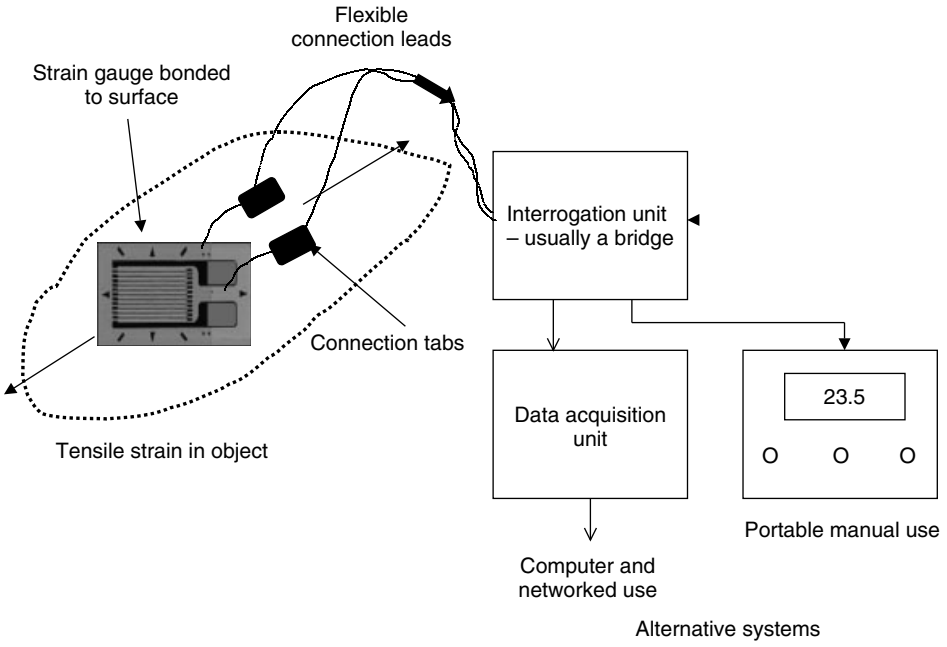
Strain gauges are produced in many forms of which the majority is a thin planar device glued, or (less used) clamped, to the surface of the test object, Figure 2. Their characteristics are covered for the two main types in Sections 4 and 5.

The major use of strain gauges is its application to a suitable surface of the object under test. This object could be a bridge support, the surface of a wing, or an automobile chassis member. They are also applied to rotating shafts, using slip rings or wireless communication to read their values. Sometimes, the object is specially formed into a load cell on which the gauges are applied; this permits the measurement of loads on crane hooks, in tensile test machines, weighing scales, portable tensile load measurement, and more.

To measure more than one of the possible strain components, it is necessary to apply a strain gauge for each component of strain. If it is known that pure tensile strain can be measured, then one gauge element is sufficient. In many cases, at least two components are required so manufacturers offer a range of multiple sets of gauges forming one unit – see Figure 3 for a small selection.

The sequence of tasks for a strain-gauge application that need early consideration is given in the following sequence:

1. Determine what kind of strain measurement is required. Determine how many axes are needed. Approximate calculations of expected stress and strain levels are performed to size up the gauge type that is needed. As a rule, the smaller the length of the gauge is, the lower is their sensitivity and the larger the effect of influences. Even this early, the designer needs to consider whether the task will be able to use a simple DC bridge interrogator – see Section 7. Use a gauge maker's catalog to see what is available.



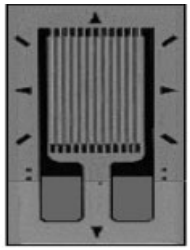


Figure 2. Basic units of a strain-gauge system.

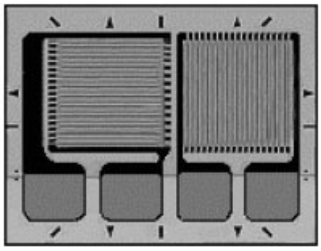
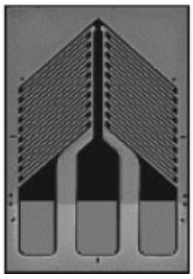


2. Decide where to place the gauge(s).
   This is dictated by there being sufficient strain to detect (a minimum of around 10-μ strain is needed as the discrimination) and there being good access for applying the gauge(s) where they can also be wired in and protected. The type of gauge initially selected is important as multiaxis types integrate several gauges into one unit that takes less space than when using several single-axis sensors. Orientation of the axes is likely to be more accurate in a self-contained unit than it would be when laying down a set of singles.
3. Learn how to apply them for a long reliable and repeatable lifetime.
   While the gauge type to be used is not yet decided, it is useful to look ahead at the process of application. Gauge makers often provide full pictorial instructions for cementing gauges to the various kinds of surfaces. The process needs some degree of hand skill, with lots of care and attention to detail. Every step they suggest is needed to obtain a long-lasting installation. The steps are as follows:

   (a) Roughen the application area to make it clean and ready.
   (b) Clean the area with the proprietary cleaner provided in the kit supplied.
   (c) Position the gauge with tape to hold it in place.
   (d) Apply the provided proprietary adhesive suited to the application.
   (e) Spread the adhesive with an applicator.
   (f) Press the gauge to the surface to displace spare adhesive. The thinnest possible layer of the adhesive is essential to keep self-heating effects to the minimum by the layer being less of a thermal insulator than the surface it is mounted upon.
   (g) Where possible, cure the adhesive with heat at the recommended time and temperature for the cycle time recommended. Where the gauge is not mounted on a portable object, heat lamps may be used. Follow the maker's recommendations.
   (h) Lay down the connection tabs and solder on the strain-gauge ribbons.
   (i) Solder in the special light gauge connection wires to the fixing cable tabs and secure the ends of the cables well.
   (j) Coat the gauge with the right kind of coating compound. This protects the gauge from a modest amount of mechanical impact and from chemical attack. Use the proprietary coatings supplied. Definitely, do not use the commonly available acetic acid–based silicon compounds as they will eat the gauge foil away in days!

   If all goes well, the gauge readings, when first set up, will give a reasonably well-balanced bridge condition, at least within ±2%. If not, then something has gone wrong and application of a new gauge is needed from the beginning of the process given here. Take care not to test arm resistances with too high a voltage test set as that can open-circuit the gauge. Foils can be very small



Uniaxial pattern

Figure 3. Range of strain-gauge foils. (Images Copyright of Vishay Technology, Inc. Used by permission.)

in cross-sectional area and are thus unable to tolerate more than milliamps of current.

One's first application of a gauge is not likely to be totally successful. It is suggested that a trial run is made with a gauge mounted on a surrogate object to develop some experience. The extra cost and time usually pays off.

4. Establish what are the influence effects that are likely to introduce error.

   Here, one is looking to establish the temperature excursions that may arise from consideration of the minimum- and maximum-operating and storage/transport temperatures. The latter are often much larger than the operating range. These decide the type of adhesive needed. It also points up the kind of compensation required; it is always needed. A range of options are available. Extra gauges are used to overcome thermal error, see Section 6.

   Ensure that any t/c, magnetostrictive, and other unwanted effects are not large enough to corrupt the measurement values. Simple calculations will usually suffice to find the order of magnitude needed to make this design decision. Where they are significant, use of AC modulation interrogation methods may be the way to go – *see* **Article 184, Photon Counting, Volume 3**. They can usually overcome these. Good design, however, can often avoid the need for an AC system.

   Also, investigate what level of gauge mechanical protection is needed.

5. Decide the appropriate kind of interrogation circuit needed.

   Before any gauges are bought, the full design of the gauges and influence effects is needed as this will dictate the interrogation method and the number and type of gauges to be purchased. Choices are to purchase a suitable off-the-shelf interrogation box or to construct one from basic components to fit a certain space. Time, and available skills and experience will come into play here. Makers offer special IC units for building the block into an installation. Portable general-purpose instruments are offered for testing many gauges.

6. Decide how the influence errors will be controlled.

   Compensation for temperature will be needed and there are several means available – see Section 6. Decide which scheme is appropriate.

7. Consider how the installation will be calibrated initially and, thereon, over its useful life.

   Before committing to any purchases it is a good idea to look into how the units will be calibrated, for this could well influence some of the design decisions.

Any sensor, once installed, should be subjected to several tests to ensure it is operating correctly. The tests need also to ascertain that the sensor is only responding to the measurand of interest. These tests should establish the discrimination, stability, and repeatability before any calibration is carried out.

In theory, each strain gauge of a multiple gauge installation can be directly calibrated by applying a force that generates a known length change in the gauge. This method is fine for load cells and for other self-contained mechanical objects that can be set up to experience known forces.

Often, however, this is quite impractical because the strain gauge is mounted on an object that cannot be

deformed under the controlled conditions needed to perform a calibration. In such cases, an indirect method of calibration has to be employed. This is done by viewing the full system as being formed of two parts, the gauge set, and the rest of the electrical parts forming the interrogation system.

The strain gauge has its resistance changed by the input strain in a reasonably well-known manner. This means, for purposes of calibrating and setting the interrogation system, the gauge arm(s) can be replaced by a calibrated stepwise variable resistance(s) for which each of its increments of resistance takes the interrogator unit through known steps of simulated strain input. This setup will allow zeros and offsets to be set in the bridge and amplifiers and the overall gain to be established. This calibrates the electrical system leaving the only unknown, the gauge set. Gauge calibrators, constructed using precision resistors and low thermoelectric switch contacts are offered by manufacturers for setting up a system.

With the interrogation stage calibrated, it leaves the gauge set to be calibrated. The performance of a gauge when cemented in place can vary from the unbonded gauge value. Well-executed installations can be expected to reproduce the unbonded performance within a band from 0.04 to 5%. Thus, the weak link in the overall calibration of a strain-gauge sensor system, a fixed type of installation, is the gauge calibration. This limits accuracy of use in such cases. If the uncertainty in the calibration must be low, then the structure carrying the gauge must be built so as to allow the strain-gauge element of the structure cemented to its host object to be removed for traceable calibration in a quality test facility.

When all of the above issues are understood and roughly sized out, the complete design and installation details should start to become clear. This will take some time, for iteration will surely be needed.

4 ELECTRICAL RESISTANCE STRAIN GAUGES

The information given above is generic to all types of strain gauges. Now it is time to discuss the two mostly used types of electrical strain gauge – the metal resistance foil and the semiconductor element. Here, there are more design decisions to make.

In brief, the metal gauge is the most stable type, with more certainly known performance and linearity in operation. The semiconductor gauge has the main advantage of being much more sensitive but, otherwise it does not compete as well as metal gauges in precision open-loop uses.

The metal gauge is formed from fine (15–30 μm diameter) wire or thin metal foils (3–5 μm thick) etched to create a long path in a grid form. Several forms, Vishay (2004), are shown in Figure 3. The grid is made to give maximum sensitivity on one axis when strained with a much lower strain effect in the transfer direction. Active lengths of gauges range from 0.5 to 150 mm. Values of resistance offered range from 60 to 1000 Ω, the most commonly used being 120 and 350 Ω. Different gauges variously cater for strains from 0.1 to 5%.

They are offered with a range of pure and specially alloyed metals to allow them to be matched in TEMPCO to the material of the object under test. The carrier base of the gauge, being placed between the grid and the test object surface, is designed to ensure that the gauge surface moves with the object's surface. Once bedded down to the surface, special connector pads are added to the host for the connection wires.

The theory of the metal strain gauge is well understood. For a metal gauge, the resistance R of a thin element of conducting metal material is given by

$$R = \rho \frac{L}{A} \tag{4}$$

where ρ is the specific resistivity of the material, L the gauge interval, and A the cross-sectional area of the gauge filament or foil element.

When tensioned longitudinally, for a strain less than 2%, all parameters of the above expression will vary linearly giving

$$\frac{\Delta R}{R} = \frac{\Delta \rho}{\rho} + \frac{\Delta L}{L} - \frac{\Delta A}{A} \tag{5}$$

Using Poisson's ratio μ for the metal used gives

$$\frac{\Delta R}{R} = \frac{\Delta \rho}{\rho} + (1 + 2\mu) \times \frac{\Delta L}{L} \tag{6}$$

This shows that the resistance change is made up of a strain plus a component, depending on the metal used. The value μ for most metals is much the same, being around 0.3.

Rather than working with material constants that change a little with each batch of metal formed, gauge users prefer to use the gauge factor (symbols used vary greatly – K, k, F, G, GF, s, etc.). This is defined in direct engineering terms as

$$K = \frac{\Delta R/R}{\Delta L/L} = \frac{\text{Proportionate change in resistance}}{\text{Proportionate change in strain}} \tag{7}$$

From this, indicated strain ε from the gauge stage is

$$= K \times \Delta R$$

which is easy to apply once K is known. Note that $K \sim 2.0$ for metals.

A more defined value of K is obtained from production run samples and is stated with each gauge. Strain sensors formed with several single units should use matched sets of K for the best results. Provided the thermal effects are reduced by common-mode operation, the temperature effect in the gauge factor in metal gauges is small and linear.

5 SEMICONDUCTOR STRAIN GAUGES

Semiconductors also exhibit resistance change with strain. Here, two strain effects arise – mechanical and structural. A filament of silicon or germanium exhibits strain change as follows

$$\frac{\Delta\rho}{\rho} = \Pi_L \times \sigma \tag{8}$$

where ρ is the electrical resistivity of the material, Π_L is the longitudinal piezoelectric coefficient, and σ is the applied stress. These allow more design freedom, resulting in gauges with a higher sensitivity than the metal ones; there is, however, a price paid for, the higher the sensitivity, the greater are the effects of temperature on the gauge readings.

K for semiconductor gauges can be as high as 45 to 200. However, K is not a constant when it exceeds 45 or so. Compensation is needed as both temperature and the strain magnitude alter the K value for a gauge. The input–output relationship is also not linear with strain magnitude as K varies.

An advantage of the semiconductor gauge is that its temperature dependency can be tailored to become negative as well as positive. This lends them for use on bridges where cancellation compensation can be used, see Section 6.

6 COMPENSATION FOR THERMAL ERROR

A strain gauge mounted on a surface that experiences no mechanical strain can generate three dominant thermally induced strain error effects:

1. changes in the resistance of the gauge according to its temperature coefficient of resistance (TCR);
2. changes in the physical and mechanical size of the element according to its temperature coefficient of length α;
3. changes to the gauge factor K according to the thermal coefficient of the gauge factor (TCGF).

The sum effect of these error strain signals is called the *apparent strain*. Clearly, such signals need to be controlled, by design, to adequately small magnitudes.

Other errors that can arise because of temperature effects are lead resistance and interrogation bridge changes.

Temperature-error sources in the gauge itself can be largely controlled by gauge design. Manufacturers offer a range of gauges matched to widely used materials (Table 1). These values have an uncertainty of $\pm 1 \times 10^{-6}$ and are valid for use in the range 10 to 120 °C. However, the actual spot value will be affected by the actual temperature, so they should not be taken as constants.

Semiconductor gauges use two methods of compensation for thermal effects.

1. Matched gauges with complementary coefficient polarities, that is, the same resistance value for each, one having a negative temperature effect and the other being positive. This compensates for temperature and also doubles the bridge sensitivity.
2. Using two filaments that have opposite TCGFs.

In both cases, the performance is tailored to make the common-mode action closely matched as the actual temperature varies.

Temperature-induced mechanical changes can be compensated in three ways, as shown in Figure 4:

- a dummy gauge mounted on an unstressed component;
- a dummy gauge placed orthogonally to the active gauge;
- a second active gauge placed in the undergoing compression that matches the magnitude of the tension of the other. This is suited for bending situations. Load cells often use a bending moment, not simple tension, load sensing member for this reason.

Each has its merits, depending on the situation. For best results, the gauge pair used has to have matched properties. Makers offer sets of gauges in many different configurations for this reason.

It is also possible to add a temperature sensor to the material under stress, some temperature sensors being formed integrally with the strain-gauge unit. Measuring the surrounding air temperature is not a suitable means of obtaining the compensation temperature as it does not follow the test object's temperature in the dynamic state nor is it close enough to the actual temperature of the test object.

Valuable application notes are offered by gauge makers. These are well worth obtaining as they contain very detailed explanations of all manner of issues.

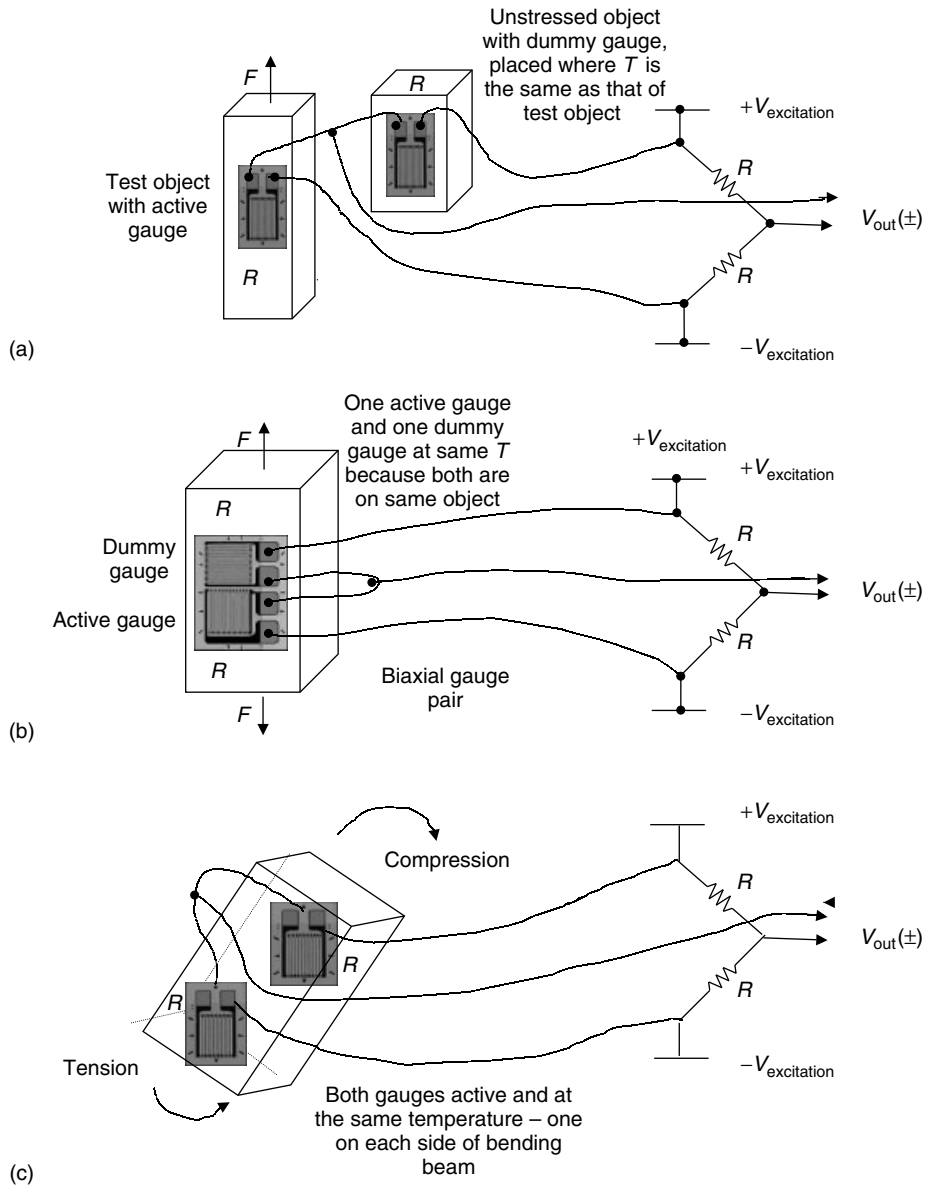

Figure 4. Temperature compensation for strain gauges (a) use of dummy gauge on separate object; (b) second gauge mounted to not experience strain; (c) use of two active gauges.

7 INTERROGATION CIRCUITRY

Resistance change of a metal gauge is proportional to strain, so interrogation needs a means to measure relatively small resistance changes with the required discrimination and uncertainty. Discerning applications can seek to determine resistance changes to as little as 0.01%, this being just 12 mΩ for a standard 120-Ω gauge. A good understanding of the circuitry needs is essential to reach such precision in practical use.

The most practical means for reading strain gauges is the Wheatstone bridge, Figure 5(a).

As discussed in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**, the basic equation describing the four-arm bridge of Figure 5(a) is

$$\frac{V_1}{V_2} = \frac{V_3}{V_4} \tag{9}$$

This can be expressed in terms of the resistances

$$\frac{R_1}{R_2} = \frac{R_3}{R_4} \tag{10}$$

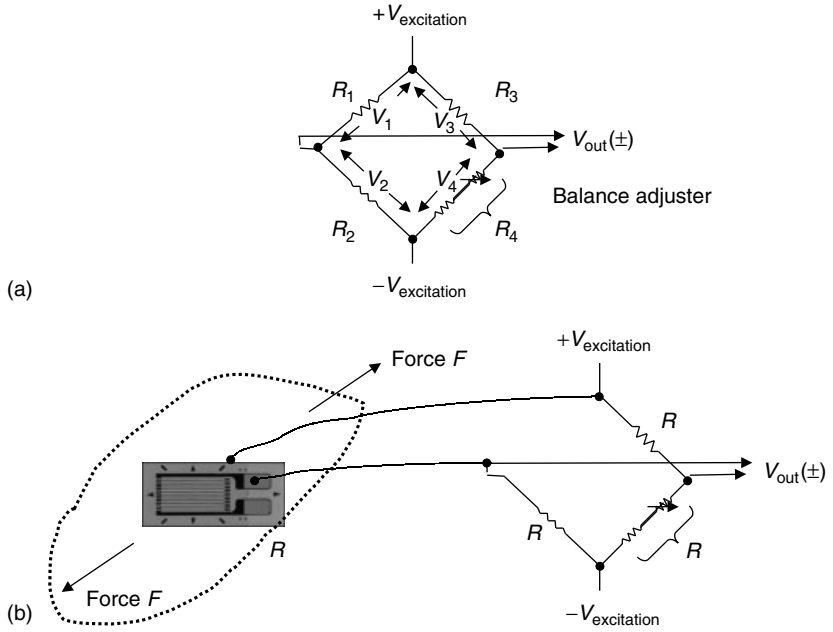

Figure 5. Circuit of Wheatstone bridge with parameters shown (a) circuit; (b) one arm active bridge.

The excitation voltage $V_{\text{excitation}}$ can be either in DC or AC form, the former being the one most commonly used, but it is not able to obtain the best performance.

When the resistance ratios are equal, the bridge output is zero and it is then in the balanced or null state. Assuming that the fixed resistances do not change, a variation in the value of a gauge changes the bridge, indicating a strain proportional to the unbalanced bridge output voltage V_{out}.

8 PRACTICAL POINTS

8.1 Bridge sensitivity and self-heating

The output measuring sensitivity of a strain-gauge bridge is directly proportional to the magnitude of the excitation voltage. This implies that large-value excitation could be used to obtain greater bridge sensitivity. There is, however, a limit to this.

What is not always appreciated is that even in the balanced condition, current flows through each arm of a bridge, the magnitude being decided by the total resistance of the arm and the magnitude of the excitation voltage. Thus, the gauge will experience a steady through current that heats it up according to the power being dissipated in each component.

It can be shown that the power W generated in the gauge is given by

$$W = V_{\text{excitation}}^2 \times \frac{R_1}{(R_1 + R_2)^2} \tag{11}$$

where, in Figure 5(a), R_1 is the gauge resistance, R_2 the other resistance in the same arm, and $V_{\text{excitation}}$ the excitation voltage.

This self-heating effect causes the gauge temperature to rise to a steady state temperature, also heating the host to a small extent, producing apparent strain. The amount of strain occurring will depend on the thermal conducting properties of the gauge, its mount, the host material, and the geometry. The actual effect is complex to model. Also, obtaining the thermal dissipation coefficient for gauges in given mounting situations is not always possible. Manufacturers of gauges sometimes offer useful advice here, HBM (2004) and Vishay (2004).

Excitation levels can vary from 1 to 40 V, or 5 to 25 mA. The larger gauges are able to dissipate more heat and, thus, can be driven harder.

A good way to test for excessive self-heating in a specific gauge installation is to monitor the strain-gauge sensor system output during its initial warm-up period. Any noticeable drift that took place when the gauge was first turned on after a long period of being off, which exceeded the allowable discrimination, indicated that the excitation was most likely too large.

In AC bridge operation, the equivalent voltage magnitude to be used is the rms value as that value represents the same power level as a DC signal of the same magnitude.

8.2 Lead error

If all gauges and resistors could be made with an exact resistance size, the bridge would balance. This cannot be achieved, so a variable balancing resistor is needed. Several means are employed, such as the use of

- a very small R in series in an arm (as shown in Figure 6a);
- a small R, center tapped, to allow resistance to be apportioned to each side of the bridge (as shown in Figure 6d);
- a high resistance R placed in parallel with an arm.

Several bridge configurations are commonly used. Many others have been reported for special purposes. The options are shown in Figure 6.

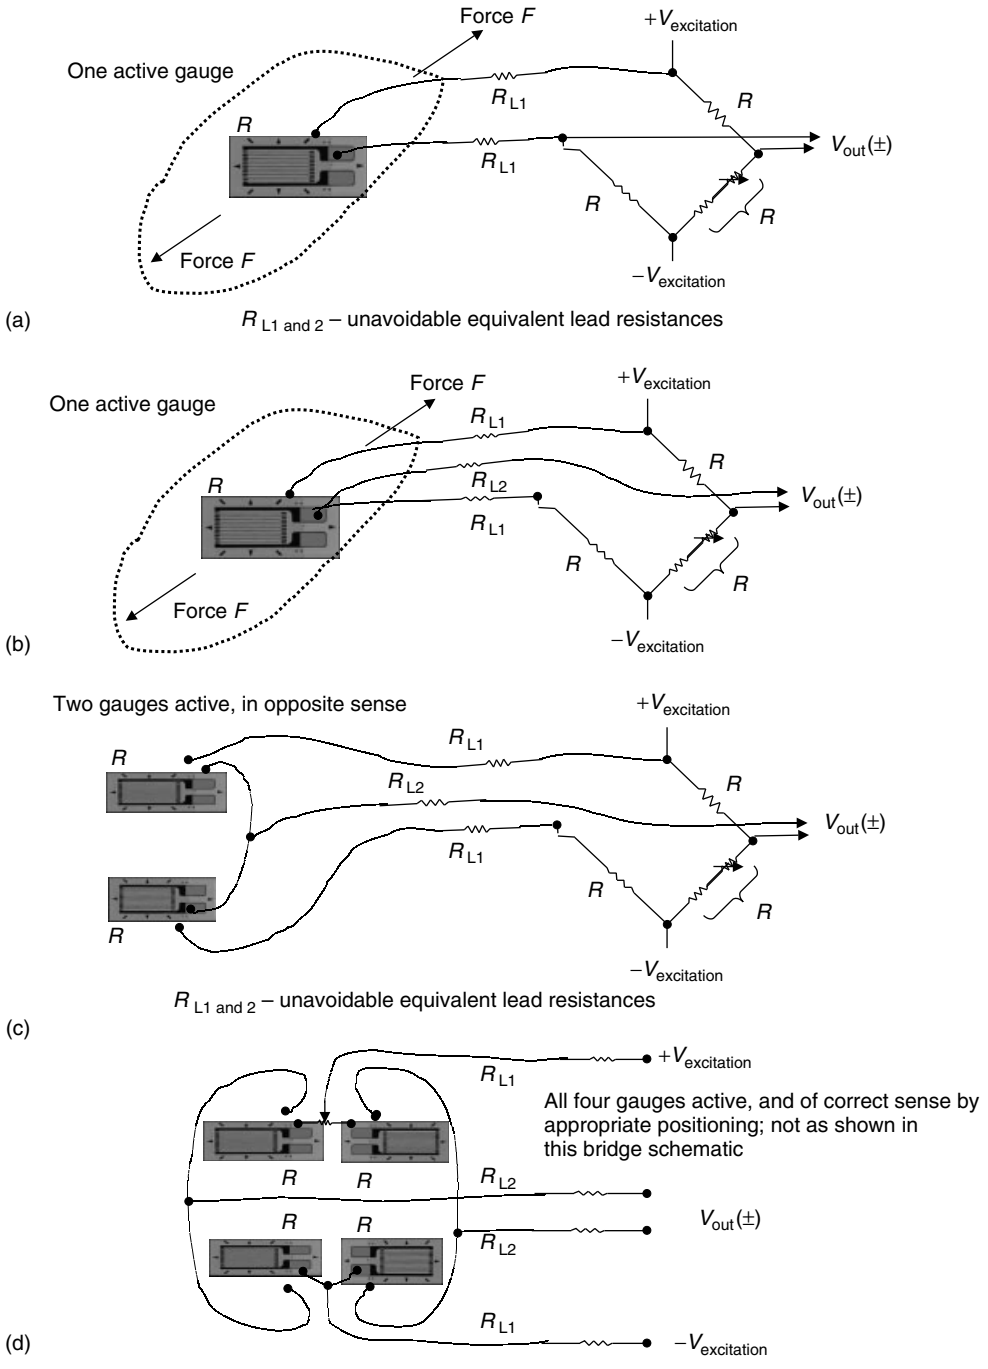

Figure 6. Reduction of lead error (a) no correction; (b) correction using 3 leads; (c) half bridge; (d) all arms active in full bridge.

The quarter bridge, Figure 6(a), is rarely used as it does not provide any temperature compensation. Also, note how the lead resistances are doubled and, thus, more temperature effect is added, possibly making the bridge a temperature sensor.

The single gauge system can be made more acceptable by adding three connection leads to the gauge, Figure 6(b). The leads R_{L1} for the gauge connection into the bridge must be identical in length and type. This provides common-mode rejection for the lead temperature effect. The third lead R_{L2} is in the output detector stage where its resistance is of little consequence.

A still better method is to use two active gauges with opposite strain senses, Figure 6(c). This is the most used method. The gauges are shown there as a schematic circuit wired to show how they form a bridge and not how they would necessarily be mounted.

An even more superior method is to make all gauges active, as shown on the schematic given in Figure 6(d). In this case, no lead resistance is significant, provided gauge connections are short.

In both cases, Figures 6(c) and (d), the gauges need to be placed to get the appropriate tension and compression. It is rarely possible to lay down four gauges that will all be active when they are all on the same surface. One exception is the use of a special foil that contains both radial and circumferential gauge grids that are used on a pinned edge circular diaphragm of a pressure gauge. Strain theory of such a membrane shows that the disk experiences both tension and compression on a single side in different places.

In any application, it is wise to make simple calculations to determine the effect of lead resistances, especially where they are long.

8.3 Transverse sensitivity

A gauge is often subjected to transverse strain. This effect on a gauge is kept minimal by their design but is not totally avoidable. Application of the gauge that is not exactly aligned with the longitudinal axis will create transverse action on the gauge.

With gauges mounted on an immovable host, its extent is hard to assess other than by carefully constructed calibration. Transverse effects can be expected to remain reasonably constant over time.

8.4 Dynamic response

In theory, a gauge becomes part of its parent material, and thus would exactly mimic the surface strains of the object being measured. In practice, however, the gauge does not move exactly with its host during dynamic operation because the bond allows some degree of compliance. Keeping the adhesive layer thin and using the recommended adhesive and curing process helps keep this effect to the minimum.

As a guide, upper limits for vibration measurement using strain gauges is 10 KHz for continuous oscillations and is higher up to 500 KHz for impulsive shocks. Application notes are available that detail how to get the best upper frequency response.

Periodic resetting is usually needed if the sensor system is pushed too hard. In long-term vibration measurement, the gauge must not suffer significant fatigue over the lifetime of its use. The constant reversing vibration will, however, result in some drift in the balance of the bridge. The main cause of this is relaxation of stresses in the host material, but the gauges also suffer from this effect. Gauge makers offer data on this, such as the recommended number of reversals for a given amplitude and frequency of reversals. Where possible, the design is derated as far as is reasonable to reduce this effect.

Some materials exhibit a noticeable amount of elastic after-effect wherein the residual strain in the host gradually relaxes back to an earlier state.

Fatigue behavior is also influenced by the adhesive used, its application, and the surface properties of the host material.

With AC interrogation systems, the modulating frequency should be around 10 times the highest frequency occurring in the host.

9 SIGNAL PROCESSING SYSTEMS

Strain signals can produce vast amounts of data, not all of which need to be captured. For example, vibration contains a large amount of data if detailed information of every cycle is recorded. For example, a 1-KHz sine wave signal logged at every 1.0% of amplitude for 100 min will produce close to 10^9 test data values. Processing all of this, while now being possible, is not always a sound way to proceed. It is better to decide just what needs to be known from the test and set up a more economical data extraction system.

Some special data sets needed in strain testing include peak values, strain pairs, frequency content, special event logging, and the period of vibration frequency.

Peak hold is a commonly used facility that captures the peak value of strain during a test, such as in destructive testing, where the breaking value is needed. This is a sampling process that tracks the maximum value. It can be achieved relatively simply in analog systems if short

hold time is satisfactory. It is a software-controlled process in digital signal processors (DSP).

In airframe testing, hundreds of hours of fatigue cycling are needed, so it is expedient to measure strain reversal pairs, for these are known to represent fatigue strength. A strain cycle counter is used.

A vibration is sometimes not at a steady single level but varies widely over time. Examples are in weighing moving railway cars where track noise adds to the situation as it passes over the automatic weighbridge. There, signal integration is needed to extract the wanted signal from the noisy situation.

Another data economizer design feature can be employed where many gauges are installed for relatively low frequency use, such as over the hull of a ship. A switching system is used to time-multiplex each strain gauge into a commonly used central interrogation unit. Strain gauges, being typically 120 Ω, need wiring, and they need switches that have much less resistance than this in the circuit when measuring.

Resetting offsets and zeros can be demanding, especially in multigauge installations. Application of smart sensor features – *see* **Article 160, Smart Sensor System Features, Volume 3** – can automate these operations. Process supervision is essential to monitor the degree of resetting that is taking place lest it be caused by a shifting parameter resulting from a significant error source, such as the gauge gradually becoming detached.

Today, the inclusion of sophisticated digital data processing allows the power of Fourier analysis and the like to be employed in smart ways to make decisions on the run, for example, as needed in machine health monitoring.

While the DSP parts of a strain sensor system have high proven reliability, the analog strain components and their practical use can be more problematic. Addition of smart features will assist in the creation of 'fit and forget' measuring systems but only if the gauge and interrogation circuits are soundly engineered and installed.

10 OTHER STRAIN MEASUREMENT METHODS

In the main, electrical strain gauges are the best way to determine stress where precision, or an electronic output, is needed. There are, however, many applications where electrical methods are not suited for cost, time to install, and installation reasons (Kuske and Robertson, 1974); (Asundi, 2002). Several of these methods might be useful:

Etched grid. Some surfaces are suitable for the application of a grid pattern, either by direct etching, printing, or gluing on a grid. Stress causes the grid to deform, the shape change being detected with a suitably graduated optical magnifier.

Brittle coating. These are applied coatings that crack if stressed beyond limits. Lacquer made from methylene chloride is one example. It is odorless, nonflammable, and is of low toxicity. It is sprayed on and left to air-dry. About 10 coats result in a film of 120 μm. The threshold strain level in room-temperature use is 500 $\mu m\, m^{-1}$.

As the sensitivity varies a lot with time and temperature, such methods need to follow manufacturer's guidelines.

A calibrator is offered for these methods that strains a sample piece in a small handheld tool.

10.1 Photoelasticity

Certain optically transparent dielectric materials exhibit optical property variations with stress level. This is the photoelastic effect.

When unstressed, the material shows no coloration when white light is used to illuminate it from behind. When stressed, the refractive index of the material changes, causing different colors to appear on the viewing side. The strain-optical coefficient K is available for the material. A special polariscope is used to view the object.

Photoelasticity can be used in several different ways to evaluate strains in a modeled member:

- modeling it in 2D
- modeling it in 3D
- coating the object.

An advancement on this method is to use scattered light photoelasticity. A sensitive optical radiation detector scans the object to produce a computer-based image that is interpreted with various schemes.

For these methods to work well enough, any residual stresses in the photo-optical material must first be removed. Stressing it in installation in the test rig will add error.

Overall, the method is useful for low-precision measurements where the object can be modeled and viewed in the special viewer.

1 SPECIAL NEEDS FOR DISPLACEMENT AND ANGLE SENSORS

This article continues discussion from **Article 191, Displacement and Angle Sensors Performance and Selection, Volume 3** in which the performance and selection of the most commonly used methods of measurement of displacement and angle are discussed.

As technology improves, many different special needs for displacement sensors appear, mainly depending on the application requirements. For example, in the automotive industry, capacitive noncontact displacement and thin gap sensors are being used often to monitor vehicle condition for safety. As in the case of fuel injection systems, due to technological improvements, the dimensions of components get smaller hence the sensors also get smaller to fit these confined spaces. Sensors often are required to fit into locations with diameters <1 mm, where they measure gaps in submillimeter region. Other special needs for the displacement sensors include high operating temperatures up to 1000 °C, small overall diameter within 100 μm, high and consistent accuracy down to 0.2 μm, immunity to magnetic fields, and so on.

In many industrial applications, displacement, angle, and gap sensors are required to have the following typical characteristics: noncontact measurements, ability to withstand high temperatures and pressures, minimum calibration requirements, operating in unusual and hostile environments such as oils or other fluids, very small size for installation in tight spots, good immunity to magnetic and electromagnetic interference, and so on. Magnetic type displacement sensors, in particular, need careful shielding against external interferences.

Optical and laser displacement sensors require careful designing and construction. They need highly stabilized light sources and the reflective index of light medium must be factored in carefully in the design process.

By suitable constructions and application of appropriate signal-processing techniques, most of the displacement sensors can be used in acceleration and vibration measurements, and velocity, inclinometer, and rotation sensors.

Optical encoder type displacement sensors are often used: they can be configured and manufactured in an amazing number of geometric forms. In those using fringing effects, careful design and precision building is necessary during constructions.

Large-scale displacement sensors that are based on optics, electromagnetic, sonic, and microwaves, generally need very bulky and expensive electronic support units for signal generation and signal processing.

The trend in small-scale displacement sensors is the miniaturized sensors based on microelectronics. Many modern microdisplacement sensors can be classified as smart

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

sensors. These sensors need the support of nonconventional components plus the software to drive them. They can be networked using techniques such as the IEEE 1451 standards for connecting transducers to digital networks. They can be connected to a variety of networks including Ethernet interfaces that will support TCP/IP, FTP, and HTTP protocols with a fully functional Web server, *see also* **Article 162, Principles of MEMS, Volume 3**; and **Article 163, Uses and Benefits of MEMS, Volume 3**.

2 PRINCIPLES AND SPECIALTY DISPLACEMENT, AND ANGLE SENSORS

Specialty displacement and angle sensors are often based on capacitive, magnetic, optical piezoelectric, and radio frequency (RF) and microwave propagation principles. They are briefly visited here. The principles and theory of some of the lesser-used displacement angle sensors are explained below.

2.1 Capacitive displacement sensors

The basic sensing element of a typical capacitive displacement sensor consists of two simple electrodes with capacitance C between them. Capacitance is a function of the distance d (meters) between the electrodes of a structure, the surface area A (square meters) of the electrodes, and the permittivity ε ($8.85 \times 10^{-12}\,\mathrm{F\,m^{-1}}$ for air) of the dielectric between the electrodes; therefore,

$$C = f(d, A, \varepsilon) \tag{1}$$

There are three basic methods for realizing a capacitive displacement sensor, namely, by varying d, A, or ε. The capacitive displacement sensors can be classified as variable plate-distance, variable-dielectric, variable plate-area, and differential capacitive sensors. More detail in capacitance measurement is found in **Article 204, Capacitance and Inductance Measurement, Volume 3**.

2.2 Magnetic displacement sensors

The majority of the magnetic displacement sensors are inductive types and they are based on Faraday's law of induction. They can be classified as reluctance, transformative, tachogenerator, induction potentiometer, eddy current, and magnetometer types. They are designed to measure linear as well as rotary displacements.

Magnetic displacement sensors can be classified as linear variable-reluctance, single-coil linear variable-reluctance, variable-differential reluctance, linear variable-inductive, variable-coupling, eddy current displacement sensors, and linear variable-differential transformers.

2.3 Resistive, piezoelectric, and piezoresistive displacement sensors

The resistive displacement sensors consist of a sliding or rotational arm of a potentiometer that is connected to the moving object while the main body of the potentiometer is kept in a fixed position. In strain gauge, displacement sensors are based on resistance properties of electrical conductors. Piezoelectric sensors are based on the change in electrical properties of materials under stress. In the case of piezoresistive displacement sensors, when a conductor is stretched or compressed, its resistance alters because of two-dimensional changes and changes in the fundamental electrical properties of the material. Resistance measurement is covered in **Article 203, Resistance Measurement, Volume 3**.

2.4 Optical displacement sensors

There are many different types of optical displacement sensors available, such as those that make use of properties of optical fibers, laser methods, encoders, and interferometric techniques.

2.5 Angular displacement sensors

Angular displacement sensors generally involve rotational capacitive or magnetic devices. The most commonly used devices involve tachogenerators, microsyns, synchros, and induction potentiometers.

3 SPECIALTY DISPLACEMENT AND ANGLE SENSOR TYPES AND THEIR APPLICATIONS

3.1 Variable-dielectric capacitive displacement sensors

The displacement may also be sensed by the relative movement of the dielectric material, attached to the object under

investigation, between the plates. The corresponding equations will be

$$C = \varepsilon_0 w\{\varepsilon_2 l - [\varepsilon_2 - \varepsilon_1]x\} \quad (2)$$

where ε_1 is the relative permittivity of the dielectric material and ε_2 is the permittivity of the displacing material (e.g. liquid).

In this case, the output of the transducer is linear. These types of sensors are often used in level measurement of fluids.

3.2 Variable-coupling magnetic displacement sensors

Variable-coupling sensors consist of a frame holding a center-tapped coil and a ferromagnetic plunger. The plunger and the two coils have the same length l. As the plunger moves, the inductances of the coils change. The two inductances are usually placed so that they form two arms of a bridge circuit with two equal balancing resistors. The bridge is excited with 5 to 25 V AC at a frequency of 50 Hz to 5 kHz. At the selected excitation frequency, the total transducer impedance at null is set to 100 to 1000 Ω ranges. The resistors are chosen to have about the same value as the transducer impedances. The load for the bridge output must be at least 10 times the resistance R-value. When the plunger is in the reference position, each coil will have equal inductances of value L. As the plunger moves by δl, changes in inductances $+\delta L$ and $-\delta L$ create a voltage output from the bridge. By constructing the bridge carefully, the output voltage may be made a linear function of the displacement of the moving plunger, within a rated range. Bridges are covered in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**; and **Article 127, Unbalanced DC Bridges, Volume 2**.

3.3 Eddy current displacement sensors

Inductive transducers based on eddy currents are mainly probe types, containing two coils. One of the coils, known as the *active coil*, is influenced by the presence of the conducting target. The second coil, known as the *balance coil*, completes the bridge circuit and provides temperature compensation. The magnetic flux from the active coil passes into the conductive target by means of a probe. When the probe is brought closer to the target, the flux from the probe links with the target, producing eddy currents within the target.

The eddy current density is greatest at the target surface and becomes negligibly small about three skin depths below the surface. The skin depth depends on the type of material used and the excitation frequency. Even though thinner targets can be used, a minimum of three skin depths may often be necessary to minimize temperature effects. As the target comes closer to the probe, the eddy currents become stronger, causing the impedance of the active coil to change, altering the balance of the bridge in relation to target position. This unbalanced voltage of the bridge may be demodulated, filtered, and linearized to produce a DC output proportional to the target displacement. The bridge oscillation frequency may be as high as 1 MHz. High frequencies allow the use of thin targets and provide good system-frequency response.

Probes are commercially available with full-scale ranges from 0.25 to 30 mm with a nonlinearity of 0.5% and a maximum resolution of 0.1 μm. For nonconductive targets, conductive materials of sufficient thickness must be attached to the surface by means of commercially available adhesives. Because the target material, shape, and the like influence the output, it is necessary to calibrate the system statistically for a specific target. The recommended measuring range of a given probe begins at a standoff distance equal to about 20% of the stated range of the probe. In some cases, a standoff distance of 10% is recommended and so this is calibrated as the standard for the system. A distance greater than 10% of measuring range can be used as long as the calibrated measuring range is reduced by the same amount.

3.4 Piezoresistive displacement sensors

Piezoresistive displacement sensors are essentially semiconductor strain gauges with large gauge factors. High gauge factors, *see* **Article 192, Strain Sensors, Volume 3**, are obtained because the material resistivity depends primarily on the stress, not on dimensions only. Most piezoresistive sensors use two or four active gauges arranged in a Wheatstone bridge. Extraprecision resistors are used as part of the circuit in series with the input to control the sensitivity, balancing, and offsetting temperature effects. The mechanical construction of a piezoresistive displacement sensor is similar to the installation in Figure 1. In some applications, overload stops are necessary to protect the gauges from high-amplitude inputs.

3.5 Synchros

The term *synchro* is associated with a family of electromechanical devices. The construction of synchros is similar

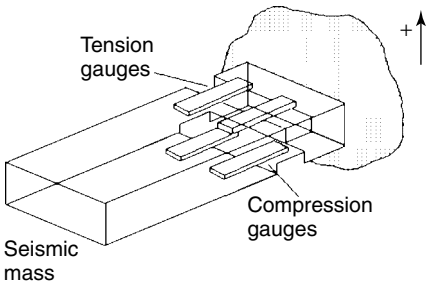

Figure 1. Bonding of piezoelectric and piezoresistive elements on to an inertial system.

to that of wound-rotor induction motors. The rotation of the motor changes the mutual inductance between the rotor coil and the three stator coils. The three voltage signals from these coils define the angular position of the rotor. Synchros are used in connection with a variety of devices, including control transformers, Scott T transformers, resolvers, phase-sensitive demodulators, and AD converters.

In some cases, a control transformer is attached to the outputs of the stator coils such that the output of the control transformer produces a resultant magnetomotive force (mmf) aligned in the same direction as that of the rotor of the synchro. In other words, the synchro rotor acts as a search coil in detecting the direction of the stator field of the control transformer. When the axis of this coil is aligned with the field, the maximum voltage is supplied to the transformer.

In other cases, AC signals from the synchros are first applied to a Scott T transformer, which produces AC voltages with amplitudes proportional to the sine and cosine of the synchro shaft angle. It is also possible to use phase-sensitive demodulation to convert the output signals to make them suitable for digital signal processing.

3.6 Induction potentiometers

A version of the rotary-type linear inductor is the induction potentiometer. Two concentrated windings are wound on stator and rotor. The rotor winding is excited with alternating current, thus inducing voltage in the stator windings. The amplitude of the output voltage is dependent on the mutual inductance between the two coils, where the mutual inductance itself is dependent on the angle of rotation. For concentrated coil-type induction potentiometers, the variation of the amplitude is sinusoidal, so linearity is restricted to the region of the null position. By carefully designing coils, a linear variation over $\pm 180^\circ$ may be obtained.

Standard commercial induction pots operate in the 50 to 400 Hz frequency ranges. They are small in size, from 1 to 6 cm, and their sensitivity can be in the order of 1 V/1° of rotation. Although the range of induction pots is limited to less than 60° of rotation, it is possible to measure displacements in angles from 0° to full rotation by suitable arrangement of a number of induction pots. As in the case of most inductive sensors, the output of the induction pots may need phase-sensitive demodulators and suitable filters. In many inductive pots, additional dummy coils are used to improve linearity and accuracy.

3.7 Interferometric sensors

There are many different types of interferometric sensors including optical fiber, laser, holographic, and monochromatic light types. In these sensors, Michelson, Sagnac, or Fizeau effects of interference of two or more light beams is used by suitable optical arrangements. The most commonly used optical arrangements are beam splitters, polarizing prisms, and diffraction gratings.

As two light beams interfere, interactions of light cause a series of bright and dark lines. If, for example, two interfering lights with wavelengths 1.5 μm are interfered, the spacing of bright and dark lines will be 0.75 μm. A suitable arrangement for an interferometric sensor is given in Figure 2. In many cases, the dark and bright points are counted in relation to the displacement of an object located within the interference. Many different designs based on different displacement mechanisms are available. Some of these include fringe counting interferometers, frequency modulation interferometers, heterodyne interferometers, phase-locked interferometers, laser Doppler and laser feedback interferometers, and fiber interferometers.

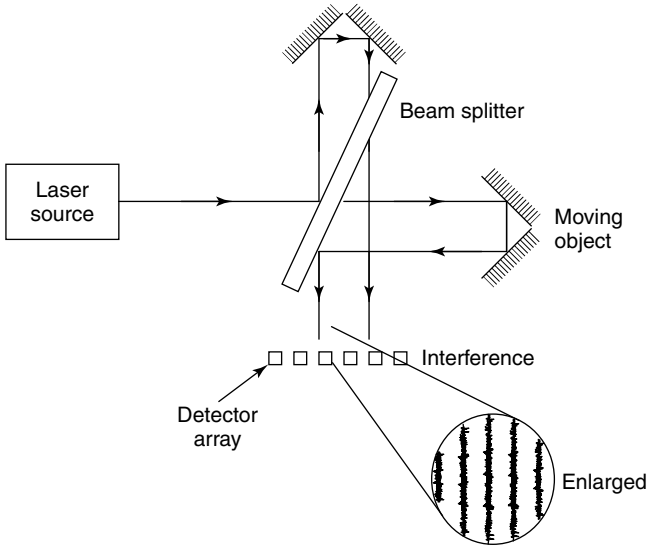

Figure 2. Interferometric displacement sensor.

4 SENSITIVITY AND INTERFERENCE ISSUES

Sensitivity and interference of displacement sensors depends on the type of sensor being used and the nature of the application environment. In the case of potentiometric displacement sensors, the sensitivity depends on the characteristics of resistive elements, the way that resistive elements are constructed, mechanical mounting methods, the linearity of the device, and the electrical loading. In these sensors, the electric, magnetic, and electromagnetic interference is minimal compared to others.

In magnetic displacement sensors, the influence of external magnetic fields and the internal magnetic fields due to coil orientation is significant as they directly effect the operation ranges and the sensitivity. These devices may need careful magnetic shielding. In many cases, multiple shields may be necessary.

Capacitive sensors may be prone to external and internal electric fields. In the design and construction stages, the fringing effect of the electric field must be taken care of carefully. The external electric field must carefully be eliminated. For this, carefully designed signal-processing techniques are used by selecting appropriate charge and current amplifiers. In many cases, appropriate liberalization techniques are employed to improve sensitivity and eliminate interference.

Piezoelectric sensors find diverse applications. They generally need to be mechanically robust. Since these transducers basically operate on electric field principles, they need to be shielded against the external fields. In some cases, instead of using ceramic type piezoelectric sensors, ferromagnetic polymer types that have high voltage sensitivity may be selected, thus minimizing the effect of external fields. In many cases, high-input impedance amplifiers are used to eliminate the influence of connecting cables.

As discussed above, the optical and laser sensors need stable power sources and good components to achieve maximum sensitivities. In these devices, the electric, magnetic, and electromagnetic interferences are minimal.

Sonic displacement sensors require a uniform transmission medium. If the transmission medium is not uniform, appropriate signal-processing techniques must be employed to maximize the sensitivity.

RF and microwave sensors are generally used for long-distance displacement measurements. They are prone to static charges in the atmosphere and variations in transmitted medium, and many other factors. Careful signal-processing techniques can eliminate most of the problems.

5 PROPRIETARY SPECIALTY DISPLACEMENT AND ANGLE SENSORS

Proprietary and lesser-used displacement sensors are constructed for two main reasons:

1. Owing to specific applications in which conventional sensors are not suitable.
2. Because of the availability of new technology and supporting software, with which companies seek competitive edge in their products.

It is not possible to cover a whole range of proprietary sensors in this article; however, some examples will be given.

Example 1 In the construction industry, traditionally, large concrete and steel structures must be monitored for years, not days. The environment is often hostile, and some changes (such as corrosion) may occur slowly, whereas seismic disturbances can occur quickly. As a result, the cost of using conventional sensors to achieve sustainable useful results under these conditions may not be desirable. A family of specially designed proprietary displacement sensors can monitor the construction continuously and can be connected to a digital network to enable remote monitoring. The technology behind such proprietary sensors can be based on various principles. The most common types are strain gauge, GPS, laser, and optical technologies.

Example 2 A new displacement sensor technology is appearing as a byproduct of CCD (charged couple device) technology. State-of-the-art CCD sensors, in combination with digital signal processors, make use of laser technology, offering many advantages in signal processing and precision aspects. These sensors are basically pixelized array detectors with 1024 discrete voltages representing the amount of light on each element of the detector. A CCD element detector can carry 1024×1024 light intensity information.

Example 3 There are many different types of proprietary microsensors offered by many companies. For example, Micro-Electro-Mechanical-Systems, MEMS-based sensors are available for a diverse range of applications from monitoring to treat paralyzed limbs of humans to orientation determination of spacecrafts. MEMS sensors became increasingly available for sensing parameters, such as acceleration, angular rate, low level magnetic fields, and so on.

The literature supporting these various devices does not contain material under specific devices but gives it in a general manner. It is, therefore, necessary to scan through texts to find material. The following bibliography lists sources.

1 DEFINITION AND RANGE OF LARGE-SCALE METROLOGY

Large-scale metrology (LSM) concerns itself with precise 3-dimensional industrial measurements at 10 micron to submillimeter accuracies over ranges of 10s of meters. It makes considerable use of optical techniques, which are the subject here – *see* **Article 89, Optical Materials, Volume 2**; **Article 90, Optical Elements, Volume 2**; **Article 91, Light Sources and Detectors, Volume 2**; and **Article 92, Optical Measuring Instruments, Volume 2**. Testing of optical measuring equipment itself is found in **Article 93, Testing Optical and Other Radiation Systems, Volume 2**. Other LSM techniques are referenced below. Fine mechanical measuring devices are covered in **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2**; **Article 81, Principles of Fine Mechanics – Systems Considerations, Volume 2**; **Article 84, Kinematical Regime – Rotary Motion, Volume 2**; **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 86, Elastic Regime of Design – Spring Systems, Volume 2**; **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2** with testing of these in **Article 88, Error Sources in Fine Mechanics, Volume 2**.

The application spectrum ranges from high accuracy aerospace and automobile manufacturing to lower accuracy ship construction and as-built process plant. LSM methods developed out of a need for mobile, on-site measurement. This contrasts with more established techniques typically represented by CMM (coordinate measuring machine) technology.

CMMs have a probe that can slide along three mutually perpendicular axes, see Figure 1. The probe, often a mechanical touch probe, contacts the surface of an object placed on the machine and so defines a point on the object. Encoders on the slides record the probe's position. A simple tutorial is available at http://www.brownandsharpe.com/introduction/intro_en.pdf.

CMMs can offer accuracies of micrometers (microns) but have a fixed volume, a fixed location, often a few meters maximum dimension, and usually need a carefully controlled operating environment. They cannot readily deal with measurement tasks such as

- operating in a hazardous environment,
- measuring dynamic robot performance,
- checking dimensions on the root end of an aircraft wing.

Geometric methods and optical equipment originally designed for making topographical maps can solve these

Figure 1. Coordinate measuring machine in use at NPL. (Crown Copyright, courtesy of NPL.)

problems and they form the core of LSM today. The instrumentation in LSM systems is inherently transportable and therefore applicable to on-site measurement. Fully electronic and automated features ensure that 3D data can be delivered online or within a short timescale.

LSM literature is limited except in photogrammetry (Section 5). Good texts are Atkinson (1996) and, in German, Luhmann (2000), Schwarz (1995) and Löffler (2002).

Not discussed here, owing to lack of space, are several closely related and complementary technologies:

- *Optical tooling* is based on the use of telescopes, prisms, and mirrors to define straight, parallel, and orthogonal lines for component assembly and alignment. Manufacturers Brunson have introductory tutorial information at http://www.brunson.us/p/LearnCenter.htm.
- *Laser radar scanners* can digitize large volumes in 3D by scanning a laser beam across the scene. Although accuracies are appropriate for, say, architecture, and civil engineering, systems offering metrology precision also exist. For an example, see www.metricvision.com.
- *Portable arm CMMs* are manually operated, mechanical arms that define a limited 3D measurement volume, extendable by additional techniques. They can avoid the line-of-sight requirement for optical systems. Web sites of some major manufacturers can be found at www.faro.com, www.romer.com, and www.romer.fr.

2 SUMMARY OF METHODS USED IN LARGE-SCALE METROLOGY

2.1 Triangulation

Triangulation locates a target using two or more directions measured from separate locations known relatively to one another. The directions are typically defined by camera views, telescope pointings, and laser beams. One direction places the target on a line in space; the second intersects this to complete the 3D location. Figures 2 and 3 illustrate triangulation by theodolite (see Section 3)

Multiple intersections can improve accuracy. This is a particular feature of photogrammetry (see Section 5), where camera views define target directions and where it is simple to take views from many different locations. Key features are as follows:

- For online work, a setup phase is required to determine relative instrument positions.
- Narrow intersection angles give poor results – 90° intersections are good.
- Measured scale bars of accurately known length provide true scale.

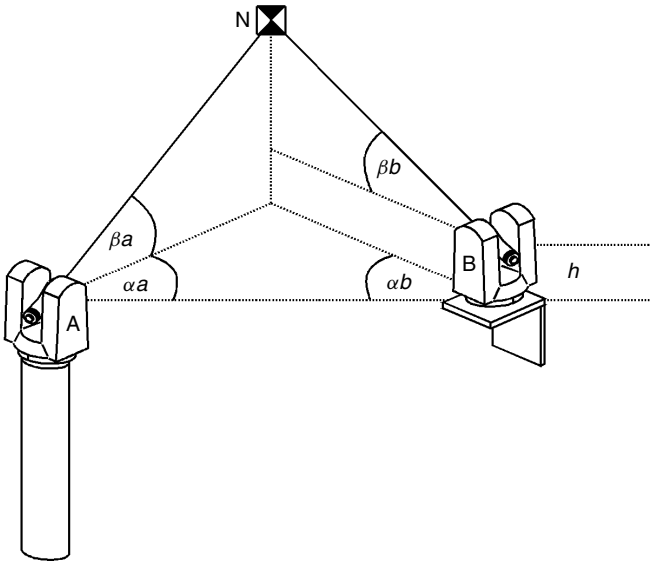

Figure 2. Triangulation by theodolite. (Reproduced by permission of Leica Geosystems.)

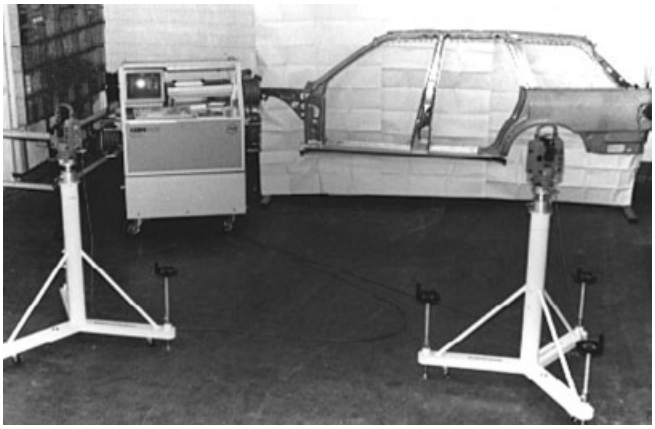

Figure 3. Audi panel measurement, 1996. (Reproduced by permission of Leica Geosystems.)

2.2 Polar measurement

Polar measurement locates object features in 3D space by direct measurement of spherical coordinates, that is, horizontal angle, vertical angle and range. Figures 4 and 5 show polar measurement by laser tracker (see Section 4).

Unlike triangulation, 3D measurement can be made from a single instrument and a setup procedure is not required. Scale is provided by range values in every measurement.

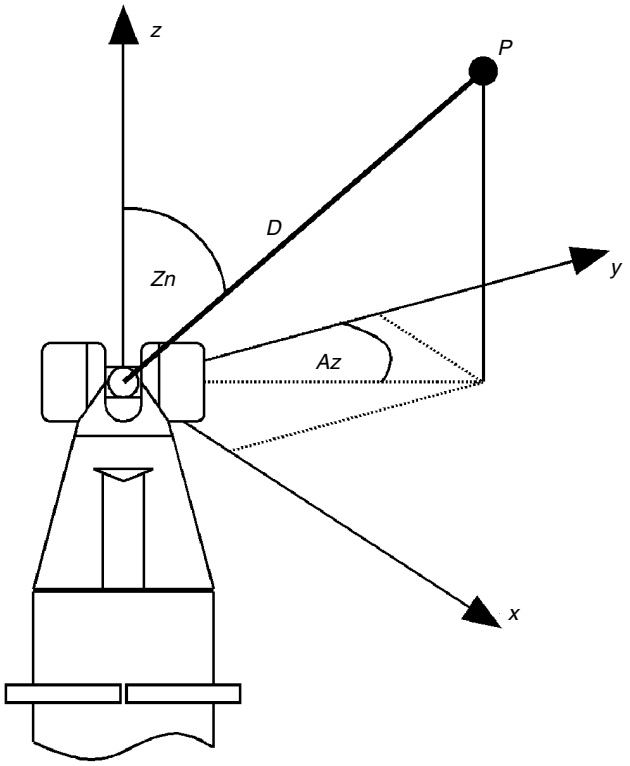

Figure 4. Polar measurement by laser tracker. (Reproduced by permission of Leica Geosystems.)

Figure 5. Robot tracking from a single position. (Reproduced by permission of Leica Geosystems.)

2.3 Multistation networks and bundle adjustment

Multiple instrument positions are a feature of triangulation measurements. Since optical instruments require line of sight, polar measurement generally also requires multiple instrument positions to view all sides of an object.

The network is commonly defined by means of a bundle adjustment. This was originally devised for photogrammetric triangulation in which the 'bundles' of target rays from each camera position were mathematically fitted together in order to obtain target coordinates as well as camera locations and orientations. The technique is easily extended to deal with pointings based on angles rather than image coordinates, and to include range measurements.

2.4 Trilateration

If range measurements *only* are made to a target from a minimum of 3 instruments with known relative positions, the target can be fixed in 3D space as the intersection of 3 spheres whose radii are the 3 range values. This is known as *trilateration*. Multilateration implies the use of multiple ranges.

Trilateration is not widely used in metrology but has application where refraction significantly disturbs accuracy. Angular pointings are then more affected than distance measurements and trilateration can achieve higher 3D accuracies than triangulation.

3 THEODOLITES AND TOTAL STATIONS

Theodolites and Total Stations are commonly used in land surveying but versions offering geodetic accuracies (arc second pointing) and optimized range measurement (submillimeter) can easily achieve 3D coordinate accuracies, which are submillimeter or better at industrial scales of measurement.

Two manufacturers explicitly address the LSM market:

1. See www.leica-geosystems.com/ims for the TPS 5000 system offering industrial theodolites and Total Stations.
2. See www.sokkia.net for Sokkia's MONMOS system based on the NET2100 Total Station.

The following comments are illustrated by Leica systems, which cover a wide application spectrum.

Theodolites are manually operated angle-measuring instruments based on a telescope that can be rotated about two intersecting orthogonal axes. When the telescope's crosshairs are centered on a target, readings from the angle encoders on these axes define the pointing.

The instrument has 3-foot screws that enable it to be precisely leveled. The pointing is then defined by a horizontal angle and a vertical angle (Figure 6). However, leveling is not a requirement for industrial measurement and the instruments can be operated on floating objects.

A Total Station (Figure 7) is a theodolite equipped with a coaxial EDM (Electronic Distance Meter) which can measure range to retroreflecting prisms and tape, or even directly to object surfaces, using the principle of phase measurement. By modulating an infrared or visible laser beam, the phase difference between the transmitted and reflected beams indicates the fractional part of the distance to the target. Different modulation frequencies enable the whole number of wavelengths to be determined and hence the absolute distance.

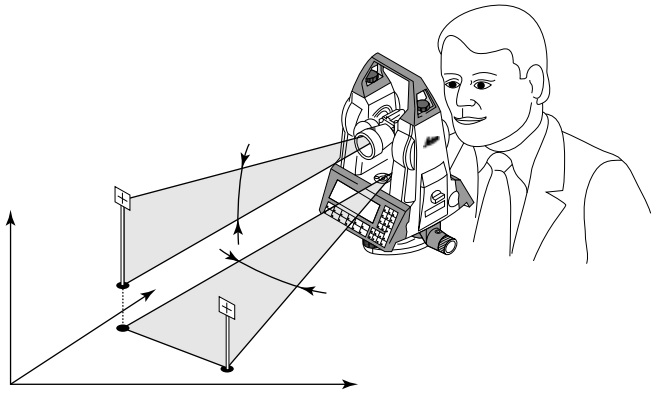

Figure 6. Theodolite angles. (Reproduced by permission of Leica Geosystems.)

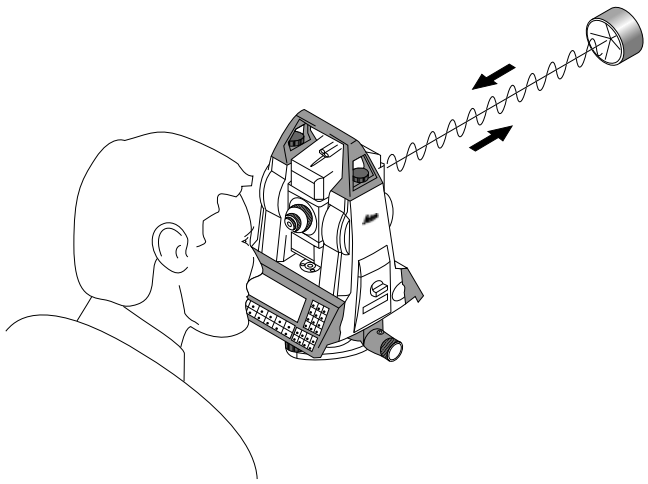

Figure 7. Range measurement by Total Station. (Reproduced by permission of Leica Geosystems.)

Figure 8. Theodolite and Total Station targets. (Reproduced by permission of Leica Geosystems.)

A wide range of targets and adapters are available for the direct and indirect measurement of points of interest. These include high-contrast adhesive targets for use with theodolites, reflective tape targets for use with Total Stations and targets in special adapters to measure hole centers (Figure 8). Hidden points can be located using rods with multiple targets offset from the contact point of interest at one end (Figure 9). Laser target spots, projected using a laser eyepiece, can provide fully noncontact targets for inaccessible or delicate surfaces (Figure 10).

Motor drives, target sensing, and radio control all provide mechanisms that automate and accelerate the measurement process, for example, by enabling target tracking.

Note that the theodolite intersection method is currently in decline, with much stronger interest being shown in the

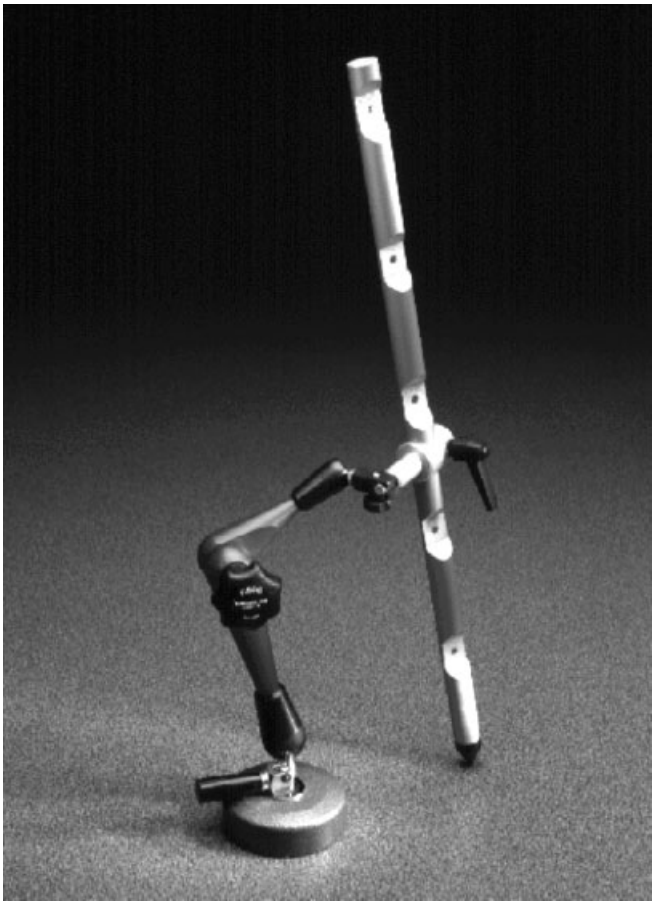

Figure 9. Hidden point rod. (Reproduced by permission of Leica Geosystems.)

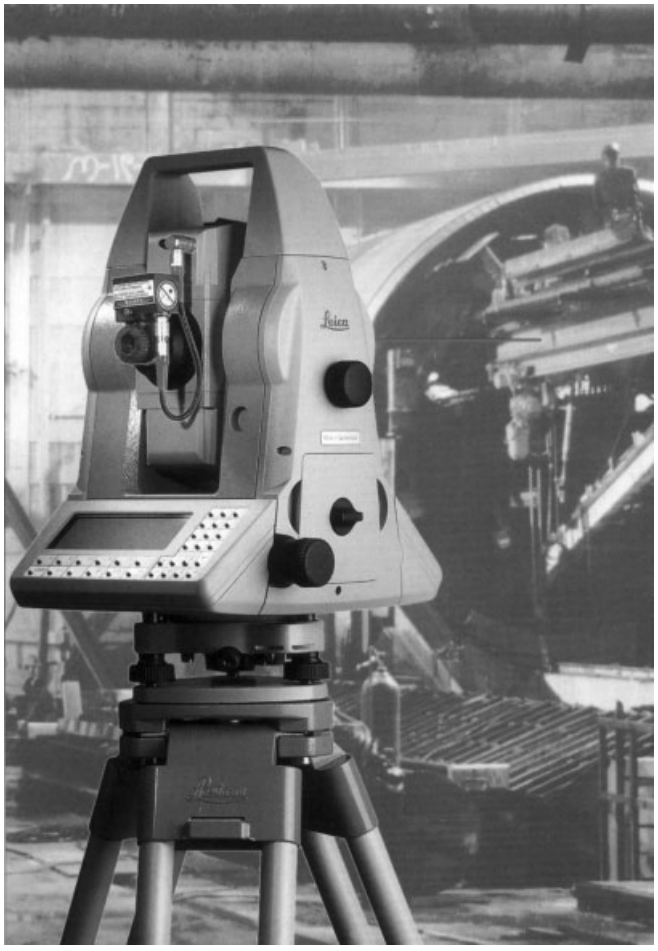

Figure 10. Laser eyepiece. (Reproduced by permission of Leica Geosystems.)

application of Total Stations, laser trackers (Section 4) and digital photogrammetry systems (Section 5).

4 TRACKING LASER INTERFEROMETERS

The tracking laser interferometer or laser tracker locates a moving reflector in 3D. Current manufacturers are Leica Geosystems (*see* Kyle (1999) and www.leica-geosystems.com/ims), Faro (www.faro.com) and API (www.apisensor.com) – *see* **Article 92, Optical Measuring Instruments, Volume 2** and **Article 91, Light Sources and Detectors, Volume 2** for more on interferometers.

A conventional interferometer (Figure 11) reflects a fixed laser beam off a retroreflector (see below). The reflector slides along the beam, returning it to the interferometer, which uses the wave property of interference to detect the reflector's movement to submicrometer resolution.

A tracking interferometer can point the interferometer beam in different directions, for example, by reflecting off a rotating mirror or by rotating the housing. It can therefore follow a retroreflector moving in 3D. The following description is based on the Leica laser tracker (see Figure 12 and Figure 13).

Tracking operates as follows (Figure 14):

- A mirror in the head is rotated about two orthogonally intersecting axes.
- An interferometer beam is reflected off the mirror and onto a retroreflector.
- The reflector returns the beam along the same path.
- Reflector movement along the beam is detected by the interferometer.
- Lateral reflector movement causes a lateral beam displacement, which is detected by a PSD (Position Sensing Device).
- The PSD signal moves the mirror to keep the beam on target.

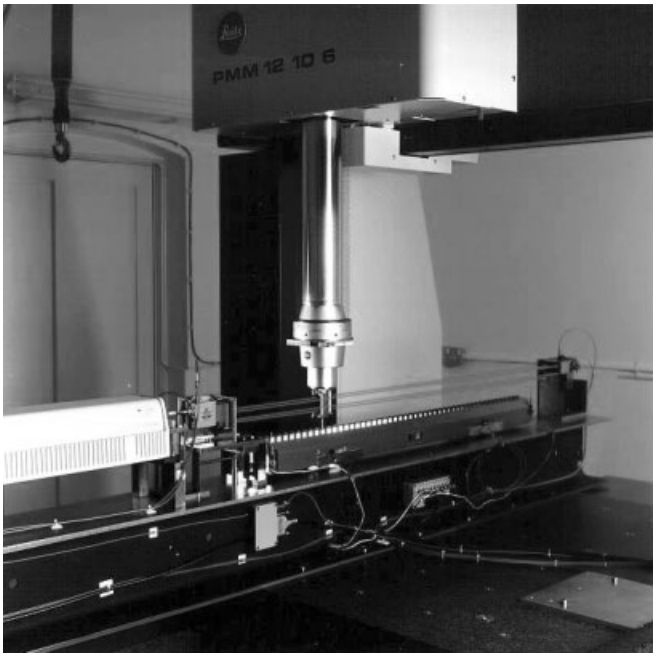

Figure 11. Conventional interferometer in use at NPL. (Crown Copyright, courtesy of NPL.)

- The mirror pointing is detected by angle encoders.
- Interferometer and angle encoders are read 3000 times a second.

The mirror angles (*Zn, Az*), and distance (*D*) locate the reflector at P by spherical coordinates (Section 2).

Since an interferometer can only measure a change of distance, not an absolute value, the tracker has a fixed point on its housing where measurements can be initiated and whose absolute distance is known by prior calibration. Interferometer changes are added to this fixed value to generate absolute distances. Alternatively, a separate coaxial ADM (Absolute Distance Meter) can initialize the distance at any temporarily stable reflector position. This uses phase measurement (Section 3) to calculate absolute distance but the process is not itself fast enough for tracking.

Retroreflection can be provided by a corner-cube reflector made up of 3 orthogonal plane mirrors. Figure 15 illustrates the principle. Figure 16 shows an actual reflector. Other types of retroreflectors are possible.

Since the reflector is not necessarily the point of interest, target probes that have offset probing points and that can be tracked in all 6 degrees of freedom (6DOF) have been developed, see Loser and Kyle (2003).

5 CAMERAS AND PHOTOGRAMMETRY

With knowledge of a camera's geometry, and precise measurement of the *xy* image coordinates of an object target

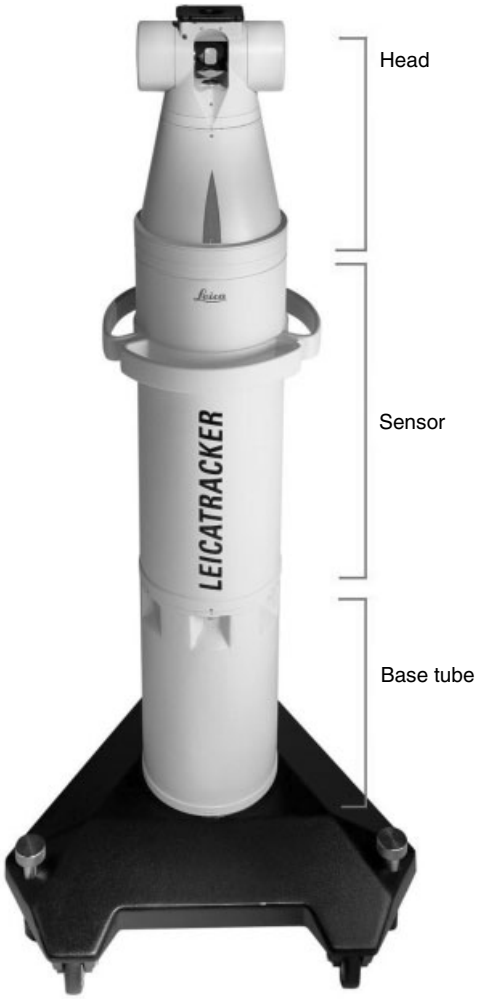

Figure 12. Leica tracker LTD 800. (Reproduced by permission of Leica Geosystems.)

point, the imaging ray from camera to target can be accurately reconstructed. Figure 17 shows how intersecting rays from two or more images locate targets in 3D space using triangulation (Section 1).

The techniques and equipment involved in making precise 3-dimensional measurements from photographic images are covered by the science of photogrammetry. Here, the reference model for cameras is the pinhole camera whose simple geometry is easy to handle mathematically. It implements the collinearity condition that target, pinhole, and image lie on a straight line and ensures that straight lines in object space create straight lines in the image (Figure 18). Its internal geometry is defined by the Principal Point, which is the foot of the perpendicular from pinhole to image plane, and Principal Distance, which is the length of this perpendicular (Figure 19).

A real camera has a complex glass lens in place of the pinhole and its geometric properties are only a close

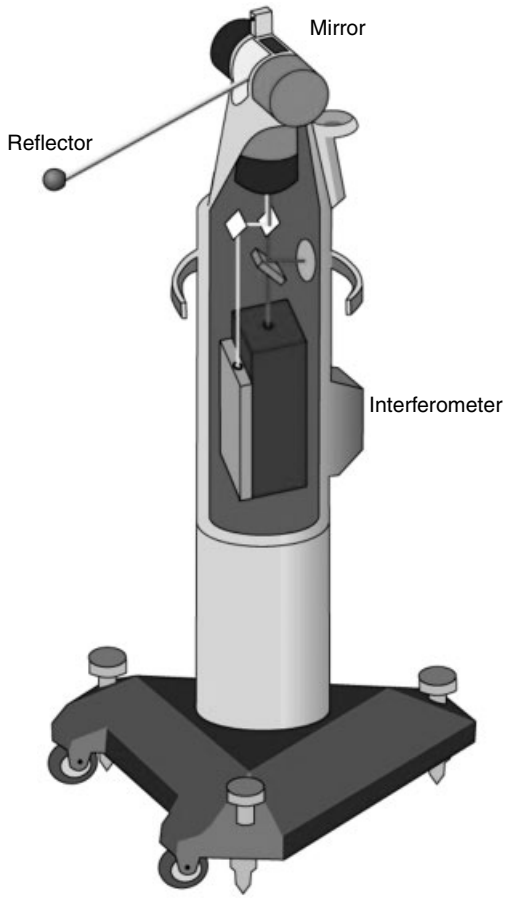

Figure 13. Leica tracker cutaway diagram. (Reproduced by permission of Leica Geosystems.)

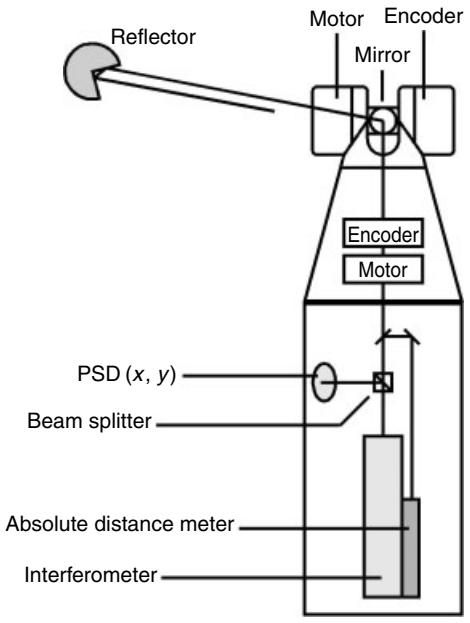

Figure 14. Leica tracker components. (Reproduced by permission of Leica Geosystems.)

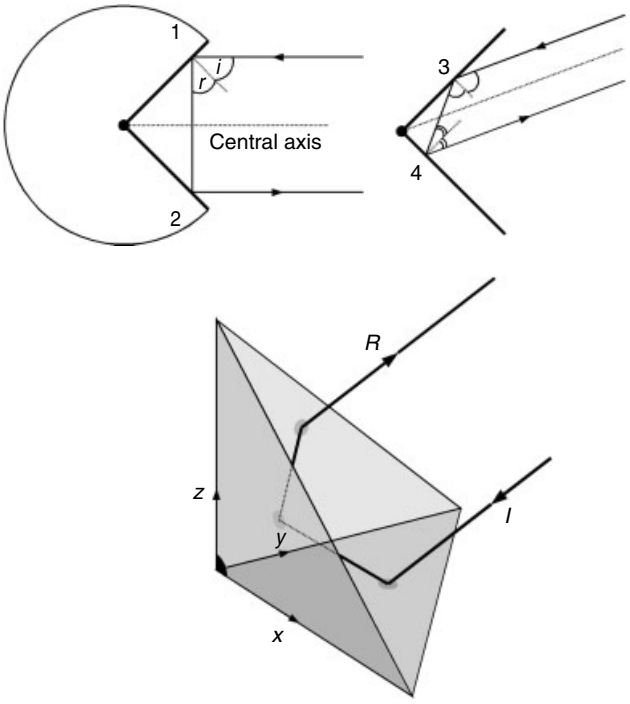

Figure 15. Principle of corner-cube reflector. (Reproduced by permission of Leica Geosystems.)

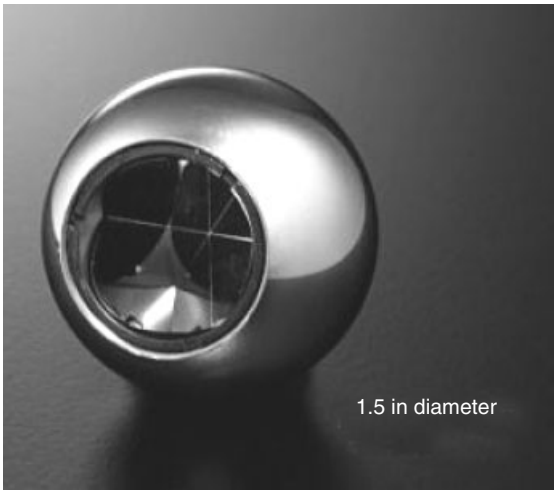

Figure 16. Example of corner-cube reflector. (Reproduced by permission of Leica Geosystems.)

approximation to a pinhole camera. To achieve metrological accuracy, real images must therefore be corrected to equivalent pinhole camera images using some process of camera calibration (Section 6).

Unlike everyday cameras, cameras for use in metrology have a more rugged and stable design, often with fixed focusing. With calibration, they then function like pinhole cameras of known internal geometry.

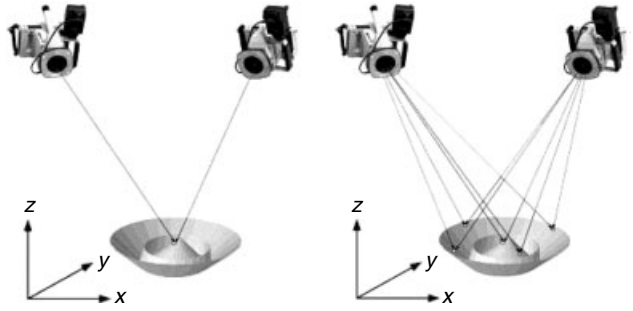

Figure 17. Single and multipoint triangulation by camera. (Reproduced by permission of Geodetic Systems.)

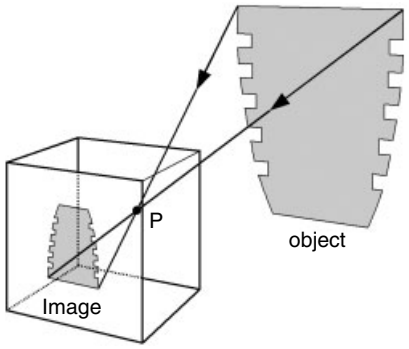

Figure 18. Pinhole camera operation. (Reproduced by permission of Leica Geosystems.)

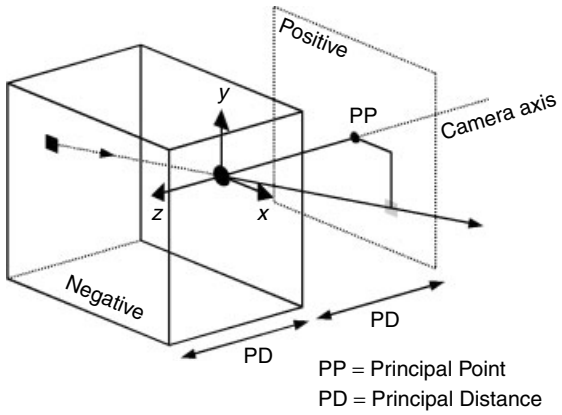

Figure 19. Pinhole camera parameters. (Reproduced by permission of Leica Geosystems.)

Early applications of photogrammetry in metrology had to accommodate the chemical processing of film and plate, and the separate measurement of the image outside the camera.

Modern digital photogrammetric systems use electronic cameras in which high resolution imaging chips of 2×3 K pixels are not unusual. With integrated image processing, they enable highly automated and online measurement procedures. Figure 20 shows the latest INCA3 camera from Geodetic Systems Inc. (www.geodetic.com).

Figure 20. INCA3 metric camera. (Reproduced by permission of Geodetic Systems.)

Object targeting typically makes use of highly reflective targets illuminated by camera flash. Images then resemble star fields, which simplifies image processing and improves image coordinate accuracy, leading to more accurate 3D data. Targets can be on adhesive tape for general surface measurement or on adapters for locating specific object features. Coded targets, coupled with appropriate image processing, provide unique identifiers for further automation. Figure 21 shows a range of GSI targets.

Target probes as in Figure 22 are used for online measurement.

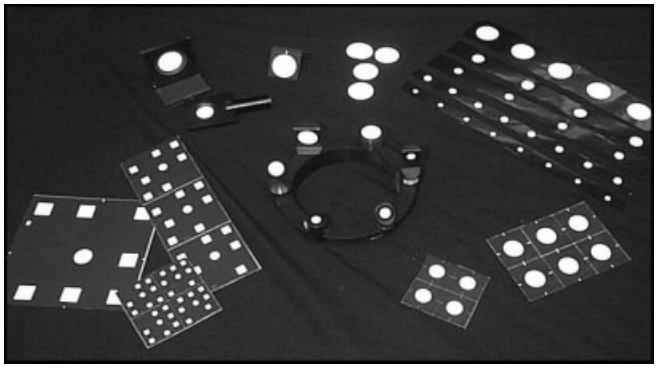

Figure 21. Photogrammetric targets. (Reproduced by permission of Geodetic Systems.)

Figure 22. Photogrammetric target probe. (Reproduced by permission of Geodetic Systems.)

Figure 23. ProSpot target projection. (Reproduced by permission of Leica Geosystems.)

Optically projected targets enable fully noncontact measurement as illustrated in Figure 23.

6 CALIBRATION OF INSTRUMENTS

Manufacturing tolerances and optical properties ensure that instruments do not conform to an idealized design model. Calibration is needed in order to achieve optimal object coordinate accuracy and some of principal features are presented here. Instrument calibration in general is discussed in **Article 217, Instrument Evaluation, Volume 3**. Test facilities are covered in **Article 216, Test Facilities, Volume 3**.

6.1 Reversal technique

Telescope reversal is illustrated by a theodolite telescope (Section 3), which can be rotated into two different positions in order to sight a target (Figure 24).

The following three examples show how this can detect errors and their sources by changing the sign of the error.

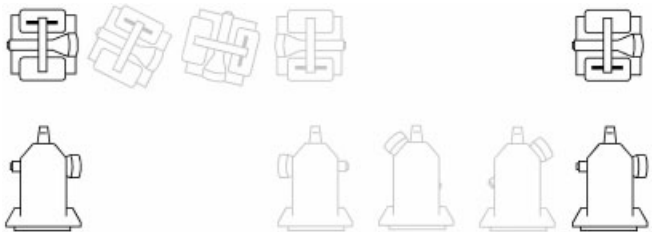

Figure 24. Telescope reversal. (Reproduced by permission of Leica Geosystems.)

6.1.1 Transit axis tilt

The transit axis is the telescope's horizontal axis of rotation. Transit axis tilt is present when this is not perpendicular to the vertical axis of rotation (Figure 25).

6.1.2 Horizontal collimation error

Horizontal collimation error is present when the telescope's line of sight is not perpendicular to the transit axis (Figure 26).

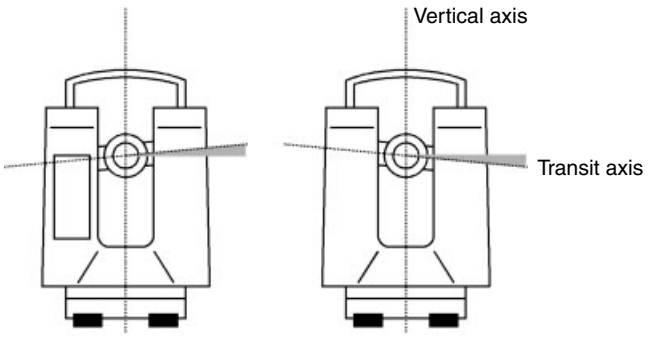

Figure 25. Transit axis tilt – sign change on reversal. (Reproduced by permission of Leica Geosystems.)

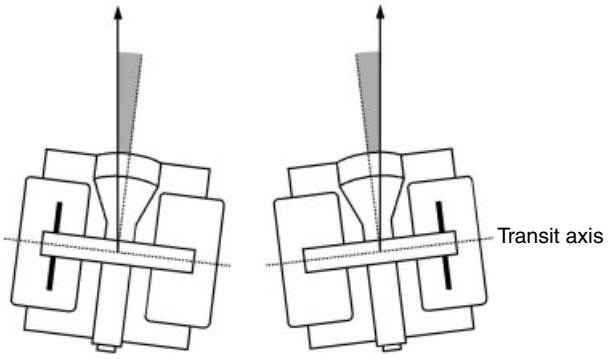

Figure 26. Horizontal collimation error – sign change on reversal. (Reproduced by permission of Leica Geosystems.)

6.1.3 Vertical index error

The zero mark on the vertical angle encoder may not be identical with a horizontal or vertical pointing, but this vertical index error can be found by summation (Figure 27).

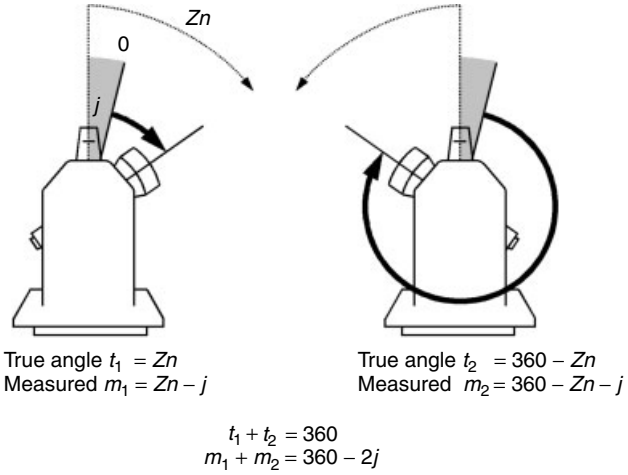

Figure 27. Vertical index error calculated by summation of pointings. (Reproduced by permission of Leica Geosystems.)

6.2 Mechanical model

A laser tracker (Section 4) has a number of subcomponents, which should have an ideal alignment and position relative to one another. Deviations from the ideal are illustrated by the Leica tracker.

Figure 28 shows three possible tilt parameters.

Figure 29 shows four possible offset parameters.

Figure 30 shows three possible encoder errors.

On-board reference distances are also required to initialize absolute range measurement. Determining the full parameter set requires measurement throughout the tracker's working range, including mirror reversal and measurements of accurate reference circles generated by attaching the reflector to a precision ball bar.

6.3 Optical model

In the pinhole camera (Section 5), which is the reference model for a real camera, straight lines in object space

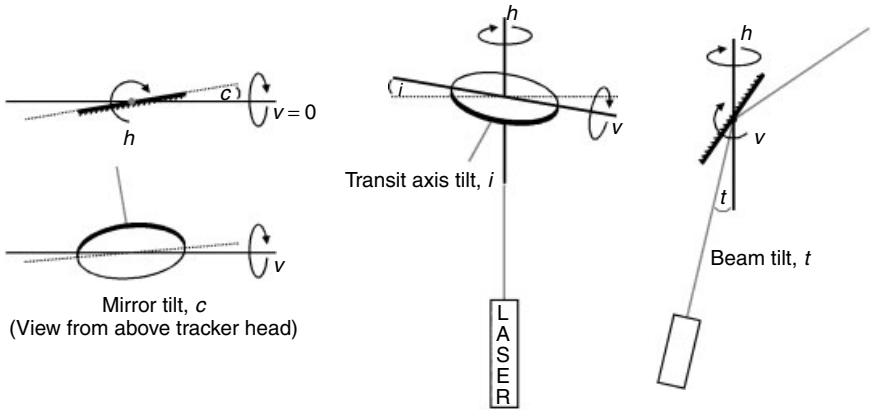

Figure 28. Leica tracker tilt parameters. (Reproduced by permission of Leica Geosystems.)

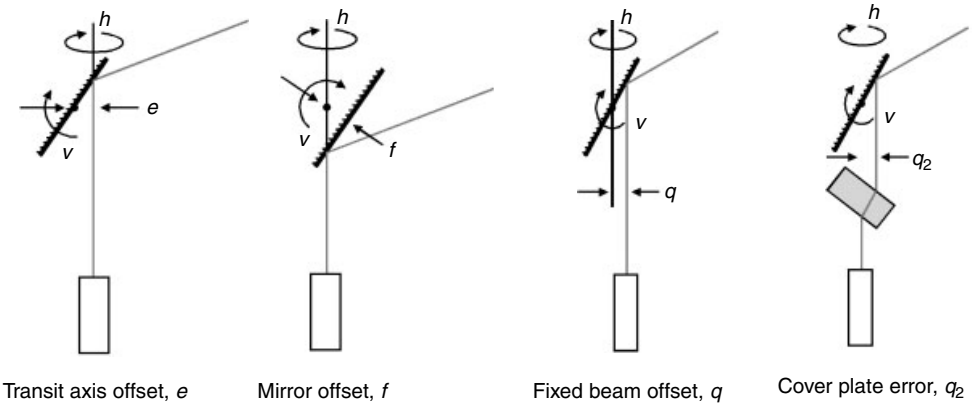

Figure 29. Leica tracker offset parameters. (Reproduced by permission of Leica Geosystems.)

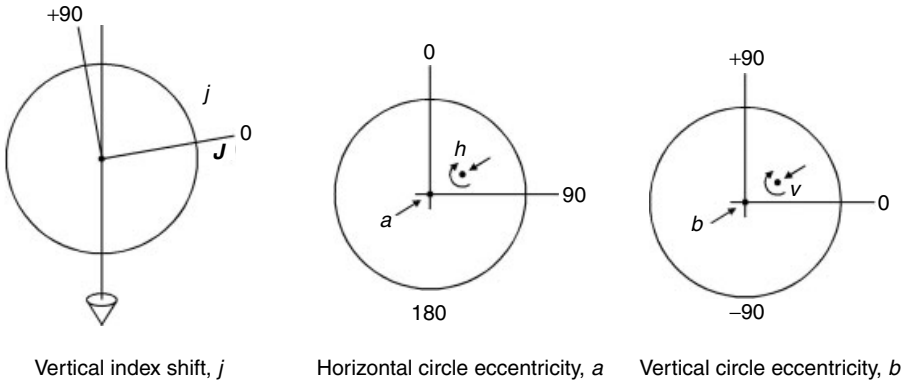

Figure 30. Leica tracker encoder parameters. (Reproduced by permission of Leica Geosystems.)

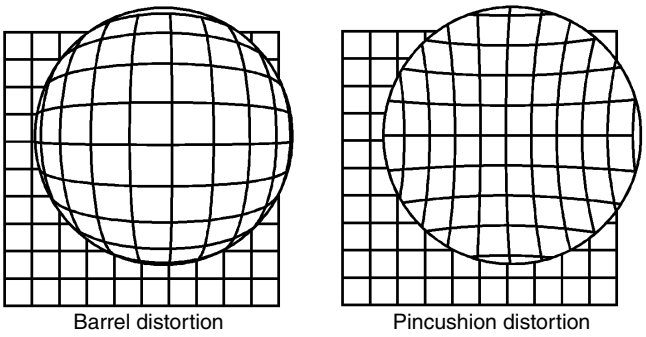

Figure 31. Lens distortion – barrel and pincushion. (Reproduced by permission of Leica Geosystems.)

generate straight lines in image space. However, lens distortion in a real camera will cause the imaged lines to bend, as illustrated in Figure 31.

A four- or five-parameter model is typically required to remove the distortion effects. In addition, parameters for Principal Point and Principal Distance must also be calculated. Only then can the rays in object space be accurately regenerated from image measurements.

Cameras can be calibrated by multiple images of a set of accurately positioned reference targets. However, a common alternative includes the parameters of a camera model as additional unknowns when calculating the coordinates of an unknown set of target points. This technique is known as *self-calibration*.

7 ORIENTATION TECHNIQUES

This section describes some common ways of directly determining the relative positions and angular orientations of measured objects and measuring instruments, which is a fundamental requirement in LSM. These use minimal data and can be further optimized by techniques that cannot themselves initialize the calculation. The methods require either manual or automatic identification of instruments and targets.

7.1 Collimation

Theodolites and Total Stations (Section 3) can be oriented to one another by first sighting along the line joining their rotation centers. This collimation procedure makes their telescope axes parallel (and superimposed). Since the rotation centers cannot normally be targeted, an indirect procedure requiring an external target, and telescope reversal (Section 8) is employed. The average pointing is the one required (Figure 32).

Given collimation pointings between instruments S1 and S2, intersecting an offset target at T1 provides sufficient data to calculate relative orientation, apart from a scale value D. Intersecting a second target at T2, a known distance L from T1, enables correct calculation of D (Figure 33).

7.2 Space resection

A method particularly used for camera/object orientations requires the image of four target points known in an object coordinate system (Figure 34).

From image coordinates and calibrated camera geometry, the space angle, a, between any two targets can be measured. When combined with target separation, D, the camera's possible position is restricted to a set of circles of specific radius and common chord (Figure 35). Three target images provide three circle sets from which the possible positions can be reduced to a maximum of four specific locations. Measurement of a fourth target resolves the problem. This technique is known as *space resection* and many possible solutions exist. See, for example, Smith (1965), Kyle (1990) and Munjy and Hussain (1996).

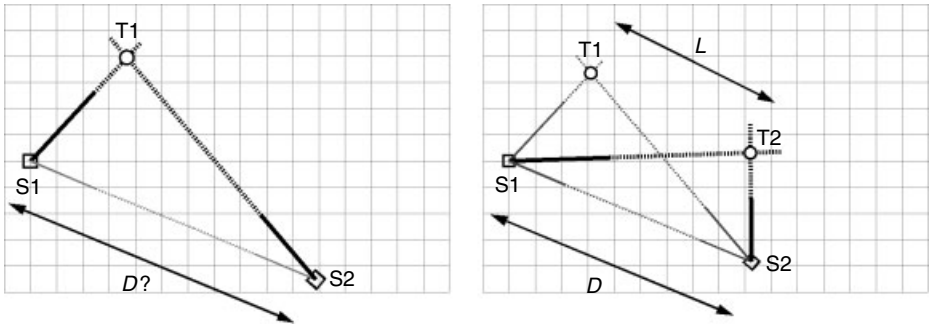

Figure 33. Orientation by collimation and offset targets. (Reproduced by permission of Leica Geosystems.)

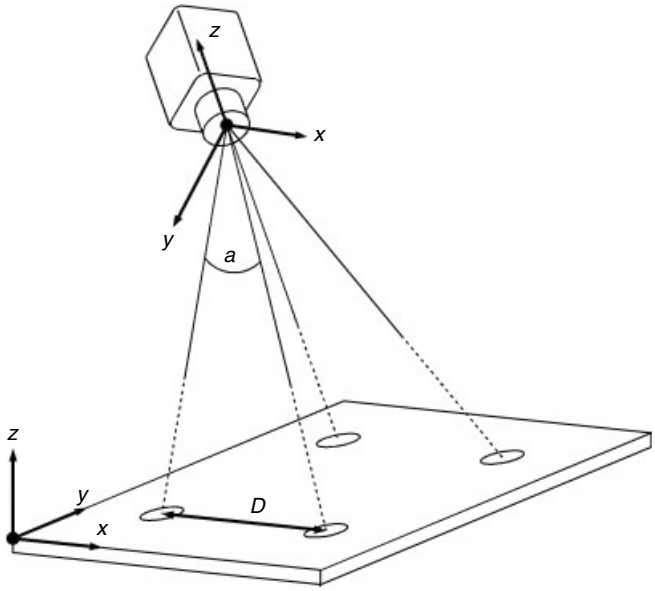

Figure 34. Space resection of camera relative to targeted object. (Reproduced by permission of Leica Geosystems.)

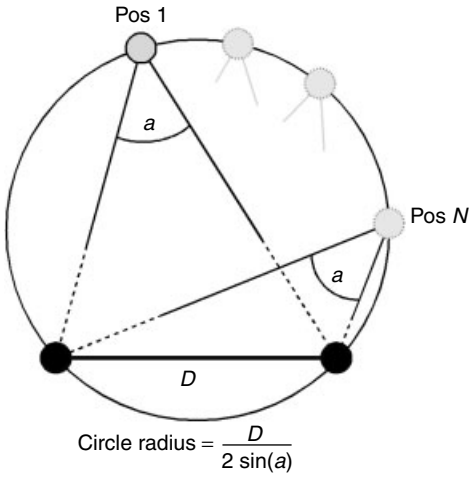

Figure 35. Resection circle. (Reproduced by permission of Leica Geosystems.)

7.3 3D transformation

Total Stations (Section 3) and laser trackers (Section 4) can be oriented with respect to one another if they have measured three common points forming a triangle. The same technique is applied to objects where three or more locations are measured in an arbitrary coordinate system but known, say, in a CAD coordinate system. By applying the parameters of a 3D transformation, illustrated in Figure 36, measurements ($P_1 \ldots P_3$) can be converted to CAD values ($R_1 \ldots R_3$).

The calculation requires a shift, S, between two corresponding points (Figure 37).

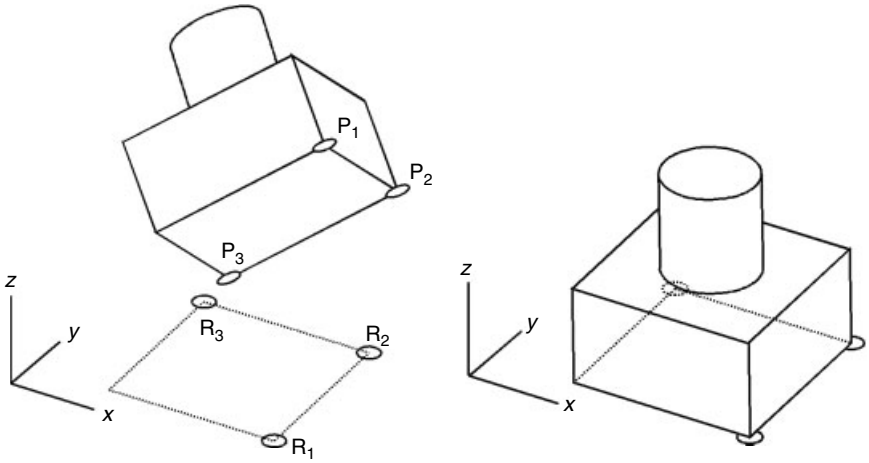

Figure 36. 3D transformation – overview. (Reproduced by permission of Leica Geosystems.)

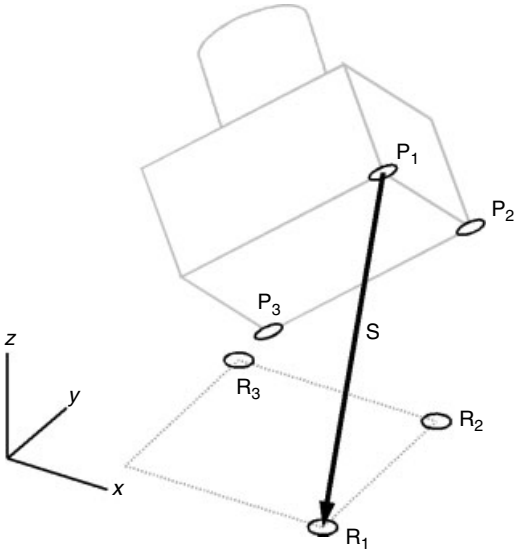

Figure 37. 3D transformation – shift vector. (Reproduced by permission of Leica Geosystems.)

Transformation is completed by a 3D rotation, **Ro**, derived from corresponding unit vectors, (Figure 38).

8 STANDARDS AND GOOD PRACTICE

Standardized procedures enable comparison between measurement systems and confirmation that a system is operating as specified. Good practice procedures enable users to optimize measurement results. Both are ultimately concerned with a system's coordinate accuracy.

Despite similarities with CMMs, for which standards exist, only very limited standards are available for LSM systems. CMMs have a fixed measurement volume and accuracy expressible in simple mathematical terms. In contrast, LSM networks have a volume dependent on task and an accuracy, which varies in a complex way within the network. Figure 39 shows a plan view of a dual theodolite triangulation network.

Uncertainties in mechanical systems are discussed in **Article 88, Error Sources in Fine Mechanics, Volume 2**. The theodolites have a fixed angular uncertainty indicated by the dotted lines on either side of the solid intersecting rays. This results in an area of positional uncertainty indicated by the gray quadrilaterals. Optimal accuracy is indicated by the 90° intersection, which applies to points on the dashed semicircle. No scale is indicated and the instruments could be 2 or 20 m apart, with a corresponding scale change in uncertainty. Features of an LSM system that contribute to the complex uncertainty analysis include

- very flexible choice in position, number, and type of measuring instruments, all of which can contribute to the measurement of a particular point;
- variable uncertainty due to intersection of two or more pointings to a target;
- different methods of introducing scale, from one or more scale bars to a range value in every measurement;
- an unrestricted measurement volume;
- simultaneous multiple point measurement in the case of photogrammetry.

In Germany, a proposal exists for photogrammetric systems in the form of VDI/VDE 2634. A common theme in developing possible standards for comparing and evaluating LSM systems is the use of reference lengths placed in different parts of the workspace. In fact, acceptance, and verification tests for CMMs are essentially length-measuring tasks. Reference length measurement is a simple

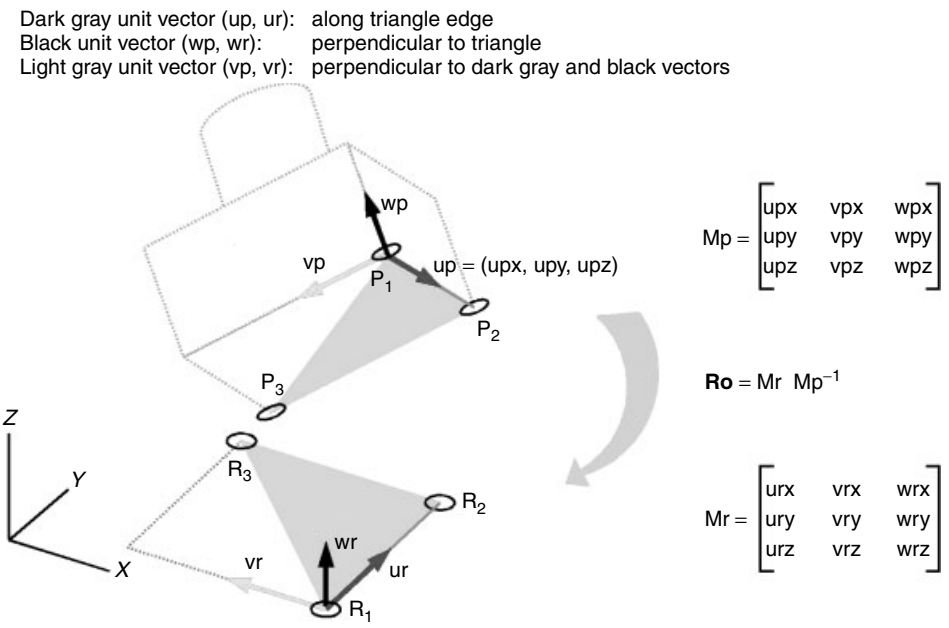

Figure 38. 3D transformation – rotation matrix. (Reproduced by permission of Leica Geosystems.)

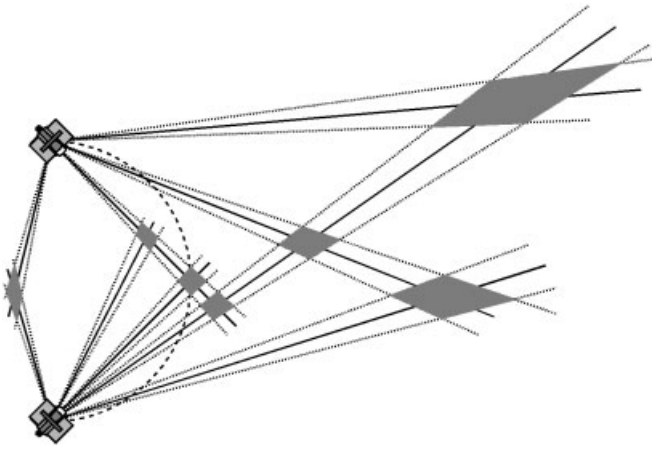

Figure 39. Effect of intersection error on accuracy. (Reproduced by permission of Leica Geosystems.)

and recommended procedure, which is frequently used on site to check system operation.

These comments lead on to good practice guides of which the most accessible example has been created at University College London, in cooperation with the UK's National Physical Laboratory and Leica Geosystems. See http://www-old.ge.ucl.ac.uk/research/projects/NMSPU_Best_Practice_Guide.pdf

This guide concentrates on laser trackers and to a lesser extent on theodolite systems. It does not explicitly consider photogrammetric systems although many comments are also relevant here. The project behind this guide is presented by Kyle *et al*. (2001).

9 SAMPLE APPLICATIONS

These examples provided by Leica Geosystems (www.leica-geosystems.com/ims) and Geodetic Systems Inc., (www.geodetic.com) indicate the scope of LSM applications and the advantages of using LSM methods.

9.1 Digital photogrammetry

Figure 40 shows a 2×3 m aircraft tooling jig being measured with a hand-held metric electronic camera, which demonstrated an efficient way of achieving the same results as theodolite intersection.

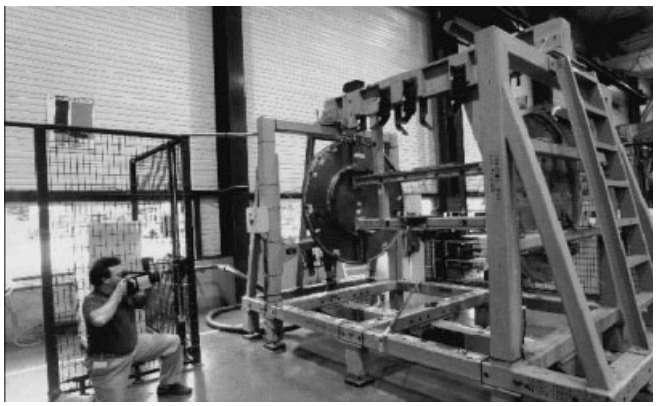

Figure 40. Using digital photogrammetry to measure an aircraft tooling jig. (Reproduced by permission of Leica Geosystems.)

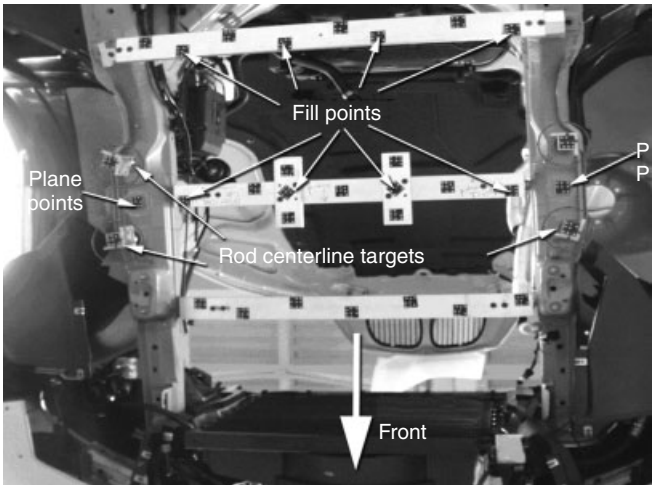

Figure 41. Photogrammetric targeting on axle carrier. (Reproduced by permission of Leica Geosystems.)

Total measurement time was 35 min as follows:

- Place 150 targets: 15 min.
- Record 60 images: 10 min.
- Process the images: 10 min.

Coordinate accuracy achieved: $<50\,\mu m$

BMW evaluated photogrammetry for production line measurement of an axle carrier (Figure 41) using special coded targets (Section 5).

Only 5 min were permitted for placing targets, taking images, and removing targets. 18 images were taken of 8 targets and 8 scales in a 2-min window, resulting in RMS accuracies in x, y, and z of $8\,\mu m$, $7\,\mu m$, and $17\,\mu m$ respectively.

9.2 Laser tracker

Daimler–Chrylser Aerospace had been measuring an aircraft rudder using a traditional mechanical gauge (Figure 42).

Manufacture of the gauges is expensive and their use is not efficient. They adopted an alternative approach using a laser tracker (Figure 43).

The advantages of using a tracker have been

- simpler, more compact system,
- faster data acquisition,
- more accurate data,
- immediate comparison with reference values,
- elimination of traditional gauge with associated cost and space savings.

NASA's X-38 space vehicle is a possible model for transporting astronauts and the atmospheric reentry requirement demands very precise assembly. Traditional alignment techniques were time consuming and so replaced by laser tracker (Figure 44)

Figure 42. Gauge for aircraft part checking at Daimler–Chrysler Aerospace. (Reproduced by permission of Leica Geosystems.)

Figure 43. Tracker measures aircraft component at Daimler–Chrysler Aerospace. (Reproduced by permission of Leica Geosystems.)

Advantages have been

- 70% reduction in inspection time with 'ring frame' inspection down from 2 weeks to under 3 days;

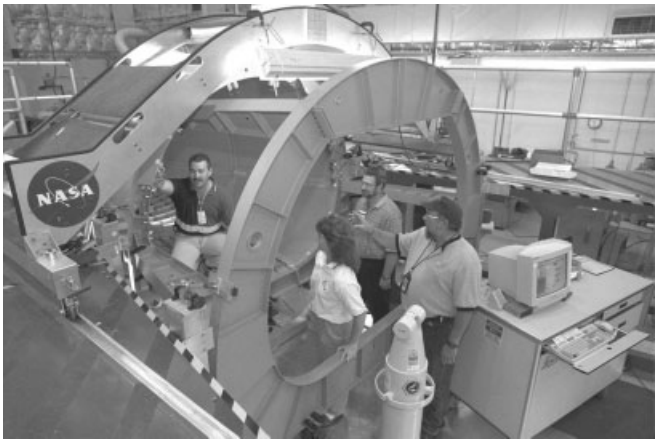

Figure 44. NASA X-38 measured by tracker. (Reproduced by permission of Leica Geosystems.)

- parts referenced in a single coordinate system within a tolerance of 0.05 inch;
- portability in bringing the system to and around the object.

9.3 Total Station

Leica's precision Total Stations are appropriate instruments for controlling the construction of a ship as they can achieve submillimeter accuracy at ranges up to 120 m.

One task is the positioning of bulkheads (Figure 45). These define cargo storage areas, which must be accurate in order to facilitate loading/unloading and prevent cargo movement.

Another task is roundness checks on submarine hulls. An older technique involving elaborate scaffolding and restricted mechanical measurement (Figure 46) has been considerably simplified by direct 3D measurement using the Total Station (Figure 47).

1 CONCEPT OF TEMPERATURE

The concept of temperature is closely related to the physiological experience of hotness or coldness when some object is touched or approached. Indeed, *hotness* and *coldness* were regarded as two separate properties of matter in ancient Greece. Fuzzy qualitative descriptions, which are used when objects are described as relatively cold, cool, or tepid, or perhaps as hot, warm, or boiling, are intuitive ways of expressing notions related to personal comfort.

As soon as thermometers were invented, an immediate need arose for refinement of the concepts of temperature and hotness. Heat is transferred from hot to other cooler bodies in such a way that both bodies tend to equalize their temperatures, approaching a new common intermediate temperature.

This notion is contained in the definition of temperature given by the Scotsman James Clerk Maxwell. He stated that the temperature of a body is its thermal state, which is regarded as a measure of its ability to transfer heat to other bodies.

This assumption, that heat flows from warmer to cooler bodies, forms the basis of the International Temperature Scale of 1990, commonly referred to as ITS-90. The agreement to internationally adopt this *Temperature Scale* is the latest step in the long, difficult, and tortuous route, which error-prone science has taken toward a contemporary definition of temperature.

2 HISTORICAL DEVELOPMENT OF TEMPERATURE SCALES

During the second century B.C., the Greek physician C. Galen associated four degrees of coldness with the effects of different medicines upon human physiology during his medical treatments. The purpose of the medicines was to warm his chilled patients or to cool his feverish patients.

Building upon Galen's basic assumption, later 'scientists' tried to credit the effects of these medicines to different bodies by giving them different degrees of warmth or coldness.

The first device, which was used to measure the degree of warmth or coldness, seems to have been invented by Galileo Galilei sometime between the years 1592 and 1603 A.D. This instrument, which is shown in Figure 1(a), consisted of an air-filled glass bulb connected to a long tube immersed in a colored liquid. The liquid column rose or fell as a function of the ambient temperature, which influenced the entrapped air, thus indicating the degree of warmth or coldness. In the absence of any evidence that the instrument had graduations, it is better to call it an *air thermobaroscope*. Attempts to measure the length of the column were probably made using dividers or compasses. As the indicated values were also a function of the atmospheric pressure, its precision must have been quite poor.

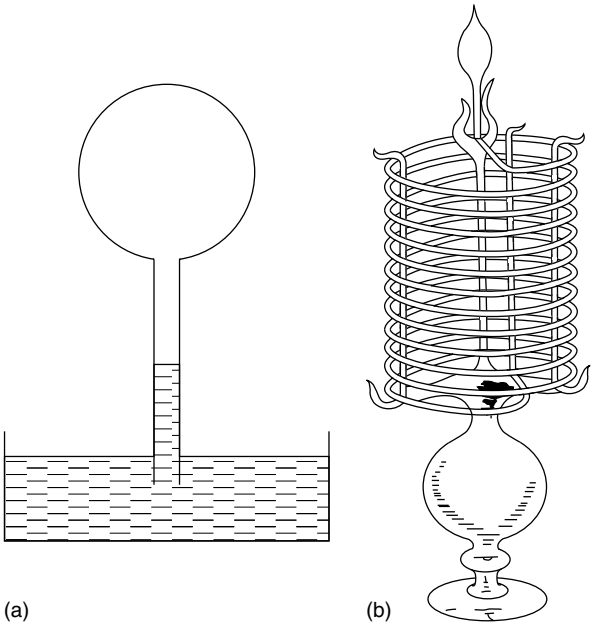

Figure 1. Early types of thermometer (a) Galileo's air thermoscope and (b) thermometer of Florentine Academy of Sciences.

The concept of atmosphere was unknown at that time. Subsequently, these atmospheric dependencies were removed by applying suitable corrections. It is apparent from these observations that although the response of a thermometer to variables other than temperature causes errors in the measurement, these errors may be compensated for by using appropriate corrections.

About the year 1650 A.D., members of the Florentine Academy of Sciences made the first thermometer, which is represented in Figure 1(b). This consisted of a spiral-shaped tube with a closed end. Although a graduation was a part of the device, numbers were not associated with it.

In due course, confidence in the stability and repeatability of physical states led to their association with defined temperature fixed points. It was realized that intercomparison of existing thermometers could only be performed by tests conducted in systems, which duplicated these states.

One of the first proposals, from H. Fabri from Leida in 1669, was for two fixed points. The lower point should be the temperature of snow and the higher point, the temperature of the hottest summer day.

A later proposal, which was made by C. Rinaldi from Padua in 1693, suggested that the fixed points should be the temperatures of the melting point of ice and the boiling point of water. Between these two points, 12 divisions should be introduced. In the same year, and for the first time, the British scientist E. Halley applied mercury as the thermometric liquid.

Rømer, a thermometrist working in Copenhagen at the end of the seventeenth and beginning of the eighteenth century, developed a scale in which zero degrees was associated with the coldest day, while the normal temperature of the human body was associated with 24 degrees. This made the temperature of boiling water equivalent to ≈ 50 to 55 degrees on this unusual scale, which was influenced by the predominant use of thermometers for meteorological purposes at that time. Hence, if the freezing point of water had been taken as zero, the repeated use of negative values for winter temperatures would have occurred. Winter temperatures of $-16\,^{\circ}\mathrm{C}$ ($\approx 0\,^{\circ}\mathrm{F}$) are quite common in continental Europe.

To avoid this, it seemed obvious to use the lowest attainable temperature of those days as zero. Shortly after Rømer proposed his scale, his laboratory was visited by D. G. Fahrenheit from Danzig (now the city of Gdañsk in Poland).

Fahrenheit's description of the mercury-in-glass thermometer in 1724 was a notable milestone in the development of thermometry. Fahrenheit, evidently influenced by Rømer's scale, proposed his own, very well known scale, which associates 32° with the freezing point of water and 212° with its boiling point. Why did he choose these divisions for this scale? Although the reasons are unclear, the upper fixed point, the temperature of boiling water ($\approx 212\,^{\circ}\mathrm{F}$), was probably rejected as being unnecessarily high for meteorological purposes. Instead, he merely changed Rømer's 24 degrees for body temperature to 96. This change, which was equivalent to four subdivisions on each degree of the Rømer scale, was also probably made because 96 is divisible not only by 2 but also by multiples of 3 and hence 12 – the decimal system commonly used now was not in general use at that time. The Fahrenheit scale, which persists today, is essentially the same as that described by him to The Royal Society in 1724.

Further development of the mercury-in-glass thermometer, in 1742, was due to the Swedish astronomer and physicist A. Celsius. He assigned 100° to the temperature of melting ice and 0° to the temperature of boiling water. The region between these two points was divided into 100 equal steps. Subsequently, after the death of Celsius in 1744, M. Strømer, his friend and scientific collaborator, reversed these values.

Eventually, as science developed, a need to measure temperatures above the melting point of glass arose. Prinsep's air thermometer, which used a gold bulb to measure temperatures of $1000\,^{\circ}\mathrm{C}$, in 1828, was followed soon after, in 1836, by a platinum bulb in a similar thermometer by Pouillet.

A true Thermodynamic Temperature Scale, described in Section 3, had been the unconscious aim of all the previous efforts. Such a scale was not possible until 1854 when its foundations were laid by William Thompson,

later afforded the title Lord Kelvin of Largs, and other contemporary scientists.

3 THERMODYNAMIC TEMPERATURE SCALE

The aim of any scale of temperature, especially the thermodynamic scale, is the representation of hotness and hotness relations between objects and events in the real physical world by real numbers. As numerical values are correlated to some defined temperatures, temperature fixed points are required to attribute certain temperature values. Interpolation then allows the definition of temperature between these temperature fixed points.

A thermometric working substance is needed one of whose properties and a correlating function must be assumed. The chosen function provides the means of attributing the chosen property of the working substance to a certain temperature. Because of the diversity of materials and their properties, there is an unlimited number of these temperature scales.

The material that most closely approximates this ideal thermometric working substance is an ideal gas. Indeed, it was the work of Robert Boyle and his coworkers in the middle of the seventeenth century that led to the conviction of many later scientists that there was such a thing as an *absolute zero* of temperature. These eminent individuals included G. Amontons, in Paris in 1699; J. H. Lambert, in 1770; and Gay-Lussac, in 1790. Gay-Lussac gave credit to J. A. C. Charles for the latter's previously unpublished researches. All of their efforts resulted in what is now called the *ideal gas law*, which is written in the usual form

$$PV = nkT \tag{1}$$

where P is the pressure, V is the volume, n is the number of moles of gas, k is Boltzmann's constant ($= 1.3807 \times 10^{-23}$ J K^{-1}) and T is the absolute temperature.

When the temperature is held constant, (1) corresponds to *Boyle's Law*.

Similarly, *Charles' Law* is obtained from (1) when the pressure is held constant.

Since there are no direct methods for measuring temperature, as there are with, say, length measurement, some difficulties are associated with temperature measurement. As only indirect temperature measurements are possible, any temperature scale depends upon the chosen thermometric working substance and its chosen property. Although any working substance may be applied in principle, its use will be restricted to some finite range determined by its thermal behavior.

For example, the application of mercury-in-glass thermometers is limited on the low-temperature side by the solidification of the mercury as it freezes and on the high-temperature side by the inability of the glass to expand indefinitely as well as by its melting temperature.

Melting of the glass was responsible for the Prinsep and Pouillet thermometers.

An ideal solution to the problem of proposing a suitable temperature scale would be to find one that is valid in any temperature range and is totally independent of the working substance.

The Kelvin Thermodynamic Temperature Scale, based upon the efficiency of the ideal reversible Carnot cycle, is such a scale. A reversible Carnot Cycle consists of a reversible heat engine operating between two isotherms at the temperatures T_2 and T_1, with $T_2 > T_1$, and two adiabatic processes. A reversible heat engine absorbs the heat Q_2 from the high-temperature source, at the temperature T_2, and discharges the heat Q_1 to the low-temperature source, at the temperature T_1. The difference between the absorbed heat Q_2 and the discharged heat Q_1, which is the external work, W, performed by the engine, may be written as

$$W = Q_2 - Q_1 \tag{2}$$

Reversing the engine action indicates that it may be driven by a second identical engine working between the same heat sources. The effect of such an action may be the heat flow from the lower to the higher temperature source. Using the properties of reversible processes, it may be proven that the ratio Q_2/Q_1 is a function of only the two source temperatures, so that

$$\frac{Q_2}{Q_1} = f(T_1, T_2) \tag{3}$$

Following Kelvin's proposal, it may be assumed that the functional relation in (3) is

$$\frac{Q_2}{Q_1} = \frac{T_2}{T_1} \tag{4}$$

Equation (4) is the basis of the thermodynamic temperature scale. From (2) to (4), the efficiency of a reversible heat engine is defined as

$$\eta = \frac{W}{Q_2} = \frac{Q_2 - Q_1}{Q_2} = \frac{T_2 - T_1}{T_2} = 1 - \frac{T_1}{T_2} \tag{5}$$

This efficiency and the definition of temperature, which is based upon the former, may be shown to be independent of the working substance. As a result, it may be used to

define the thermodynamic temperature scale.

$$T_1 = T_2(1 - \eta) \tag{6}$$

By means of this scale, any chosen thermal state, such as the melting point of ice, may be assigned a certain value of thermodynamic temperature. The Thermodynamic Temperature Scale may thus be founded upon a defined temperature difference between two temperature fixed points or a defined value of one temperature fixed point.

In the course of the development of technology, the manner of defining the thermodynamic temperature scale has changed. Until 1954, it was assumed that 100° represented the difference between the boiling point of water and the melting point of ice. Since then, there has been a return to the original and older proposals of Kelvin, in 1848; Mendeleiev, in 1874; and Giauque, in 1939. Thus, since 1954, the thermodynamic temperature scale is based upon the temperature fixed point, which is the triple point TP of water.

Triple points of physical materials are stable, repeatable temperatures where the solid, liquid, and gaseous forms of the material exist in thermal equilibrium. The triple point of water occurs at that temperature where ice, water, and water vapor exist in thermal equilibrium. A temperature of 273.16 has been assigned to this temperature fixed point.

In 1967, the 13th Conférence Général des Poids et Mesure (CGPM) introduced a new definition for the scale and a new symbol for the unit of thermodynamic temperature. This unit is called the *kelvin*, denoted by the symbol K. Notice that when the unit is being referred to, it is spelled with a small letter to avoid confusion with the person Kelvin. It is defined as 1/273.16th part of the thermodynamic temperature of the triple point of water.

However, an ideal Carnot cycle is impossible to realize in practice. Nevertheless, it can be demonstrated that the thermodynamic scale may be reproduced by a gas thermometer with an ideal gas as the working substance, in accordance with the ideal gas law given in (1). Either pressure difference at constant volume or volume difference at constant pressure can be chosen as the measure of temperature.

Here again, although the ideal gas is quite fictitious, it could be replaced by a noble gas at very low pressure. When the readings at constant volume, T_v, and the similar readings at constant pressure, T_p, are extrapolated to zero they tend to the same value, $T_v = T_p = T$, independently of the properties of the gas. Thus, the thermodynamic temperature scale may be reproduced using gas thermometers, which have an application range up to about 1350 K.

Another simple method of reproducing the scale at thermodynamic temperatures above 1337 K is allowed by means of thermal radiation from heated bodies. When this radiation is in thermodynamic equilibrium with the radiating body, some properties of this radiation are directly linked to the temperature of the body. The concepts of black-body radiation are essential for proper utilization of the method. These concepts, which are beyond the scope of this article, use the relation known as *Planck's law*.

4 INTERNATIONAL TEMPERATURE SCALES

Temperature measurement requires a

- primary standard
- practical measuring system
- system or body whose temperature is to be measured.

A primary standard system for measuring temperature is the *Kelvin Thermodynamic Temperature Scale* referred to above. Because of the difficulties that are involved in realizing this primary standard system, realizations are based upon *boiling points, freezing/melting points*, and *triple points*.

Boiling points correspond to characteristic temperatures where the liquid and gaseous states of a material exist in equilibrium.

Freezing/melting points are temperatures where a material undergoes an equilibrium change in its physical state from liquid to solid or solid to liquid respectively. They are preferred to boiling points as they are less sensitive to pressure changes.

Triple points are temperatures at which the solid, liquid, and gaseous forms of the material exist in equilibrium.

Practical realizations of temperature scales have been disseminated by previously adopted resolutions of the CGPM in 1889, 1927, 1948 (revised in 1960), 1968 (supplemented in 1976), and 1990. Figure 2 summarizes all of these scales for comparative purposes. The fixed points of these various scales, also given for comparative purposes, appear in Table 1.

The Normal Hydrogen Scale, or NHS, which was based upon the work conducted by Chappius, was proposed in 1887. Using hydrogen gas as the thermometric material, Chappius built a gas thermometer calibration facility covering the range −25 to +100 °C. This early scale, which was used to calibrate mercury-in-glass thermometers, was a true centigrade scale as its fixed points were the ice-point, at 0 °C, and the boiling point of water, at 100 °C.

Although work on the International Temperature Scale of 1927, or ITS-27, commenced as early as 1913, its

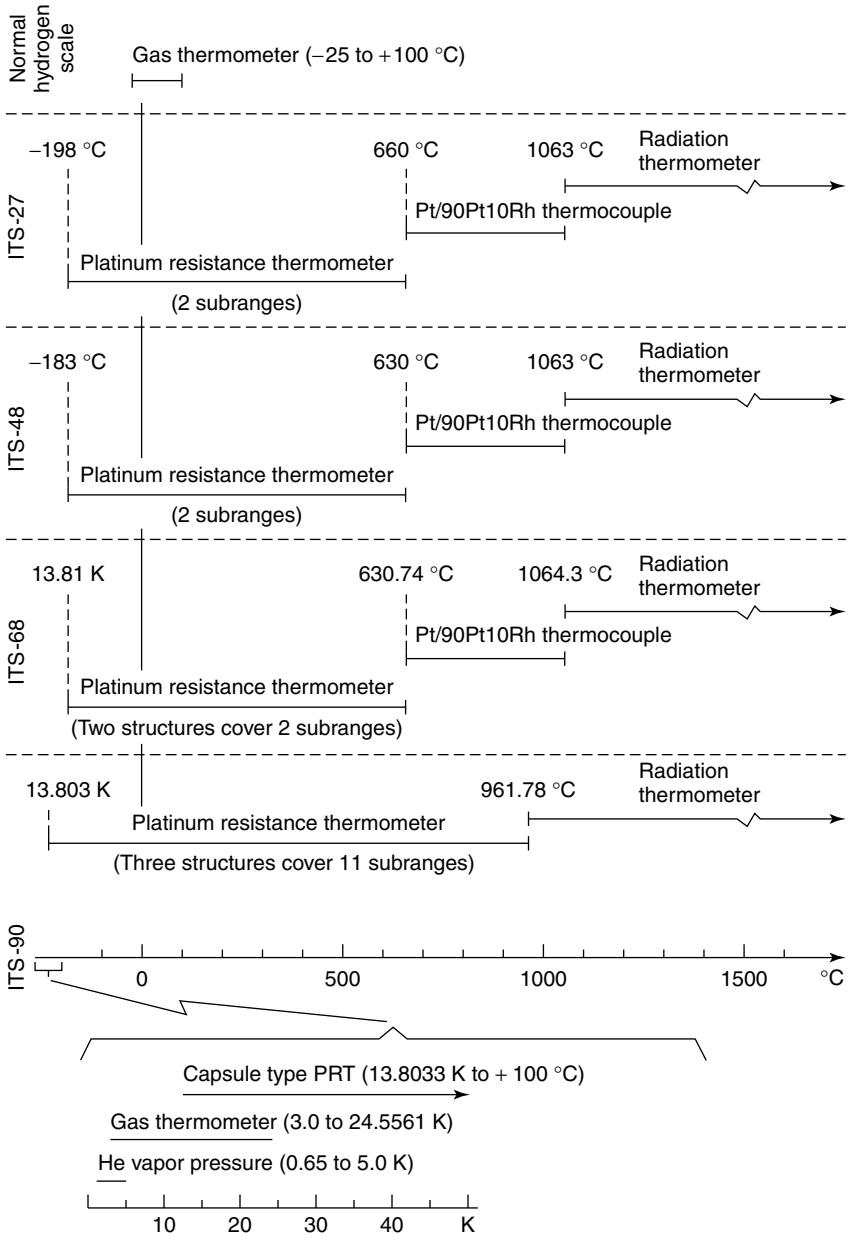

Figure 2. Comparison of the various temperature measurement scales and the measuring ranges of their standard interpolating instruments/sensors.

completion was delayed by the outbreak of World War I. It was defined with the assignment of six defining or fixed points. Development of thermometers using the noble metal Platinum gave rise to the Platinum Resistance Thermometer, or PRT, followed the pioneering groundwork of Siemens, in 1871, and Callendar, in 1887. By the end of World War I, PRTs were acknowledged as precision thermometers. This confidence provided the basis for their specification as one of the standard interpolating instruments of ITS-27. Over the range −190 to +660 °C, in the subranges −190 to 0 °C and 0 to 660 °C, the interpolating instrument was specified as the PRT made from platinum with defined properties exhibiting resistances at three temperatures, expressed as ratios with respect to the resistance at 0 °C. From 660 to 1063 °C, the scale was to be interpolated using a platinum/90% platinum-10% rhodium (Pt/90Pt10RH) thermocouple made from materials with specified properties. The Wien Law of Radiation defined temperatures above 1063 °C. ITS-27 was a major step forward in the universality of thermometry as it removed previously observed ambiguities in the specification of temperature.

Table 1. The temperature fixed points of various temperature scales (decimal point given to level of uncertainity).

Fixed point of scale \ Scale	Normal hydrogen scale	ITS-27	IPTS-48	IPTS-68	ITS-90
Vapour pressure point of helium					3–5
Triple point of equilibrium hydrogen				13.81	13.8033
Boiling point of hydrogen				17.042	17
Gas thermometer point of helium				20.28	20.3
Triple point of neon					24.5561
Boiling point of neon				27.102	
Triple point of oxygen				54.361	54.3584
Triple point of argon				83.798	83.8058
Condensation point of oxygen		90.18	90.18	90.188	
Triple point of mercury					234.3156
Freezing point of water	273	273.15	273.15		
Triple point of water			(273.16)	273.16	273.16
Melting point of gallium					302.9146
Boiling point of water	373	373.15	373.15	373.15	
Freezing point of indium					429.7485
Freezing point of tin				505.1181	505.078
Freezing point of zinc			(692.655)	692.73	692.677
Boiling point of sulfur		717.75	717.75		
Freezing point of aluminum					933.473
Freezing point of silver		1233.65	1233.95	1235.08	1234.93
Freezing point of gold		1336.15	1336.15	1337.58	1337.33
Freezing point of copper					1357.77

The tortuous path in the development of a temperature scale, which truly represented the thermodynamic scale, soon uncovered the inadequacies of ITS-27. Thus was born the International Temperature Scale of 1948 (ITS-48), which possessed the same number of fixed points as ITS-27 but with the freezing point of silver now specified as 960.8 °C instead of 960.5 °C, as in ITS-27. The lower PRT interpolating limit was also raised to −183 °C to coincide with the oxygen boiling point of −182.970 °C. Otherwise, the PRT standard interpolation subranges remained the same, as did that of the Pt/90Pt10Rh interpolating thermocouple.

In the case of the interpolating thermocouple, a quadratic interpolating equation was introduced with new constraints placed upon the acceptable values and tolerances of the emf. Above 1063 °C, the Wien Radiation Law was replaced by the Planck Law to improve the thermodynamic consistency of the temperatures in this range and also to allow the use of ITS-48 at higher temperatures than ITS-27.

In 1960, a revision of ITS-48 became known as the International Practical Temperature Scale of 1948(60), or IPTS-48(60), to avoid confusion with ITS-48.

The changes, which specified the water triple point temperature as 273.16 K, that created the present Kelvin Thermodynamic Scale also included the adoption of the triple point temperature instead of ice-point temperature as a fixed point of the scale. The name of the unit of temperature was changed to Celsius in place of centigrade. ITS-47 was a true centigrade scale as it had 100 degrees as the fundamental interval between the ice-point and the water boiling point. As the freezing point of zinc, at 419.505 °C, was more precisely realized, it was proposed as a replacement for the sulfur boiling point at 444.60 °C. New restrictions were placed upon one of the PRT ratios and upon the standard thermocouple emf.

The International Practical Temperature Scale of 1968, or IPTS-68, which was based upon *boiling points, melting/freezing points*, and *triple points*, arose from the need to extend IPTS-48 to lower temperatures because of the availability of improved measurement methods.

A total of 13 fixed points were used to define this scale. Although the interpolating instruments were the same as for IPTS-48, the PRT range was extended to cover the lower-temperature region down to 13.8 K using four wire resistance connections in two different sensor structures. The scale was also more closely defined in terms of a reference function, with four different deviation functions defined to provide correction in the four different temperature subranges for the particular PRT being calibrated.

In the original statement of IPTS-68, the same thermocouple covered the same range as in IPTS-48(60), with the

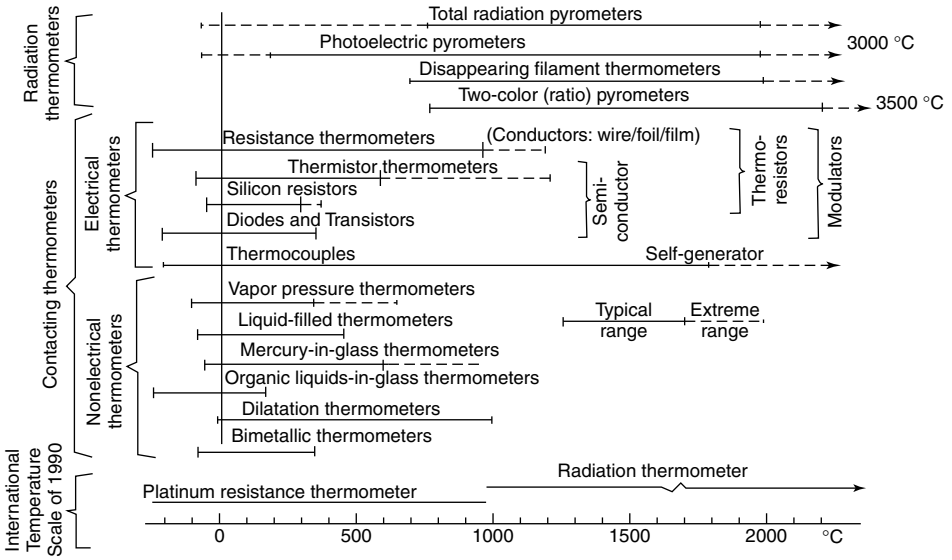

Figure 3. (Repeated in **Article 111, Classification of Sensors, Volume 2**) Classification of temperature-measuring instruments/ sensors by measuring range.

same quadratic form for the emf defining equation. The range, subsequently adopted by the 15th CGPM in 1975, was changed to 1337 K in IPTS-68(75) with a commensurate tightening of the emf specifications. Above 1337 K, the Planck Radiation Law defined the scale. An Extended Practical Temperature scale of 1976, or EPT-76, which includes revisions to IPTS-68, allowed IPTS-68 to be extended at low temperatures with the addition of 11 fixed points in the cryogenic range from the superconducting transition point of cadmium at 0.519 K to the boiling point of neon at 27.102 K.

IPTS-68 and EPT-76 have now been superseded by ITS-90, the International Temperature Scale of 1990. This scale, which has most boiling points eliminated, allows an extension of the lower range to 0.65 K. It agrees better with the thermodynamic scale and has greater continuity, precision, and reproducibility with appropriate subranges. As indicated in Figure 2, four classes of thermometers are used to establish the scale. The Helium vapor pressure thermometer covers the range from 0.65 to 5 K, where the saturated vapor pressure temperature relations of ^{3}He and ^{4}He hold. Constant volume gas thermometers, in which the gas pressure is a function of temperature, are standard thermometers over the range from 3 K to the triple point of neon at 24.5561 K. Over the temperature range from the triple point of equilibrium hydrogen, at 13.8033 K, to the freezing point of silver, at 961.78 °C, the standard instrument is a platinum resistance thermometer calibrated at specified sets by defining fixed points and using specified interpolating procedures. The Planck Radiation Law is used to define ITS-90 above the freezing point of silver. Overall, ITS-90 represents Thermodynamic Temperature with an uncertainty of ±2 mK from 1 to 273 K, increasing to ±7 mK at 900 K.

As already stated, ITS-90 is established using a total number of 17 fixed points. These comprise 1 vapor pressure point, 6 triple points, 8 freezing/melting points, and 2 boiling points. A comparison between the fixed points of the ITS-90 with the previous temperature scales, described above and illustrated in Figure 2, appears in Table 1.

5 GUIDE TO TYPES OF TEMPERATURE SENSORS

It is also possible to classify temperature sensors on the basis of their temperature range of application. Such a classification is repeated for completeness in Figure 3 – *see* **Article 111, Classification of Sensors, Volume 2** for more on the classification of temperature sensors.

General accounts on temperature measurement and its practice are available in ASTM (1993), Childs (2001), Nicholas and White (2001), Michalski, Eckersdorf and McGhee (1991), TC (2004), and U.S. Sensor (2004). More information is available: Thermocouples in **Article 196, Thermocouple Temperature Sensors, Volume 3**; resistance temperature detectors (RTD) in **Article 197, Metallic Resistance Temperature Detectors (RTDs), Volume 3**; and standards and practice of calibration in **Article 198, Calibration and Standards in Temperature Measurement, Volume 3**.

1 PHYSICS OF THERMOELECTRIC EFFECT

1.1 Thermoelectric force (emf)

It was Seebeck who discovered that a current flows in a closed loop of two dissimilar metals when their junctions are at two different temperatures.

In 1834, Peltier, discovered that a junction of two dissimilar metals is respectively heated or cooled when a current is passed through it either in one direction or the other.

Another effect discovered by Lord Kelvin (W. Thomson) in 1854 was that a homogeneous current-carrying conductor, lying in a temperature gradient, will absorb or generate heat, in addition to and independently of Joule heating.

Of these three thermoelectric effects, only the Seebeck effect is the real source of thermoelectric force, electromotive force (emf). This force results from the variation of electron density along a conductor subject to a nonuniform temperature distribution, and is given by

$$\mathrm{d}E = \sigma_{\mathrm{A}}(\vartheta)\,\mathrm{d}\vartheta \tag{1}$$

where σ_{A} is the Seebeck coefficient of metal A.

The Seebeck thermoelectric force, E_{A}, in a homogeneous conductor whose ends are at temperatures ϑ_1 and ϑ_2 respectively, has a value given by

$$E_{\mathrm{A}}(\vartheta_1, \vartheta_2) = \int_{\vartheta_2}^{\vartheta_1} \sigma_{\mathrm{A}}(\vartheta)\,\mathrm{d}\vartheta \tag{2}$$

or

$$E_{\mathrm{A}}(\vartheta_1, \vartheta_2) = E_{\mathrm{A}}(\vartheta_1) - E_{\mathrm{A}}(\vartheta_2) \tag{3}$$

In a thermoelectric circuit composed of two homogeneous conductors A and B, whose joined ends are at the temperatures, ϑ_1 and ϑ_2, the resultant sum of both thermoelectric forces is

$$E_{\mathrm{AB}}(\vartheta_1, \vartheta_2) = E_{\mathrm{A}}(\vartheta_1, \vartheta_2) - E_{\mathrm{B}}(\vartheta_1, \vartheta_2) \tag{4}$$

Summing the partial emfs in the circuit of Figure 1 gives the resultant emf, E, as

$$E_{\mathrm{AB}}(\vartheta_1, \vartheta_2) = e_{\mathrm{AB}}(\vartheta_1) + e_{\mathrm{BA}}(\vartheta_2) \tag{5}$$

It should be emphasized that the resultant thermoelectric force of the circuit of Figure 1 is only a function of the types of metal A and B and of the temperatures, ϑ_1 and ϑ_2.

In the application of a circuit of two metals, A and B, it will be assumed that the temperature, ϑ_2, of one of the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

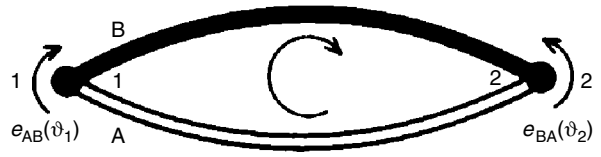

Figure 1. A closed thermoelectric circuit. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

junctions, called the *reference junction* will be held constant at the reference temperature, ϑ_r. For $\vartheta_2 = \vartheta_r = \text{const}$, (5) may be written as

$$E_{AB}(\vartheta_1, \vartheta_r) = e_{AB}(\vartheta_1) - e_{AB}(\vartheta_r) = f_2(\vartheta_1) \qquad (6)$$

Equation (6) indicates that the emf of the circuit of two metals A and B is a function of the measured temperature, ϑ_1, of the measuring junction, which is junction 1 in Figure 1. It is of cardinal importance as it is the foundation of thermoelectric thermometry.

1.2 Law of the third metal

The practical application of a circuit with the two metals A and B, for the purpose of temperature measurement, also requires the introduction of an emf measuring device. Insertion of such a voltage measuring instrument necessarily involves the connection of a third metal, C, in the circuit. Fortunately, this addition is covered by the law of the third metal as shown in Michalski *et al*. (2001). This states that introducing a third metal, C, into a circuit of the two metals A and B, does not alter the resulting emf in the circuit, provided that both ends of the third metal C are at the same temperature. The third metal, C, may be introduced into a circuit at any point.

2 THERMOCOUPLES

Two dissimilar conductors, which may be metals, alloys or nonmetals, connected at one end is known as a thermocouple. In the notation shown in Figure 2, their point of connection is called the *measuring junction* and their free ends, the *reference junction*.

The thermal emfs of different materials used to form thermocouples, with platinum as the reference material are given in Michalski *et al*. (2001).

The International Standard International Electrotechnical Commission (IEC) 584 of 1995 covers standardized thermocouples. It states their emf values as a function of temperature, as shown in Figure 3.

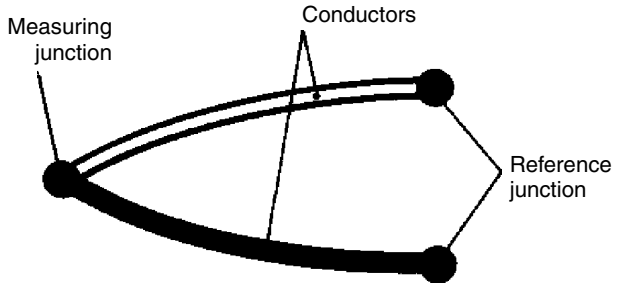

Figure 2. The physical structure and notation of a thermocouple. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

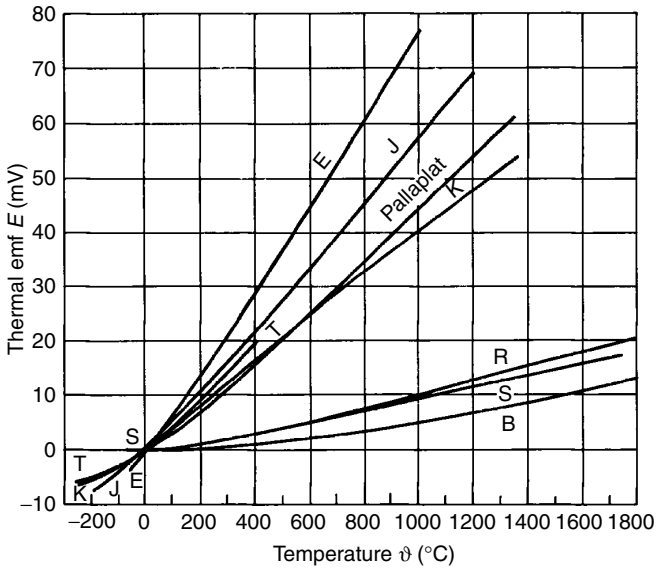

Figure 3. Thermal emf, E, of commonly used thermocouples as a function of temperature. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

Some selected properties of standardized thermocouples are given below:

Platinum–rhodium/platinum, code (or type) S, (90% Pt–10% Rh/Pt), is the most popular of all the rare-metal thermocouples. It is specified for normal continuous use in the range −50 °C to +1300 °C. As its structure gives a high resistance to corrosion, thin wires may be used, resulting in low cost and low thermal inertia thermocouple.

Platinum–rhodium/platinum, code R, (87% Pt–13% Rh/Pt) has similar properties to the type-S unit described above.

Platinum–rhodium/platinum–rhodium, code B, (70% Pt–30% Rh/94% Pt–6% Rh), has the following advantages over the type-S unit

- a higher upper temperature range of 1800 °C,
- in the temperature range up to about 100 °C, the emf is negligibly small so that no reference temperature stabilization is needed.

Iron/copper–nickel, code J, (Fe/55% Cu–45% Ni), is standardized in IEC 584-l. It is a popular thermocouple, used up to 1000 °C, with a high emf and good resistance to oxidizing and reducing atmospheres.

Copper/copper–nickel, code T, (Cu/55% Cu–45% Ni) is rated for continuous use within the temperature range from −200 °C to +500 °C. It is commonly used in laboratory measurements.

Nickel–chromium/copper–nickel, code E, (90% Ni–10% Cr/55% Cu–45% Ni) corresponds to the Chromel/Constantan structure popular in the United States. With the highest emf of all metal thermocouples, it is used from −270 °C to +800 °C.

Nickel–chromium/nickel–aluminum, code K, (90% Ni–10% Cr/95% Ni, balance Al, Si, Mn) is a commonly used base-metal type in the temperature range of −200 °C to 1100 °C.

Nickel–chromium–silicon/nickel–silicon, code N, is similar to that of the code K type, but it is more resistant to corrosion.

Detailed descriptions of all these thermocouples and also special, nonstandardized high-temperature thermocouples are given in Michalski *et al*. (2001) and in Kinzie (1973).

The measuring junction of a thermocouple is formed by brazing, soldering, welding, twisting or rolling the two dissimilar materials together, as described by Baker, Ryder and Baker (1953).

3 THERMOCOUPLE TEMPERATURE SENSORS

3.1 Construction

The sensor is more than just the junction. A thermocouple sensor is a structure consisting of a thermocouple, which has associated wires, their insulation, and terminal head, mounted in a suitable protective tube, sometimes called a *well* or *sheath*.

The most common industrial thermocouple sensors are general purpose, straight sheathed units, for application at atmospheric pressure. As shown in Figure 4, its leads are insulated with ceramic tubes or beads. Protection from chemical and mechanical influences is provided by a tubular, metallic, or ceramic sheath. The terminal head, which contains a terminal block, is also equipped with a tight sealing gland through which the compensating or connecting cable enters the head. The unit is often made such that the thermocouple unit itself can be replaced without losing any liquid, in which the outer sheath is placed.

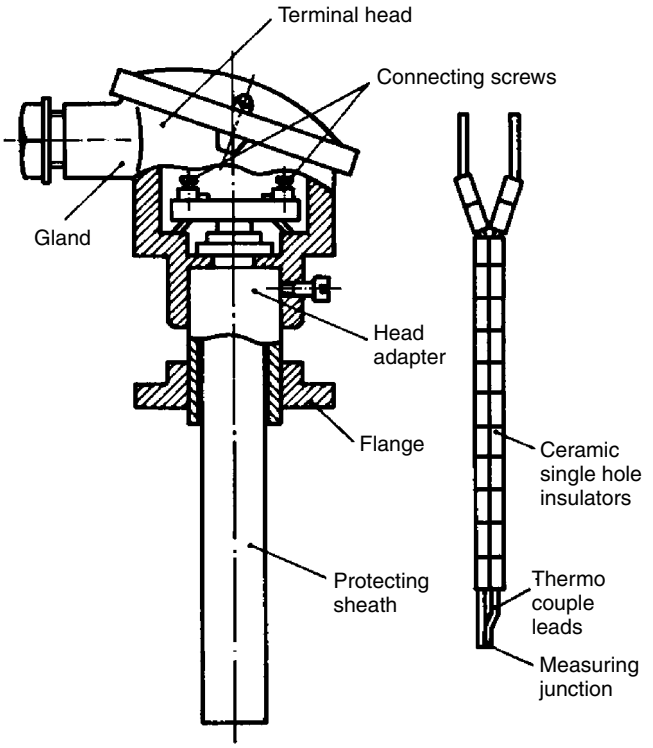

Figure 4. Industrial thermocouple assembly. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

Standardized wire diameters for thermocouples may vary from 0.2 mm up to 4 mm for base metals and from 0.1 mm to 0.5 mm for rare metal units.

3.2 Sheath materials

Protecting sheaths are characterized by

- resistance to high temperatures,
- mechanical strength,
- corrosion resistance,
- chemical resistance,
- noncontamination of the given thermocouple,
- resistance to thermal shocks,
- imperviousness to gases.

Sheath materials influence the stability of calibration as well as the dynamic properties of a thermocouple; their properties and applications are given in Michalski *et al*. (2001).

3.3 Review of structures

A wide range of constructional forms, including the dimensions, sheath material, and applications for each of the thermocouple structures is given in Michalski *et al*. (2001).

The most popular industrial, straight thermocouple is shown in Figure 4.

Right-angle (corner) thermocouples are used for measuring the temperature of molten metals or salt baths.

High-pressure thermocouple sensors, as specified in DIN (Deutche Industrie Normen), are composed of a thermocouple insert placed in a thermocouple well. Thermocouple inserts, usually contain an easily exchanged short MI (mineral insulated) thermocouple.

Cylindrical screw-in thermocouples are normally mounted in tank or pipeline walls using welded fixing attachments.

Conical well thermocouples may be used for high-pressure measurements.

Mineral insulated thermocouples, which have a metal sheath, were originally designed in 1957 for temperature measurement in gas-cooled nuclear reactors. As they have important properties, they are now widely applied. A considerable advantage is their thin, robust, flexible structure, which permits easy bending combined with a short thermal response time.

Figure 5 illustrates the lateral cross-section of mineral insulated thermocouples. A continuous protective metallic sheath contains the wires of the thermocouple, which are placed in a densely compacted mineral powder that is electrically, but not thermally insulating. The sheaths may have diameters between 0.2 and 8 mm, while they may be many meters long.

4 REFERENCE TEMPERATURE

Compensating cables A′ and B′ described in Kinzie (1973) are used as an extension of the thermocouple from the terminal head, which is subject to big variations of temperature, to the new reference junction located at constant temperature as shown in Figure 6. As the temperature of the thermocouple terminal head is never very high, the emf versus temperature matching of the compensating cable to the thermocouple is only necessary in the temperature range 0–200 °C. When the compensating leads are made from the same material as the thermocouple wires, they are called *extension leads*.

If it is assumed that the characteristics of the thermocouple AB and of the compensating leads A′B′ are identical at the reference temperature, ϑ_r, it is apparent that

$$e_{A'B'}(\vartheta_r) = e_{AB}(\vartheta_r) \tag{7}$$

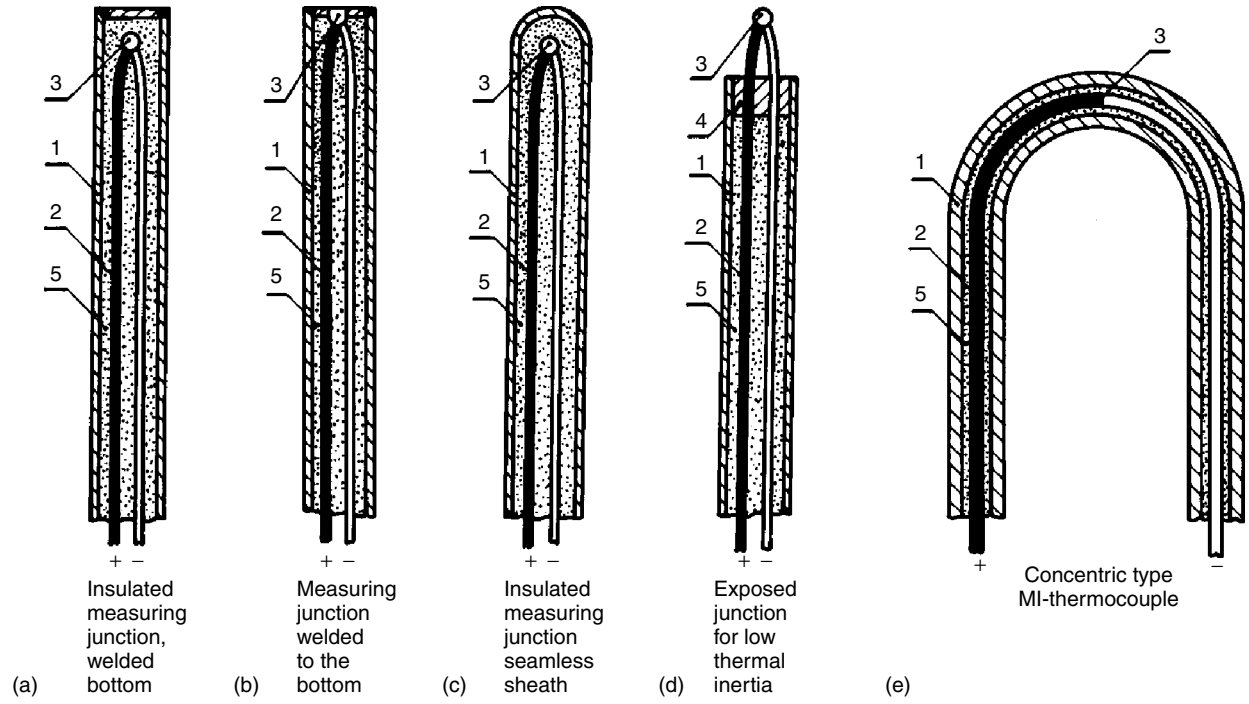

Figure 5. Cross-section of mineral insulated thermocouples, 1–metal sheath, 2–conductor, 3 – measuring junction, 4 – refractory cement, 5 – mineral insulant. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

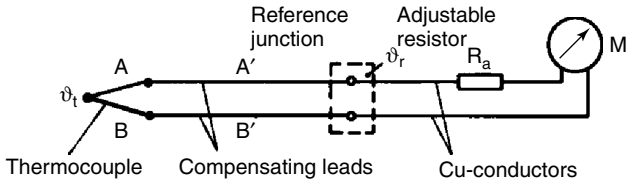

Figure 6. Thermocouple with compensating cable. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

Equation (7) shows that the resulting emf equals that value of the emf exhibited by a thermocouple having its reference junction at the temperature, ϑ_r. It is then apparent that the temperature, ϑ_r, may be called the *reference temperature* in this case.

The outputs of compensating cables conform to IEC 584-1. The type of compensating cable can be identified on the basis of internationally standardized color-coding given by IEC Standard Project 60584-3.

The output emf of values of thermocouples and thus the thermometer indications are correct if the reference temperature ϑ_r equals its nominal value $\vartheta_{rn} = 0\,^{\circ}\mathrm{C}$, which rarely occurs in practice. Michalski *et al.* (2001) provides details of the following procedures for use when $\vartheta_{rn} \neq 0\,^{\circ}\mathrm{C}$:

- calculation of the true emf E at $\vartheta_r = 0\,^{\circ}\mathrm{C}$ based on an indicated value E' at $\vartheta_r \neq \vartheta_{rn}$, applicable for short time measurements;
- assumption that ϑ_r equals ambient temperature, for less precise measurement;
- reference junction placed in ice-point;
- reference junction placed in $0\,^{\circ}\mathrm{C}$ thermostat;
- reference junction placed in electrical thermostat operating at 50 or $60\,^{\circ}\mathrm{C}$;
- applying automatic correction devices, which add or subtract the necessary correcting signals to or from the measured emf E-value.

5 MEASURING CIRCUITS

Thermoelectric thermometers use the following measuring circuits, shown in a simplified way in Figure 6.

- deflection type circuits,
- variable voltage and variable current potentiometers,
- circuits with IC-amplifiers and transmitters,
- circuits with digital indicators,
- computer-based circuits.

The direct deflection method shown in Figure 6 is the oldest way of measuring the electrothermal signals generated in thermocouples. By virtue of its simplicity and low cost, this method is likely to continue to be used in many industrial applications when high precision measurement is not required. An adjustable resistor provides the facility to trim the loop resistance. Directly coupled (DC) amplifiers are being increasingly employed to boost electrothermal signals before they are measured by deflection type instruments.

The principle of operation of the potentiometer method is comparison of voltages. In the variable voltage potentiometer represented in Figure 7, the compensating voltage, V_c, is adjusted by setting the slide wire of the potentiometer, R_p, in such a way that zero is indicated by the zero current detector. The value of the emf that is to be measured is read from the slider position on an mV scale. The balance condition is then given by

$$E_x - I_c R_c = 0 \tag{8}$$

where E_x – measured emf, I – compensating current, R_c – potentiometer resistance.

Manually operated potentiometers, which are usually portable, find common use in laboratories and for more precise short-term or industrial control measurements.

Automatic variable voltage potentiometers are used for continuous operation. Electronic servo-balanced potentiometers, which are built mainly as potentiometric recorders, are also commonly used in the measurement of different physical quantities that might be transduced to electrical signals – *see* **Article 201, Voltage Measurement, Volume 3**.

Most often they are based upon the principle of the resistance bridge potentiometer. The thermoelectric force, E_x, to be measured, is compared with the off-balance

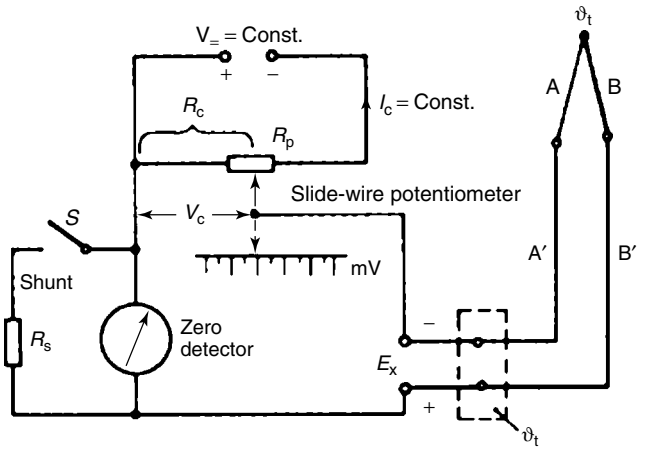

Figure 7. Manually operated variable voltage potentiometer. (*Source*: Reproduced from 'Temperature Measurement, 2nd Ed', Michalski *et al*, 2001 © John Wiley & Sons Ltd.)

voltage, of a resistance bridge – *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**; and **Article 127, Unbalanced DC Bridges, Volume 2**. This voltage depends upon the slider position of a slide-wire potentiometer. An important facility when such potentiometers are calibrated in temperature degrees is automatic compensation of fluctuations in reference temperature, ϑ_r.

In *variable current potentiometers*, the thermoelectric force E_x to be measured is opposed by an adjustable voltage, generated as a voltage drop across a constant resistor. This voltage drop is adjusted by changing the compensating current I_c using a slide-wire resistor.

The value of the current, I_c, is a measure of the E_x, to be determined. A zero detector is used to indicate the null balance condition. They are also built as self-balancing potentiometers based upon an operational amplifier with feedback – *see also* **Article 113, Force-feedback Sensors, Volume 2**.

6 TESTING AND CALIBRATING

Thermocouple sensors used as working standards are of types S, R, and B. They are calibrated by the comparison method against a resistance thermometer and at the higher temperatures against standard optical pyrometers. They are also calibrated by the fixed points method. The reference junction is usually kept at 0 °C. They are used in the temperature range from 300 to 1300 °C for the calibration and testing of the same types of thermocouples of lower accuracy, as well as of other thermocouples.

Testing methods of industrial thermometers are

- the comparison method,
- the differential comparison method,
- the measurement of emf at fixed points,
- the measurement of emf at fixed points by the wire method.

The comparison method is used for all of the standardized thermocouples. In the range 300 to 1200 °C, the tested thermocouples are placed together with the standard thermocouple in an electrical furnace so that the temperature of their measuring junctions are equal.

For the thermocouples of non rare-metals, furnaces with metal blocks are used.

In the range below 300 °C, the thermocouples are tested in well-circulated baths using a mercury-in-glass thermometer as the standard. The emfs of the tested and standard thermocouples are measured by specialized digital voltmeters or calibrators.

The differential comparison method, following the American Society for Testing Materials (ASTM) E220-80 standard, is used only for rare-metal thermocouples. The same type of thermocouple is used both as the standard and as the tested thermocouples. Measuring junctions of all thermocouples are bound together by a platinum wire. The differential emf values between conductors of the same polarity of the standard and the tested thermocouples are measured. The same type of electric furnace is used as in the comparison method.

The measurement of emf at fixed points is mainly intended for testing rare-metal thermocouples. The tested thermocouple is immersed consecutively in crucibles with metals and salts of different freezing temperatures. The emf values are recorded as a function of time with the horizontal part determining the sought after emf value.

In the wire method mainly used for rare-metal thermocouples, the measuring junction of the tested thermocouple is cut in two with a short pure metal wire or plate and then soldered to both thermocouple conductors. The thermocouple is slowly heated up in the electric furnace till the inserted wire melts. The recorded emf versus time value clearly indicates the constant temperature part of the curve until the circuit is broken.

Thermocouple sensors should not be tested in a laboratory environment after a long working life or after becoming contaminated. Testing is made by the comparison method, in which the standard thermocouple is placed in situ alongside the tested one so that their measuring junctions are at the same temperature.

Testing methods, as well as the constructions of electric furnaces, fixed points crucibles and various baths are described in Michalski *et al*. (2001).

1 PRINCIPLES AND THEORY OF RTDs

High purity, chemical resistance, and its physical properties make platinum the ideal material for resistance temperature detectors (RTDs). Platinum resistance temperature detectors (PtRTDs) exhibit a number of important advantages compared to semiconductor sensors or thermistors (http://www.heraeus-sensor-nite.de/eng/technologie/frame_pttempsens.htm), for example,

- linear change of resistance with temperature,
- stable resistance temperature characteristics,
- stable resistance over cycling of temperature,
- usable over a large temperature range,
- long lifetime,
- broad temperature range from $-200\,^{\circ}\mathrm{C}$ to $1000\,^{\circ}\mathrm{C}$.

Unfortunately, PtRTD temperature sensors have a poor average sensitivity of 0.4%/K (e.g. a 100-Ω PtRTD changes only 0.4 Ω for every 1 K change).
(http://www.teamwavelength.com/downloads/newproducts/appnote-tc02.pdf)

1.1 The International Temperature Scale of 1990 (ITS-90)

The International Temperature Scale of 1990 (ITS-90) is the official International Temperature Scale since January 1990. It provides information on how the scale may be realized at different levels of accuracy. The ITS-90 extends upward from 0.65 K, is in close agreement with the Kelvin Thermodynamic Temperature Scale, and has subranges and alternative definitions in certain ranges that greatly facilitate its use (http://www.cstl.nist.gov/div836/836.05/papers/magnum90ITS90guide.pdf) p. 13.

Temperatures on the ITS-90 are expressed in International Kelvin temperatures T_{90} with the unit Kelvin (K) or expressed in the International Celsius temperatures t_{90} with the unit degree Celsius ($^{\circ}$C). The relation between T_{90} and t_{90} is

$$t_{90}/^{\circ}\mathrm{C} = T_{90}/\mathrm{K} - 273.15 \qquad (1)$$

(http://www.cstl.nist.gov/div836/836.05/papers/magnum90ITS90guide.pdf) p. 6.

Between 13.8033 K ($-259.3467\,^{\circ}$C) and 1234.93 K ($961.78\,^{\circ}$C), the ITS-90 is defined in terms of specified fixed

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

points to which temperature values have been assigned, by resistance ratios of platinum resistance thermometers (http://www.cstl.nist.gov/div836/836.05/papers/magnum90 ITS90guide.pdf) p. 11.

Standard platinum resistance thermometers (SPRT) are the instruments specified in the ITS-90 for performing measurements within the range 13.8033 K (the triple point of hydrogen) to 961.78 °C (the freezing point of silver).

SPRTs of long stem construction may be calibrated over various temperature ranges, depending on the application and required accuracy, by measurement at the appropriate ITS-90 fixed points (Figure 1).

The National Physical Laboratory (NPL) provides calibrations with uncertainties as indicated in Table 1.

Thermometers that are not suitable for measurement in fixed-point apparatus, on account of length, immersion needs, or for other reasons, will be calibrated by comparison with standard thermometers in appropriate baths, with larger calibration uncertainties.

Figure 1. Calibration service with long stem SPRT at NPL (http://www.npl.co.uk/thermal/publications/ds_pm020102.html).

2 RTD TEMPERATURE SENSORS

RTDs are wire wound and thin-film devices that work on the physical principle of the temperature coefficient of electrical resistance of metals. They require an electrical current to produce a voltage drop across the sensor that can then be measured by a calibrated read-out device (http://www.temperatures.com).

RTDs are usually included in books covering general temperature measurement (Hofmann, 1976, 1977; Leigh, 1988; Quinn, 1990; Bentley, 1998; Liptak, 1993; Childs, 2001; Michalski *et al.*, 2001; Nicholas and White, 2001).

The resistance change of platinum-temperature sensors basically depends on the length and diameter of the platinum wire. Categorized in various resistance classes from 100 to 1000 Ω, the sensors provide different signals as temperature increases. According to their design, two sensor types are distinguished:

2.1 Wire-wound Pt-temperature sensors

The measuring element of this sensor type is a wound platinum wire of defined length and diameter with two connecting wires at the end. Two different temperature sensors of this type on the market are given below.

Glass wire-wound Pt-temperature sensors (Figure 2) can be applied without protection in aqueous liquids, solvents, and oils. They consist of one or two platinum bands, wound on a glass core and homogeneously fused with a glass sleeve. They feature high shock and shake resistance and present high strength against external forces and pressure.

Ceramic wire-wound Pt-temperature sensors (Figure 3) are particularly suitable for applications in which a very

Table 1. Calibration ranges and uncertainties for SPRTs (http://www.npl.co.uk/thermal/publications/ds_pm020102.html).

Point	Temperature t_{90} (°C)	Uncertainty (°C)				
		Range 1	Range 2	Range 3	Range 4	Range 5
TP argon	−189.3442	–	0.002	0.002	0.002	–

FP aluminum	660.323	–	–	–	0.004	0.005
FP silver	961.78	–	–	–	–	0.010

Note: TP = triple point, MP = melting point, FP = freezing point.

Figure 2. Glass wire-wound Pt-temperature sensor (http://www.heraeus-sensor-nite.de/eng/produkte/frame_pt_glas_gew.htm).

Figure 3. Ceramic wire-wound Pt-temperature sensor (http://www.heraeus-sensor-nite.de/eng/produkte/frame_pt_keram_gew.htm).

high temperature stability and high temperature shock resistance are required. They consist of a platinum coil that is embedded in an ultrapure ceramic body of aluminum oxide. They have an extremely low drift even in long-term use.

2.2 Pt thin-film sensors

Temperature sensors of Pt thin-film technology (Figure 4) are particularly suitable for mass applications. They feature an extremely small space requirement. They cover the large temperature range of $-200\,^{\circ}\mathrm{C}$ to $+800\,^{\circ}\mathrm{C}$.

Typical applications are in the automotive industry, white goods, HVAC, process technology, power stations, aviation and aerospace, equipment, and machines for medicine and industry.

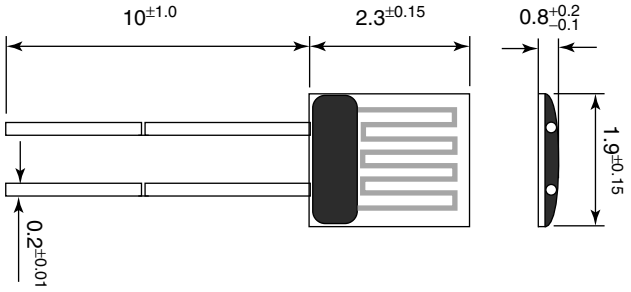

Figure 4. Pt thin-film sensor (http://www.heraeus-sensor-nite.de/eng/produkte/frame_pt_duenn_sens.htm).

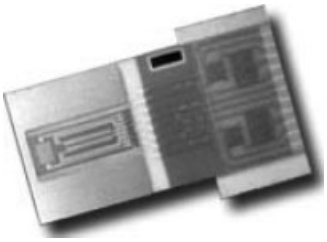

Figure 5. Pt sensor module (http://www.heraeus-sensor-nite.de/eng/produkte/frame_pt_sens_mod.htm).

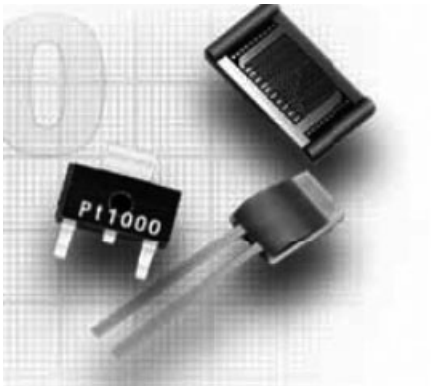

Figure 6. Primary enclosed Pt thin-film sensors (http://www.heraeus-sensor-nite.de/eng/produkte/frame_prim_geh.htm).

2.3 Pt sensor modules

Pt sensor modules (Figure 5) have a multifunctional design. They usually perform tasks such as air-volume determination (http://www.heraeus-sensor-nite.de/eng/produkte/frame_luftmassensensor.htm) or air-quality measurement in air-conditioned rooms (http://www.heraeus-sensor-nite.de/eng/maerkte/frame_klimatisierung.htm).

2.4 Primary enclosed sensors

For special applications, elementary sensors are assembled in standard housings or applied on personal computer boards (PCB) (Figure 6). These modules are created for direct use by the customers for further processing. Time-consuming and cost-intensive steps for production preparation are not needed.

3 RTD CHARACTERISTICS

Operating on the principle that resistance of any given metal changes with temperature, thermoelectric RTDs are the sensors of choice in applications in which accuracy, stability, and repeatability are critical. To maximize linearity and temperature ranges, thermoelectric RTDs are produced from

high-purity platinum. In addition, special high-temperature platinum delivers high stability and durability of RTDs at 650 °C (1202 °F). Thermoelectric RTDs are available in diverse configurations with two-, three-, and four-wire construction ranging from −200 °C to 650 °C (−328 °F to 1202 °F). Tolerances meet the standards of ASTM E1137 Grade A or B and IEC 751 Class A or B, depending on the customers needs.

(http://www.thaiinstrumentation.com/thermocouple_rtd.html).

3.1 Temperature circuits

2-wire circuit: A Wheatstone bridge, *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2** and **Article 127, Unbalanced DC Bridges, Volume 2**, is the most common approach for measuring an RTD (http://content.honeywell.com/sensing/prodinfo/temperature/technical/c15_139.pdf). As RT increases or decreases with temperature, V_{out} also increases or decreases. Use an operation amplifier to observe V_{out}. Lead wire resistance, L_1 and L_2 directly adds to the RTD leg of the bridge (Figure 7).

3-wire circuit: In this approach, L_1 and L_3 carry the bridge current. When the bridge is in balance, no current flows through L_2 so no L_2 lead resistance is observed. The bridge becomes unbalanced as RT changes. Use an operation amplifier to observe V_{out} and prevent current flow

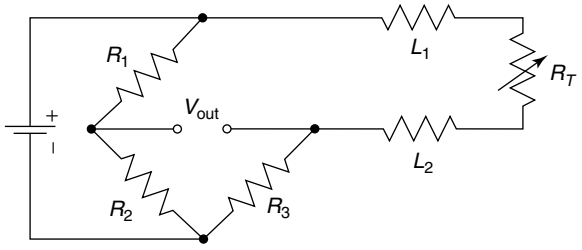

Figure 7. Two-wire circuit for RTDs (http://content.honeywell.com/sensing/prodinfo/temperature/technical/c15_139.pdf).

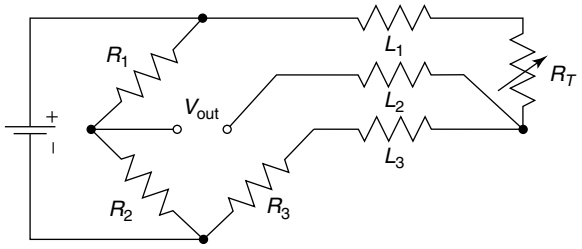

Figure 8. Three-wire circuit for RTDs (http://content.honeywell.com/sensing/prodinfo/temperature/technical/c15_139.pdf).

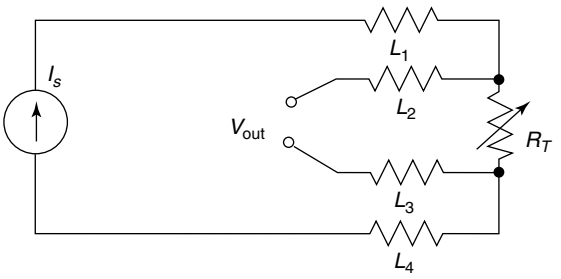

Figure 9. Four-wire circuit for RTDs (http://content.honeywell.com/sensing/prodinfo/temperature/technical/c15_139.pdf).

in L_2. The effects of L_1 and L_3 cancel when $L_1 = L_3$, since they are in separate arms of the bridge (Figure 8).

4-wire circuit: A 4-wire approach uses a constant current source to cancel lead wire effects even when $L_1 \neq L_4$. Use an operation amplifier to observe V_{out} and prevent current flow in L_2 and L_3 (Figure 9).

4 PRACTICAL RTD SETUPS

Sensor sensitivity affects a temperature control circuit's set point accuracy, measurement accuracy, and temperature stability operation. Parasitic resistances created by the wire leads of an RTD affect the set point and measurement accuracy (Figure 10).

The practical example in Figure 10 demonstrates the effect of lead resistance on the resistance measurement accuracy of a 100-Ω RTD. The sensor resistance measured in Figure 10 includes the parasitic lead resistances, which can be on the order of the sensor's sensitivity. The parasitic

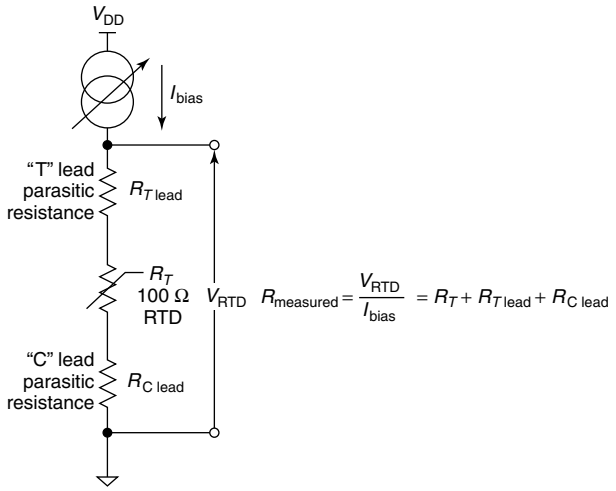

Figure 10. Effects of lead resistance on RTD measurement accuracy (http://www.teamwavelength.com/downloads/newproducts/appnote-tc02.pdf).

lead resistances are not easily measured since most RTD sensors are sealed against corrosion. A 100-Ω RTD with 0.1-Ω parasitic resistances in its leads will have an average temperature measurement offset of +0.5 °C.

5 PERFORMANCE FACTORS OF RTD TEMPERATURE SENSORS

Platinum's resistance versus temperature function is accurately modeled by the Callendar-Van Dusen equation. This equation uses constants A, B, and C, derived from resistance measurements at 0 °C, 100 °C, and 260 °C (Figure 11).

Callendar-Van Dusen Equation:

$$R_T = R_0(1 + AT + BT^2 - 100CT^3 + CT^4) \quad (2)$$

R_T = Resistance (Ω) at temperature T (°C)
R_0 = Resistance (Ω) at 0 °C
T = Temperature in °C.

For $T > 0$ °C, the quadratic formula can be used to solve for temperature as a function of measured resistance with the following result:

$$0 = R_0BT^2 + R_0AT + (R_0 - R_T) \text{ implies} \quad (3)$$

$$T_R = \frac{\{-R_0A + [R_0^2A^2 - 4R_0B(R_0 - R_T)]^{-2}\}}{2R_0B} \quad (4)$$

Platinum RTDs are specified by resistance at 0 °C, R_0, and alpha (α), a term related to the temperature coefficient of resistance (TCR). The Callendar-Van Dusen constants A, B, and C are derived from alpha (α) and other constants,

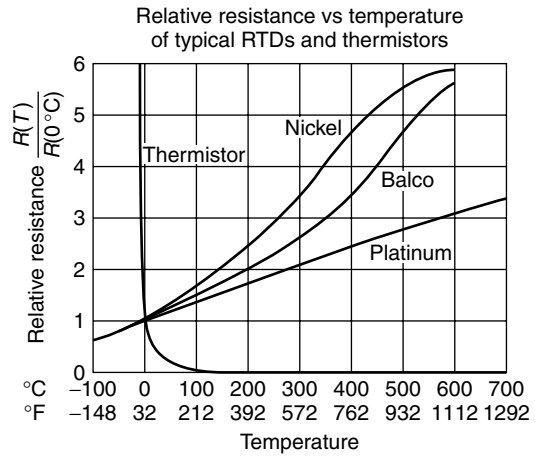

Figure 11. Platinum RTD resistance versus temperature function (http://content.honeywell.com/sensing/prodinfo/temperature/technical/c15_136.pdf).

Table 2. Callendar-van Dusen constants for platinum RTDs with $R_0 = 100\,\Omega$ and different temperature coefficients α (http://content.honeywell.com/sensing/prodinfo/temperature/technical/c15_136.pdf).

Alpha, α (°C)	0.003750 ± 0.00003	0.003850 ± 0.0001
Delta, δ (°C)	1.605 ± 0.009	1.4999 ± 0.007
Beta, β (°C)	0.16	0.10863
A (°C)	3.81×10^{-3}	3.908×10^{-3}
B (°C)	-6.02×10^{-7}	-5.775×10^{-7}
C (°C)	-6.0×10^{-12}	-4.183×10^{-12}

Note: Both $\beta = 0$ and $C = 0$ for $T > 0$ °C.

delta (δ) and beta (β), which are obtained from actual resistance measurements. Common Callendar-Van Dusen constant values are shown in Table 2.

The definitions of the Callendar-Van Dusen constants A, B, C, and alpha, delta, and beta (α, δ, and β), and their interrelationships are given by (5) to (10).

$$A = \frac{\alpha + (\alpha \bullet \delta)}{100} \quad (5)$$

$$B = \frac{-\alpha \bullet \delta}{100^2} \quad (6)$$

$$C_{T<0} = \frac{-\alpha \bullet \delta}{100^4} \quad (7)$$

$$\alpha = \frac{R_{100} - R_0}{100R_0} \quad (8)$$

$$\delta = \frac{[R_0(1 + 260\alpha) - R_{260}]}{[4.16\alpha R_0]} \quad (9)$$

$$\beta = \text{Constant for } T < 0\,^\circ\text{C} \quad (10)$$

The fundamental accuracy and repeatability performance of an RTD is determined by the repeatability of the empirically measured values $R_0 \pm \Delta R_0$; $R_{100} \pm \Delta R_{100}$ and $R_{260} \pm \Delta R_{260}$.

For tolerance standards and accuracy, *IEC 751*, the most commonly used standard for PtRTDs defines two performance classes for 100 Ω 0.00385 alpha PtTRDs, *Class A* and *Class B*. These performance classes (also known as *DIN A* and *DIN B* because of DIN 43760) define tolerances on ice point and temperature accuracy. These tolerances are also often applied to PtRTDs with ice point resistance outside of IEC 751's 100 Ω assumption.

Class C and *Class D* (each doubling the prior tolerance level) are also used.

6 TESTING AND CALIBRATION OF RTDs

The National Institutes of Metrology provide calibration services for SPRTs from 13.8 K to 1235 K. From 13.8 K

to 83.8 K, SPRT calibrations are performed by comparison with a set of reference thermometers. From 83.8 K to 962 °C, calibrations are performed using the ITS-90 defining fixed points. Maximum expanded calibration uncertainties are given in Table 3 (http://ts.nist.gov/ts/htdocs/230/233/calibrations/thermodynamic/resistance%20_thermometry.htm#33010C).

The comparison calibration of rhodium–iron resistance thermometers (RIRTs) in the temperature range from 0.65 to 26 K, using the NIST-maintained ITS-90, is based on a set of reference capsule-type RIRTs. The expanded uncertainty of those calibrations is given in Table 4.

It is important that resistance thermometers be protected from any mechanical shock that could alter their calibration. For shipment, the thermometer should be softly supported within a case but not be free to rattle. This necessitates the use of packing material that does not become compacted. The thermometer case should be softly packed inside a shipping container. Suitable containers will be provided when a thermometer shipping container is not satisfactory for reuse (http://ts.nist.gov/ts/htdocs/230/233/calibrations/thermodynamic/resistance%20_thermometry.htm#33010C).

Table 3. Maximum expanded uncertainties of SPRTs at NIST (http://ts.nist.gov/ts/htdocs/230/233/calibrations/thermodynamic/resistance%20_thermometry.htm#33010C).

Temperature subrange (K)	Maximum expanded uncertainty (mK)
13.8033–273.16	0.54[a]
24.5561–273.16	0.40[a]
54.3584–273.16	0.29[a]
83.8058–273.16	0.39
234.3156–302.9146	0.20
273.15–302.9146	0.04
273.15–429.7485	0.32
273.15–505.078	0.37
273.15–692.677	0.54
273.15–933.473	0.68
273.15–1234.93	1.1

[a]The uncertainties used at the Ar, Hg, and H_2O triple points are based on the fixed-point realization.

Table 4. NIST expanded uncertainties for comparison measurements of RIRTs (http://ts.nist.gov/ts/htdocs/230/233/calibrations/thermodynamic/resistance%20_thermometry.htm#33010C).

Range (K)	Expanded uncertainty (mK)
0.65–2.0	0.5
2.0–5.0	0.08
5.0–8.8	0.17
8.8–13.8	0.21
13.8–17.0	0.34
17.0–20.3	0.18
20.3–24.5561	0.24
24.5561–54.3584	0.27
54.3584–83.8058	0.22

6.1 Efficient calibration methods for platinum resistance thermometers

Calibration methods for platinum resistance thermometers can be simplified by reducing the number of calibration points. For applications that do not require the low uncertainties of the ITS-90 definitions, several modifications are available to improve calibration efficiency. The proposed schemes utilize the ITS-90 reference functions, simplified deviation equations, and in some cases correlations between resistance ratio values. Calibration ranges of interest include 20 K to 273 K, 273 K to 933 K, and various subranges spanning the ice point from 77 K to 505 K. Thermometers are tested using two to three calibration temperatures with media, convenient for comparison calibration. The methods apply to a broad class of thermometers constructed with high-purity platinum. Several examples of fit error are presented for SPRTs and for more rugged aerospace sensor designs. Recommendations to minimize the influence of thermal hysteresis are also discussed (http://www.cstl.nist.gov/div836/836.05/thermometry/symposium/program.htm). The approximations introduce errors typically between 10 and 100 mK depending on thermometer type and temperature range. For many applications, these calibration methods satisfy the trade-off between cost and uncertainty. More information is available in **Article 198, Calibration and Standards in Temperature Measurement, Volume 3**.

7 REDUCTION OF PARASITIC LEAD RESISTANCES

Adding a third lead to the RTD and employing a balanced bridge circuit can reduce the effect of parasitic lead resistance (Figure 12).

The practical example in Figure 12 shows a 3-wire RTD connected to a compensated-lead bridge circuit. The lead resistances can be compensated for the situation in which the ratio resistors R_1 and R_2 are equal and R_X equals the resistance of the RTD. Changes in the bridge's voltage reference have little effect when the bridge is balanced.

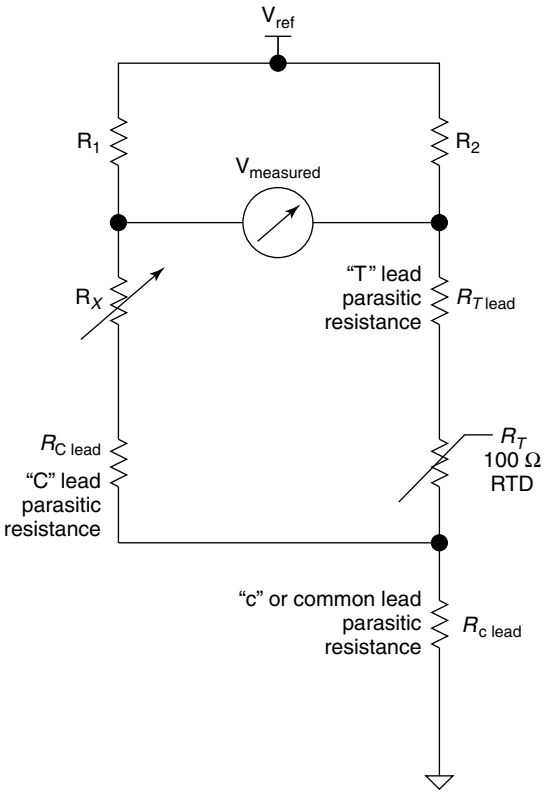

Figure 12. Compensated three-wire RTD bridge circuit (http://www.teamwavelength.com/downloads/newproducts/appnote-tc02.pdf).

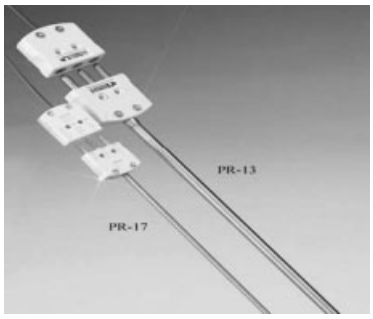

Figure 13. Quick disconnect RTD probe (http://www.omega.com/ppt/pptsc.asp?ref=PR-13&nav=temc03).

8 INDUSTRIAL RTD PROBES

For easier handling, quick disconnect RTD probes with standard size connectors (Figure 13) are used.

8.1 Technical data

$\alpha = 0.00385$ standard; 6-, 9-, 12-, 18-, and 24-inch lengths standard; $R_0 = 100\,\Omega$ at $0\,^{\circ}\mathrm{C}$; Three lead configuration standard.

Figure 14. Industrial RTD probe with protection head (http://www.omega.com/ppt/pptsc.asp?ref=PR-12&Nav=temc05).

Options: Two and four lead configurations; Teflon coating of probe; $\alpha = 0.00316$; Nonstandard probe lengths; other values of R_0.

For stronger environmental conditions, the industrial RTD probes with cast iron protection heads (Figure 14) are used.

8.2 Technical data

Three-wire configuration standard; $R_0 = 100\,\Omega$; 1/4-inch diameter; 18-inch length, European curve with $\alpha = 0.0385$.

9 DYNAMICAL CHARACTERISTICS OF RTDs

Industrial RTDs are enclosed in a heavy protective thermo well. The thermo well slows down the step response of the RTD significantly, increasing the time constant in the range of seconds.

To estimate the time constant, the RTD can be moved from a temperature bath Θ_{initial} to another temperature bath Θ_{final}. A typical step response is shown in Figure 15.

If at time t the indicated temperature is $\Theta_{\text{indicated}}$, then the time constant T may be estimated from the step response using

$$\Theta_{\text{final}} - \Theta_{\text{indicated}} = (\Theta_{\text{final}} - \Theta_{\text{initial}})\mathrm{e}^{-t/T} \qquad (11)$$

The transfer function of the inertial system with first-order characteristic is

$$F(p) = \frac{k}{Tp + 1} \qquad (12)$$

with p as the Laplace operator.

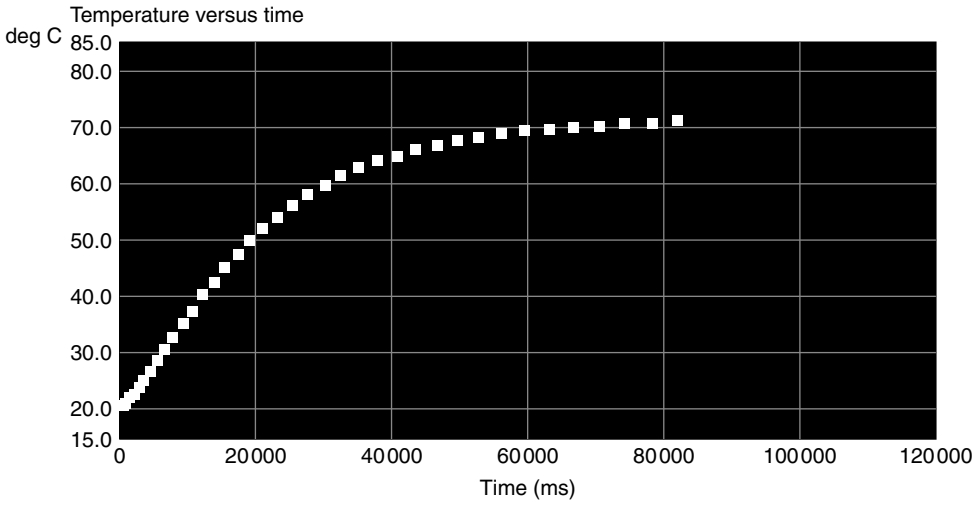

Figure 15. Transient function (step response function) of an industrial RTD (http://pasture.ecn.purdue.edu/∼abe591s/Temperature_Lab.pdf).

For quicker estimation, the time constant can be taken from the subtangent of the transfer function (Figure 15).

10 MEASUREMENT ASSURANCE PROGRAM FOR TEMPERATURE

The purpose of the Measurement Assurance Program (MAP) (http://ts.nist.gov/ts/htdocs/230/233/calibrations/thermodynamic/resistance%20_thermometry.htm#33010C) is to assure the accuracy of the calibration of temperature standards (83 K to either 420 °C or 661 °C) conducted by participating laboratories when using platinum resistance thermometry. The MAP transport standard consists of sets of three commercial SPRTs packaged in a special shock-proof shipping container. These SPRTs are used to assess both the reproducibility and the uncertainty of calibrations performed by the participating laboratory.

In order to achieve high accuracy, SPRTs used as standards should be either metal sheathed or of the matte-finish glass-sheathed type to avoid systematic errors arising from light-pipe effects in the glass sheath. The participant must have a triple point of water cell and an appropriate resistance bridge.

The National Institute of Standards and Technology (NIST) (http://www.nist.gov) provides worksheets on which the participant records data. The participant calculates the thermometer constants from experimental data, records them, and prepares tables of either resistance ratio or resistance versus temperature. These completed worksheets and the participant's calibration reports are sent to NIST with the return of the MAP SPRTs.

The SPRTs are recalibrated upon return to NIST and the participant's data are compared with NIST's calibration results. NIST provides a plot of the participating laboratory's temperature deviation from NIST values and a written analysis of the data, including any pertinent observations. In a typical MAP transfer, the participant records measurements over a period of 1 to 2 months. A typical turnaround time from the date NIST receives the participant's data until a test report is sent to the participant is 4 to 6 weeks. Former participants in the MAP have had expanded uncertainties that ranged from about 1 mK to several tens of mK.

No rigid recommendations can be given concerning how often a participant should utilize the temperature MAP service. Experience has indicated that when temperature measurements are in a state of statistical control, as evidenced by in-house check standards and control charts used to monitor the measurement process, the participant should be able to go at least 3 years between transfers from NIST without significantly degrading the confidence in the correctness of the measurements.

Among other NIST services for temperature calibration laboratories, NIST provides standard reference materials for use as defining fixed points of the ITS-90 and as secondary reference points (http://ts.nist.gov/ts/htdocs/230/233/calibrations/thermodynamic/resistance%20_thermometry.htm#33010C).

1 TEMPERATURE SCALES AND STANDARDS

Although temperature is defined thermodynamically, it is impracticably difficult to measure thermodynamic temperature. Instead, the international measurement community, through the Conférence Générale des Poids et Mesures (CGPM), provides an approximation to the thermodynamic scale based on practical thermometers and interpolation between fixed points with defined temperatures. The fixed points are the melting-, freezing-, and triple-point temperatures of various pure substances, and the interpolating thermometers include platinum-resistance thermometers, radiation thermometers, vapor-pressure thermometers, and constant-volume gas thermometers. This scale is sufficiently accurate and reproducible, of low cost, and accessible to satisfy almost all trade, safety, and research needs. At intervals of approximately 20 years, the scale is updated to match the latest thermodynamic measurements and measurement techniques. The current scale is called the *International Temperature Scale of 1990* or ITS-90 (Preston-Thomas, 1990), and all temperature measurements should be traceable to ITS-90. Previous scales were defined in 1927, 1948, and 1968, and where necessary, scale temperature is distinguished by a subscript according to the year of the scale, for example, T_{68} (K) or t_{68} (°C) for temperatures measured on the 1968 scale.

The ITS-90 allows measurement from 0.65 K to the highest temperature measurable in terms of Planck's radiation law. A recent addition is the Provisional Low Temperature Scale of 2000, PLTS-2000, (Rusby *et al*., 2001), a low-temperature extension that allows measurement down to 1 mK. Figure 1 shows a schematic diagram of the elements of ITS-90 and PLTS-2000. Notably, the important temperature range from 13 K to 962 °C is defined in terms of standard platinum resistance thermometers, SPRT, which are the easiest to use and calibrate of the ITS-90 thermometers. The accuracy of the ITS-90 ranges from about 0.2 mK at 0.65 K, 1 mK near room temperature, about 5 mK at 960 °C for SPRTs, to about 0.1 °C at 960 °C for radiation thermometers and increases as T^2 at higher temperatures.

The Bureau International des Poids et Mesures, BIPM (www.bipm.fr), publishes guidelines with extensive references to scientific papers (BIPM, 1990a) to assist in the realization of ITS-90. A second guide (BIPM, 1990b) provides advice on calibration and techniques for approximating ITS-90 using other thermometers and methods. Secondary fixed points (Bedford *et al*., 1996) can be used to calibrate thermometers at temperatures other than those defined by the ITS-90 fixed points.

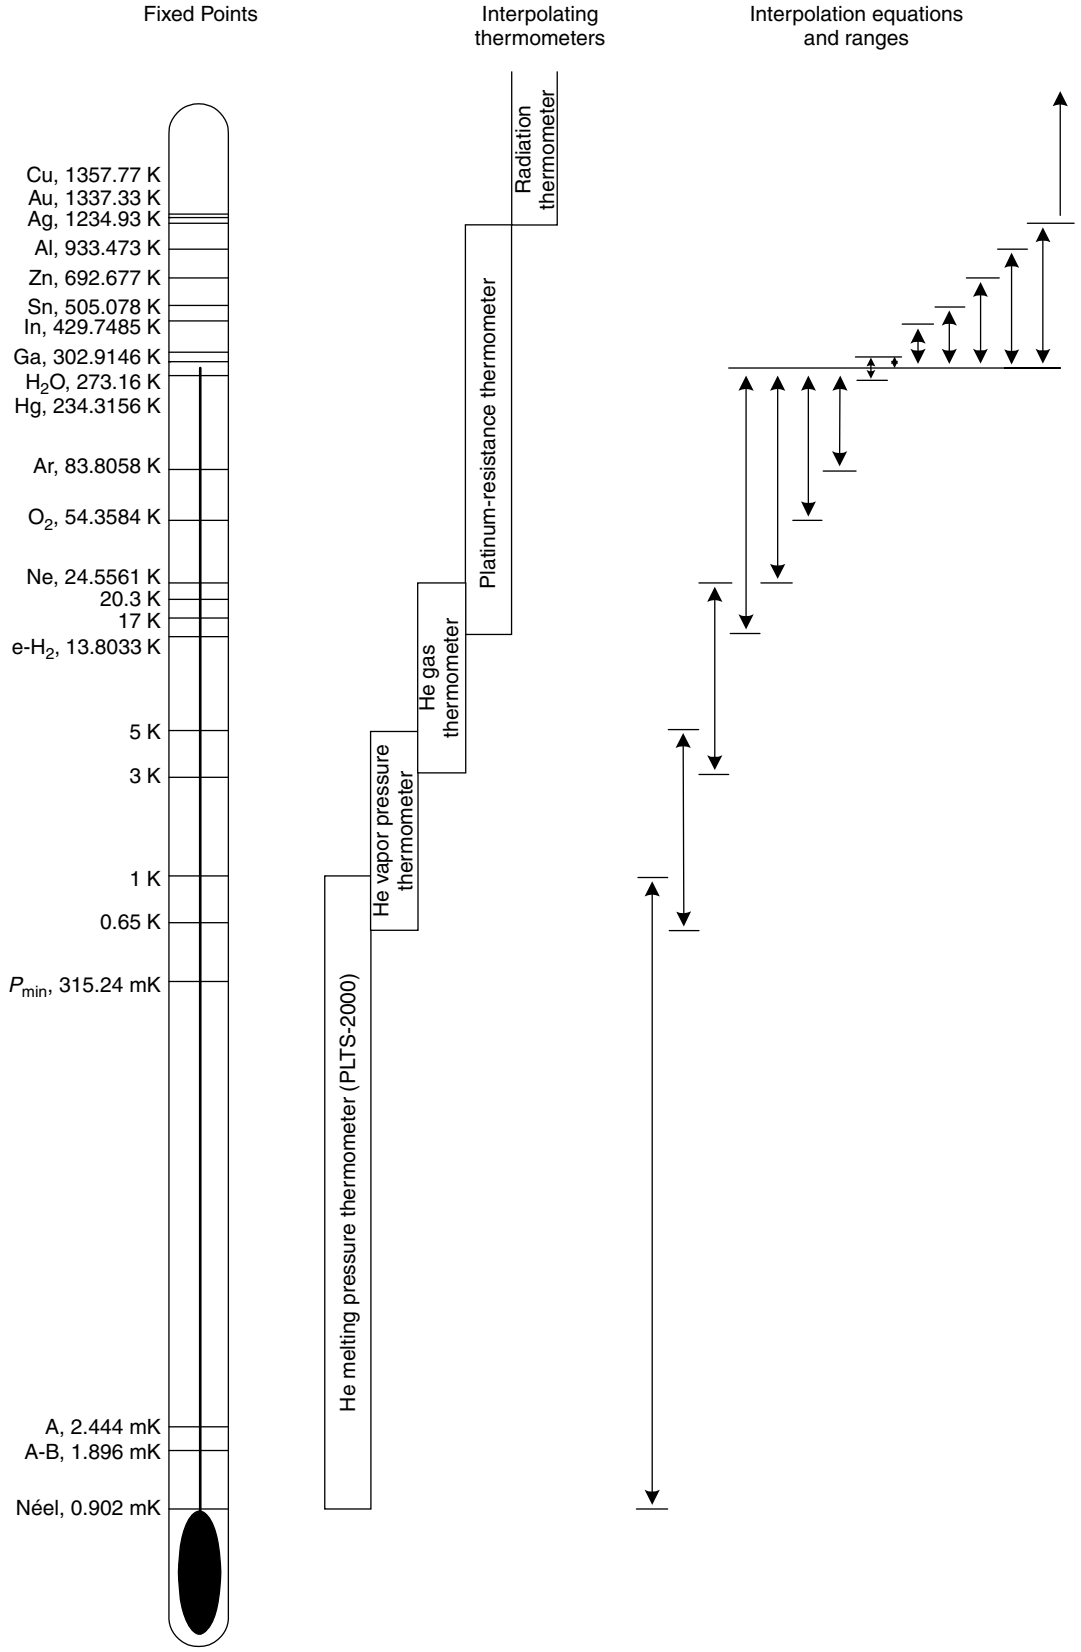

Figure 1. A guide to the main features of ITS-90. The temperatures are the temperatures of the fixed points defined by ITS-90 or PLTS-2000.

The science underlying the temperature scale is described in Quinn (1990) and Schooley (1986), while the principles of calibration and practical temperature measurement are described in Nicholas and White (2001) and Bentley (1998). More general texts providing extensive overviews of different temperature measurement techniques include Childs (2001), McGee (1988), and Michalski *et al*(2001).

2 CALIBRATION OF LOW-TEMPERATURE SENSORS

At temperatures below 150 K, material properties change significantly from their room temperature values. In particular, the thermal conductivity of good conductors, such as metals, increases and the heat capacity of all materials decreases as the temperature is reduced. Consequently, the elimination of temperature gradients and heat leaks becomes increasingly difficult. Knowledge of low-temperature techniques (White and Meeson, 2002) is necessary to carry out measurements at low temperatures.

For temperatures between 13 K and 273 K, the ITS-90 is defined in terms of capsule SPRTs (Figure 2). At lower temperatures, the ITS-90 is defined in terms of a gas thermometer and a vapor-pressure thermometer. These are not so convenient, and the realization of the ITS-90 is normally carried out simultaneously with the calibration of more convenient sensors such as rhodium–iron resistance thermometers. These are electrically similar to SPRTs but have much improved sensitivity (dR/dT) for temperatures down to 0.5 K.

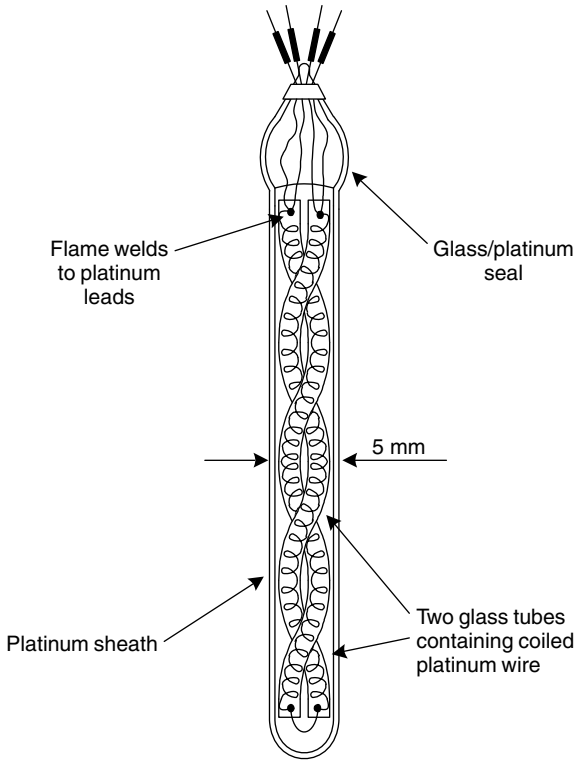

Figure 2. The construction of a typical capsule standard platinum-resistance thermometer used for temperatures below 156 °C. Rhodium–iron resistance thermometers have a similar construction.

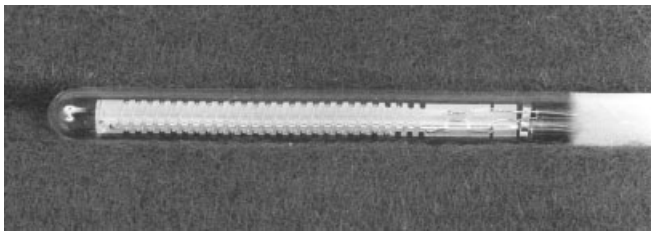
For some temperature ranges above 0.5 K, vapor-pressure thermometers may be convenient reference thermometers. They are accurate, simple to make, relatively immune to systematic effects except for impurities, and tables have been published for a number of different fluids (BIPMb). They are, however, limited to quite narrow temperature ranges, and for some ranges there is no suitable fluid.

A copper block cooled using nitrogen or helium vapor and surrounded by radiation shields is a commonly used calibration medium. The copper block has several holes for mounting platinum resistance or rhodium–iron resistance thermometers and the thermometers under calibration. Vacuum grease or helium gas is used to ensure good thermal contact. For temperatures above 4 K, it is also possible to use closed cycle refrigerators, which are more convenient and faster than liquid helium refrigeration. The BIPM Guidelines for ITS-90 (BIPMa, BIPMb) describe a number of successful designs of cryostats suitable for calibration systems.



Many different sensors are available for use at low temperatures including germanium resistance thermometers, carbon resistance thermometers, and diode thermometers. Because semiconductors are nonlinear, these devices require a relatively large number of calibration points (15 to 30 depending on temperature range).

3 CALIBRATION OF MID-RANGE TEMPERATURE SENSORS

In the range from 150 K to 350 °C, temperature is defined in terms of the long-stem SPRT (Figure 3), with an accuracy of about 1 mK. At the next level of accuracy, 5 mK to 50 mK, the most useful reference thermometers are industrial platinum-resistance thermometers. These must employ a 4-wire resistance measurement to eliminate lead resistances and have the platinum wire partially supported to prevent strain and hysteresis effects. Other suitable reference thermometers include liquid-in-glass thermometers and thermistors, which are better suited to narrow temperature ranges, and rare-metal thermocouples (*see* **Article 196, Thermocouple Temperature Sensors, Volume 3**). Other thermometers including base-metal thermocouples (nickel based) are generally not suitable due to a lack of stability and reliability.

(a)

(b)

Figure 3. A long-stem standard platinum-resistance thermometer for use at temperatures above 150 K: (a) the full assembly in carrying case and (b) a close-up of the sensing element.

Because this temperature range includes a large fraction of temperature measurement activity, most equipment is available commercially. Several companies specialize in the supply of thermometry equipment and can outfit a complete calibration laboratory for any level of accuracy ranging from a full ITS-90 implementation at ± 1 mK to a general-purpose laboratory at ± 1 K.

A wide choice of calibration media is available with stirred fluid baths (e.g. Figure 4) being the easiest to use. Depending on temperature, the fluids range from light paraffins, methanol, light mineral oils, water (with and without antifreeze), heavy mineral oils, and silicon oils, through to mixtures of salts enabling access to temperatures up to 500 °C. Generally, each fluid enables a temperature range of about 80 °C between the temperature at which it stirs well (30 centistokes max. kinematic viscosity) and the temperature at which evaporation is excessive or decomposition is likely. Silicon oils, although expensive, have a useful range of about 160 °C, and molten salts enable a range of about 200 °C.

In recent years, dry-block calibrators have become popular for calibrations. However, their thermal design is such that they are prone to temperature gradients of up to 1% of the temperature difference with respect to ambient temperature. They are suitable for some industrial calibrations but not for laboratory work. Fluidized sand beds can also be used for higher temperatures but they can be dusty and prone to large temperature gradients.

Nicholas and White (2001) provide extensive advice for thermometer calibrations in this range. They detail

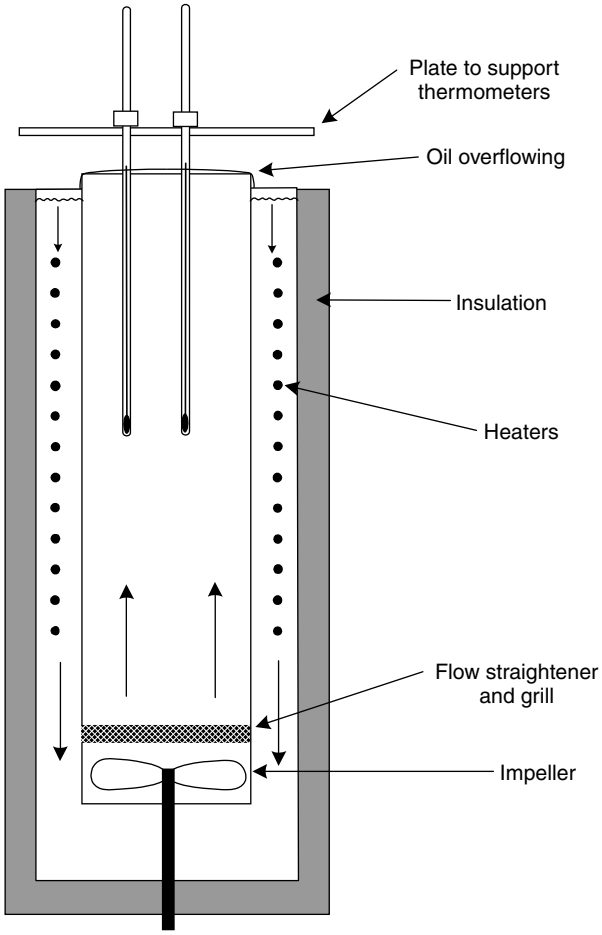


Figure 4. An overflow style calibration bath. The concentric design provides good control, nonturbulent flow, and horizontal viewing to ensure easy reading of liquid-in-glass thermometers.

important effects in the calibration of liquid-in-glass thermometers, platinum-resistance thermometers, thermocouples, and radiation thermometers, and include example procedures and uncertainty analyses. Other books describing the negative aspects of thermometers in addition to the operating principles include the BIPM Guide (1990b) and the three-volume handbook of Bentley (1998).

4 CALIBRATION OF HIGH-RANGE TEMPERATURE SENSORS

At temperatures above 350 °C, there are two thermometers defined by ITS-90 – SPRTs up to 960 °C and radiation thermometers for all temperatures above 960 °C. Radiation thermometers can also be used at temperatures down to −50 °C, but their accuracy is typically 0.1 °C at best, whereas SPRTs are accurate to a few millikelvins. Rare-metal thermocouples are also useful reference thermometers for temperatures above 450 °C where industrial platinum-resistance

thermometers become unreliable. The gold–platinum and platinum–palladium thermocouples perform almost as well as SPRTs with accuracies of 5 mK or so up to 1000 °C, and for platinum-palladium, with accuracies of 0.15 K or better up to 1500 °C.

At temperatures above 350 °C, thermal conductivity is often dominated by electromagnetic (infrared) radiation. For example, surfaces near 500 °C radiate approximately 20 kW m^{-2}. Obtaining calibration media with temperature gradients of less than 1 °C in these conditions is difficult. For the highest accuracy, heat pipes are used. These are open (pressure-controlled type) or closed vessels containing a pure liquid under vacuum (Figure 5). When the vapor-pressure of the liquid is sufficient and all surfaces in the vessel are wet, the effective thermal conductivity of the vessel can exceed 10^5 times that of copper by virtue of the absorption and release of latent heat at the surface of the fluid. Mercury, cesium, potassium, and sodium are all used for heat pipes with each covering approximately 250 °C to 400 °C temperature range. Heat-pipe furnace liners are available commercially.

Calibration of Rare-metal thermocouples (Types B, R, and S) are best carried out by welding the junctions of the thermocouples together. This satisfies simultaneously the requirements of ensuring that the reference junctions are in close thermal contact, at the same temperature, and each junction is isothermal to prevent the generation of spurious voltages. Because the Seebeck voltage is generated at the temperature gradients in the wires and not at the junction, thermocouple calibrations are only meaningful if the temperature gradients can be reproduced or the wires are homogeneous. For the highest accuracy work, a homogeneity test is essential to demonstrate that the wire is homogeneous (Bentley 1998, ASTM 1993).

Base-metal thermocouples are not usually calibrated except as representative samples of a batch. Heat treatment of the base-metal alloys introduces inhomogeneities of up to 8 °C (in Type K, less in other types), which often makes calibration of used thermocouples futile.

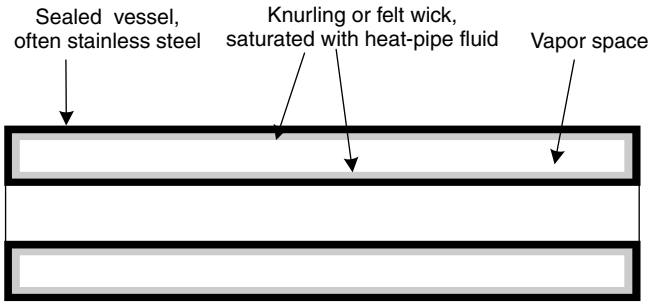

Figure 5. A section along the main axis of a closed heat-pipe furnace liner. The wick is saturated with the fluid so that evaporation at hot spots and condensation at cold spots moves heat via the latent heat of vaporization with almost zero change in temperature.

Radiation thermometers are calibrated using blackbody cavities, which simulate perfect emitters according to Planck's radiation law. For the highest accuracy, fixed-point black bodies employing the ITS-90 defined freezing points should be used. Variable temperature blackbodies using rare metal thermocouples as reference thermometers are better suited for the calibration of general purpose radiation thermometers with accuracies of about 1 °C. Both fixed-point and variable temperature blackbodies are available commercially. Quinn (1990) is a key reference for primary radiation thermometry, DeWitt and Nutter (1988) provide extensive information on the theory and practice of radiation thermometry, and Nicholas and White (2001) provide guidelines on use and calibration of general purpose radiation thermometers.

5 REFERENCE THERMOCOUPLE TABLES

The letter-designated thermocouples are no longer defined by alloy composition but by mathematical equations. This provides manufacturers with the opportunity to design alloys for different environments and temperatures. Therefore, to ensure specified accuracy, thermocouple wires should only be bought and used as a pair. The mathematical definitions are often presented as tables, and assume that the reference junction is at 0 °C (the ice point). The temperature range, composition, and manufacturing tolerance of a range of thermocouples types are summarized in Table 1.

The base-metal thermocouples (Types E, J, K, N, and T) all have nickel in one or both of the wires. They have a high Seebeck coefficient (>30 μV/°C above 0 °C), a modest accuracy (approximately 0.5 °C ± 0.5% of reading), and are of low cost. Noble-metal or rare-metal thermocouples (Types B, R, and S) all have platinum in both wires. They have a low Seebeck coefficient (approximately 10 μV/°C) but have a higher accuracy (approximately 0.2 °C ± 0.05%), and are relatively expensive. The tables for the letter-designated thermocouples are available on the National Institute for Standards and Technology, NIST, Web site (http://srdata.nist.gov/its90/main/).

Users should be aware that the same letter designation might be used for different thermocouples. For example, European equipment manufactured before 1993 using Type J wire may have been made to the older (Deutsches Institut für Normung e. V.) DIN Type J standard, which at some temperatures is several degrees different from the (International Electrotechnical Commission) IEC Type J standard. Since 1990, thermocouple standards have become

Table 1. Summary of the temperature ranges and compositions of some common and useful thermocouples.

Type designation	Composition, positive leg	Composition, negative leg	Temperature range (°C)	Tolerance	Reference	Comment
B	Pt 30% Rh	Pt 6% Rh	0 to 1820	0.5 °C or 0.4%	IEC 584	Suited for use above 1000 °C
C	W 3% Re	W 25% Re	0 to 2400	5 °C or 1%	ASTM E988	Suits reducing environment, high temperatures, brittle
D	W 5% Re	W 26% Re	0 to 2400	5 °C or 1%	ASTM E989	Suits reducing environment, high temperatures, brittle
G	W	W 26% Re	300 to 2400	5 °C or 1%	ASTM E1751	Suits reducing environment, high temperatures, very brittle
E	Ni 10% Cr	Cu 45% Cr	−270 to 1000	1.5 °C or 0.4%	IEC 584	Highest sensitivity, good at low temperatures
J	Fe	Cu 45% Cr	−210 to 900	1.5 °C or 0.4%	IEC 584	Suits reducing environments
K	Ni 10% Cr	Ni 2% Al 2% Mn 1% Si	−270 to 1372	1.5 °C or 0.4%	IEC 584	General purpose, low accuracy
L	Fe	Cu 45% Cr	−210 to 900	1.5 °C or 0.4%	DIN 43710	DIN precursor to Type J
N	Ni 14.2% Cr 1.4% Si	Ni 4.4% Si 0.15% Mg	−270 to 1300	1.5 °C or 0.4%	IEC 584	General purpose, better than Type K
R	Pt 13% Rh	Pt	−50 to 1768	1 °C or 0.3%	IEC 584	High accuracy, susceptible to contamination
S	Pt 10% Rh	Pt	−50 to 1768	1 °C or 0.3%	IEC 584	High accuracy, susceptible to contamination
T	Cu	Cu 45% Cr	−270 to 400	1.5 °C or 0.4%	IEC 584	High accuracy, general purpose, suits low temperatures
U	Cu	Cu 45% Cr	−270 to 600	1.5 °C or 0.4%	DIN 43710	DIN precursor to Type T
–	Au	Pt	0 to 1000	–	ASTM E988	Most accurate for this range
–	Au	Pd	0 to 1500	–	ASTM E1751	Most accurate above 1000 °C

Notes: 1. Letter designation for Types C, D, and G are not formal, but are recognized by many manufacturers.
2. Tolerance values are given indicative of manufacturing tolerances. Actual values vary according to grade of wire and temperature range.

harmonized and the older DIN Type J is now known as Type L. The Type T and Type U thermocouples are similarly related.

There are a number of useful specialized thermocouples without a formal letter designation. The American Society for Testing and Materials, in the ASTM E988 and ASTM E1751 standards define additional thermocouple types including three tungsten–rhenium thermocouples, which have an informal letter designation recognized by many manufacturers (Types C, D, and G), and are useful at high temperatures and in reducing atmospheres. ASTM E1751 includes the definitions for the platinum–gold and the platinum–palladium thermocouples, both of which use pure metal wires to avoid the inhomogeneity problem afflicting other thermocouples, and are accurate to a few millikelvin for temperatures below 960 °C.

Good advice on the use of the different thermocouples can be found in the ASTM manual (ASTM 1993) and in Bentley (1998).

1 DEFINITION OF TIME, TIME INTERVAL, AND FREQUENCY

Time and frequency metrologists measure three basic quantities: time of day, time interval, and frequency. Time of day is usually provided in units of years, months, days, hours, minutes, and seconds. Devices that display or record time of day are called *clocks*. Synchronization is the process of setting multiple clocks to the same time.

Time interval is the duration or elapsed time between two events. The standard unit of time interval is the *second* (s). However, many applications require measuring shorter time intervals, such as *milliseconds* ($1\,\text{ms} = 10^{-3}\,\text{s}$), *microseconds* ($1\,\mu\text{s} = 10^{-6}\,\text{s}$), *nanoseconds* ($1\,\text{ns} = 10^{-9}\,\text{s}$), and *picoseconds* ($1\,\text{ps} = 10^{-12}\,\text{s}$). The second is one of seven base units in the International System of Units (SI). The second was once defined on the basis of the earth's rotational rate or as a fraction of the tropical year. That changed in 1967 when the era of atomic time keeping formally began. The second is now defined as follows:

> The duration of 9 192 631 770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the cesium-133 atom.

Frequency is the rate of occurrence of a repetitive event. If T is the period of a repetitive event, then the frequency f is the period's reciprocal, $1/T$. Conversely, the period is the reciprocal of the frequency, $T = 1/f$. Since the period is a time interval expressed in seconds (s), the close relationship between time interval and frequency is easy to see. The standard unit for frequency is the *hertz* (Hz), defined as events or cycles per second. The frequency of electrical signals is often expressed in multiples of hertz, including *kilohertz* ($1\,\text{kHz} = 10^3\,\text{Hz}$), *megahertz* ($1\,\text{MHz} = 10^6\,\text{Hz}$), or *gigahertz* ($1\,\text{GHz} = 10^9\,\text{Hz}$). A device that produces frequency is called an *oscillator*. *Syntonization* is the process of setting multiple oscillators to the same frequency.

The three time and frequency quantities are closely related. As mentioned, the standard unit of time interval is the second. Seconds are counted to establish date and time of day. Events or cycles per second are counted to measure frequency and time interval. Time interval and frequency are measured with far less uncertainty and more resolution than any other physical quantities. Today (2002), the best time and frequency standards realize the SI second with uncertainties near 1×10^{-15}.

2 COORDINATED UNIVERSAL TIME (UTC)

The world's major metrology laboratories routinely send their measurement data to the Bureau International des Poids et Measures (BIPM) in Sevres, France. The BIPM averages data collected from more than 200 atomic time and frequency standards located at more than 40 laboratories. The BIPM uses the data to generate Coordinated Universal Time (UTC), a timescale that realizes the SI second as closely as possible. The BIPM maintains UTC as a 'paper' timescale. National metrology laboratories use data published by the BIPM to steer their clocks and oscillators, and to generate and distribute real-time versions of UTC.

When necessary, leap seconds are added to UTC on either June 30 or December 31. Leap seconds keep atomic time (UTC) within ± 0.9 s of an older timescale called UT1, which is based on the Earth's rotation frequency. Leap seconds have been added to UTC at a rate of less than once per year since 1972.

UTC is the ultimate standard for time of day, time interval, and frequency. Clocks synchronized to UTC display the same hour, minute, and second all over the world (and remain within one second of UT1). Oscillators syntonized to UTC generate signals that serve as time interval and frequency standards.

3 MEASUREMENT TERMINOLOGY

The oscillator or clock being measured is called the *device under test* (DUT). A measurement compares the DUT to a standard or reference. The test signal for time measurements is usually a pulse that occurs once per second. Pulse width and polarity varies, but amplitude is often at TTL levels. The test signal for frequency measurements is usually a sine or a square wave that produces one cycle (360° or 2π radians of phase) in one period. The signal amplitude is expressed in volts (Figure 1).

Measurement results are stated in terms of accuracy and stability. Accuracy relates to the offset from an ideal value – *see* **Article 54, Explanation of Key Error and Uncertainty Concepts and Terms, Volume 1**. For example, time offset is the time interval between a measured on-time pulse and an ideal on-time pulse that coincides with the UTC second. Frequency offset is the difference between a measured frequency and an ideal frequency with zero uncertainty. This ideal frequency is called the *nominal frequency*.

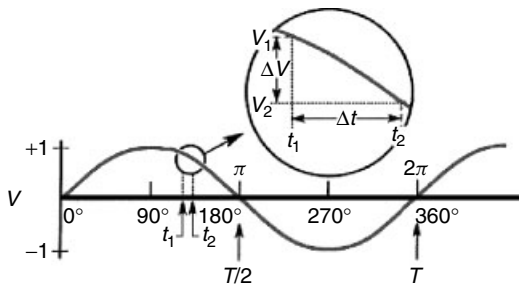

Figure 1. Oscillating sine wave.

Stability indicates how well a device produces the same time or frequency offset over a given time interval. It does not indicate whether the time or frequency is 'right' or 'wrong', but only whether it *stays the same*. Accuracy depends upon how well a device has been synchronized or syntonized, whereas stability is an inherent device characteristic.

Stability estimates are calculated from a set of either frequency offset or time offset measurements, and show time or frequency fluctuations with respect to a mean offset. The offset values are obtained by sampling or averaging over a stated interval, called tau (τ). Short-term stability refers to fluctuations over short intervals (often where $\tau = 1$ s, or at least where τ is less than 100 s). Long-term stability can refer to any τ value greater than 100 s, but usually refers to values longer than 1 day. An oscillator specification sheet usually lists stability estimates at τ values increasing in length until the point, called the *noise floor*, where the stability stops improving. The most common statistics used to estimate stability are the Allan deviation ($\sigma_y(\tau)$) for frequency stability, and the Time deviation ($\sigma_x(\tau)$) for time stability. Further information on the uncertainty of measurements is found in **Article 55, Uncertainty Determination, Volume 1**.

4 MEASUREMENT TECHNIQUES

If a single time interval or frequency measurement is made, the uncertainty is often limited by measurement system noise, or a lack of resolution. Averaging measurements usually leads to more resolution and lowers the measurement system's noise floor. To obtain a correct result, the measurement interval must be long enough to ensure that both the measurement system and reference have lower noise floors than the DUT.

Time interval is usually measured with a time interval counter (TIC). A TIC requires two signal inputs. One signal starts the counter and the other stops it, and the TIC measures the interval between the signals. The best TICs have a single shot resolution near 20 ps, which sometimes averages down to near 1 ps.

Simple frequency measurements are made with a frequency counter (Figure 2). The measurement reference

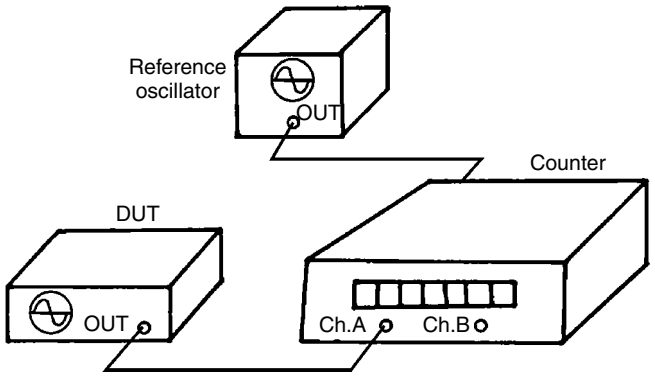

Figure 2. Frequency measurement with frequency counter.

is the counter's time base oscillator. Frequency offset (dimensionless) is determined as

$$f(\text{offset}) = \frac{f_{\text{measured}} - f_{\text{nominal}}}{f_{\text{nominal}}} \tag{1}$$

where f_{measured} is the reading displayed by the frequency counter, and f_{nominal} is the frequency labeled on the oscillator (the nominal frequency it is supposed to produce).

More advanced frequency measurements are phase comparisons between the DUT and reference signals. The concept of a phase comparison is best illustrated on an oscilloscope where the waveforms are visible (Figure 3), but higher resolution comparisons are made with a TIC, using the DUT to start the counter, and the reference to stop the counter. The time interval change is used to estimate the frequency offset:

$$f(\text{offset}) = \frac{-\Delta t}{T} \tag{2}$$

where Δt is the change in time interval, and T is the measurement period. This requires only two time interval readings, and Δt is simply the difference between the two readings. Typically, multiple readings are taken, least squares linear regression is applied to the data set, and Δt is obtained from the slope of the least squares line. If desired, the dimensionless frequency offset can be multiplied by the nominal frequency and converted to hertz.

Since standard test frequencies have short periods (100 ns in the case of 10 MHz), keeping track of cycles during a phase comparison is difficult. Therefore, phase comparisons normally test low frequencies with long periods, such as 1 or 10 Hz. The low frequency is obtained by dividing the test frequency, or by mixing it with another frequency to generate a beat frequency.

Divider systems (Figure 4) are more versatile, and can be built or programmed to work with nearly any test frequency. They can convert any test frequency to 1 Hz, for example, by simply removing $n - 1$ cycles of the test frequency. In this fashion, a 5-MHz signal can be divided and compared to a 1-Hz signal. Divider systems normally cannot detect frequency changes smaller than parts in 10^{11} in 1 s, since the single shot resolution and short-term stability of a TIC/Divider system is limited to tens of picoseconds.

Mixer systems (Figure 5) are less versatile and more complex. They are often designed for a single test frequency, they cannot measure 1-Hz timing signals or similar low frequencies, and they usually require the DUT and reference to have the same nominal frequency. The dual mixer time difference measurement system shown in the figure mixes the DUT and reference signals with a signal from a transfer oscillator offset from the nominal frequency. If the nominal frequency is 10 MHz, and the offset frequency is 10.000010 MHz, the result is 2 beat frequencies near 10 Hz that are compared using a TIC. The ratio of the nominal frequency to the beat frequency is the heterodyne factor ($10^7/10 = 10^6$ in this example). The system's resolution is the period of the TIC's time base oscillator divided by the heterodyne factor. For example, if the TIC

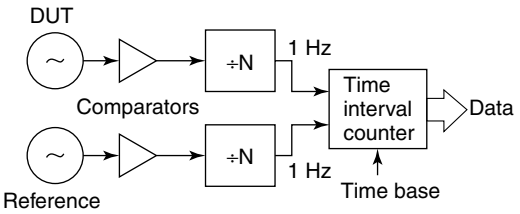

Figure 4. Time interval counter measurement system with frequency dividers.

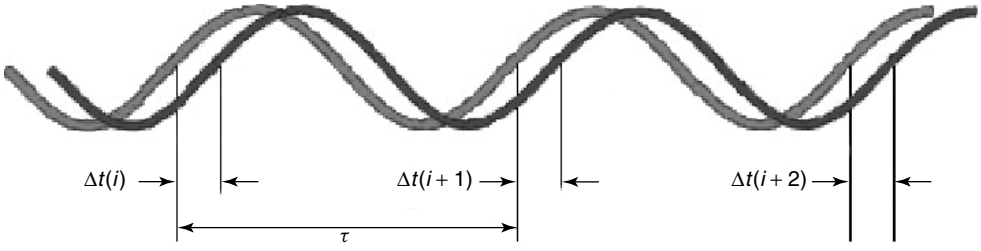

Figure 3. Phase comparison between two sine waves.

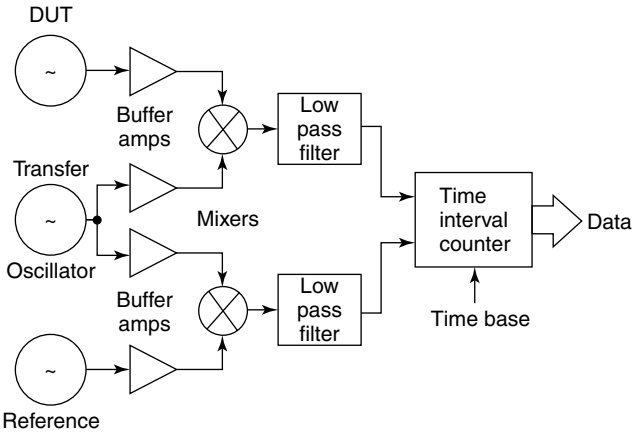

Figure 5. Dual mixer time difference measurement system.

has a 10-MHz time base, the resolution equals 100 ns/10^6 or 0.1 ps. This high resolution makes it possible to detect frequency changes of parts in 10^{13} in 1 s, and makes a dual mixer system well suited for measuring short-term stability. However, divider and mixer systems should produce the same answer when measuring long-term stability, since the noise floor of both systems eventually drops below the DUT noise floor.

5 OSCILLATORS AND CLOCKS

Oscillators consist of a resonator that produces a periodic event, and an energy source that sustains oscillation. The natural frequency of an oscillator is called the *resonance frequency*. A clock is a device that counts oscillator cycles and displays or records time. For example, a quartz wristwatch contains an oscillator that runs at 32 768 Hz. After counting 32 768 cycles, the watch circuitry records that one second has elapsed. Seconds are counted to establish longer time intervals such as minutes, hours, and days.

The Q of an oscillator is its resonance frequency divided by its resonance width, or the range of possible frequencies at which the oscillator can oscillate. High-Q resonators generally lead to more stable oscillators, since they will not resonate at all unless they are operated near their resonance frequency.

Quartz oscillators achieve the highest Q of any mechanical-type oscillators, but atomic oscillators have much higher Q factors. In theory, the atom is a perfect resonator. Atomic oscillators use the quantized energy levels in atoms and molecules as their resonance source. An electromagnetic field at a particular frequency boosts an atom from one energy level to a higher one. Conversely, an atom at a high energy level can drop to a lower level by emitting energy. The resonance frequency (f) of an atomic oscillator is the difference between the two energy levels divided by Planck's constant (h):

$$f = \frac{E_2 - E_1}{h} \tag{3}$$

Table 1 provides a summary of oscillators used as time and frequency standards.

5.1 Quartz oscillators

Quartz oscillators use a quartz crystal as a resonator. The crystal strains (expands or contracts) when a voltage is applied. When the voltage reverses, the strain reverses. This is known as the *piezoelectric effect*. The rate of expansion and contraction is the resonance frequency, and

Table 1. Summary of oscillator types.

Oscillator type	Quartz (TCXO)	Quartz (OCXO)	Rubidium	Commercial cesium beam	Hydrogen maser
Q	10^4–10^6	3.2×10^6 (5 MHz)	10^7	10^8	10^9
Resonance Frequency	Various	Various	6.834682608 GHz	9.192631770 GHz	1.420405752 GHz
Leading cause of failure	None	None	Rubidium lamp (life expectancy > 15 years)	Cesium beam tube (life expectancy of 3 to 25 years)	Hydrogen depletion (life expectancy > 7 years)
Stability, $\sigma_y(\tau)$, $\tau = 1$ s	1×10^{-8} to 1×10^{-9}	1×10^{-12}	5×10^{-11} to 5×10^{-12}	5×10^{-11} to 5×10^{-12}	1×10^{-12}
Noise floor, $\sigma_y(\tau)$	1×10^{-9} ($\tau = 1$ to 10^2 s)	1×10^{-12} ($\tau = 1$ to 10^2 s)	1×10^{-12} ($\tau = 10^3$–10^5 s)	1×10^{-14} ($\tau = 10^5$–10^7 s)	1×10^{-15} ($\tau = 10^3$–10^5 s)
Aging/year	5×10^{-7}	5×10^{-9}	1×10^{-10}	None	$\sim 1 \times 10^{-13}$
Frequency Offset after warm up	1×10^{-6}	1×10^{-8} to 1×10^{-10}	5×10^{-10} to 5×10^{-12}	5×10^{-12} to 1×10^{-14}	1×10^{-12} to 1×10^{-13}
Warm-up period	<10 s to 1×10^{-6}	<5 min to 1×10^{-8}	<5 min to 5×10^{-10}	30 min to 5×10^{-12}	24 h to 1×10^{-12}

is determined by the crystal's size and shape. Q factors for quartz oscillators range from 10^4 to 10^6.

Quartz oscillators are sensitive to changes in temperature, humidity, pressure, and vibration, but several designs reduce these environmental effects. The oven-controlled crystal oscillator (OCXO) encloses the crystal within a temperature-controlled chamber. The temperature-compensated crystal oscillator (TCXO) generates frequency changes equal and opposite to frequency changes produced by temperature. TCXOs are less expensive, but less stable than OCXOs.

Quartz oscillators have excellent short-term stability but poor long-term stability. An OCXO might be stable ($\sigma_y(\tau)$, at $\tau = 1$ s) to 1×10^{-12}. Long-term stability is limited by aging, or a frequency change with time caused by internal oscillator changes. The aging rate of a high quality OCXO might be parts in 10^9 per year, while a TCXO might age 100 times faster. Since quartz oscillators change frequency substantially over time, atomic oscillators are needed for applications requiring long-term stability.

5.2 Atomic oscillators

Rubidium oscillators are the lowest priced atomic oscillators. They operate at 6 834 682 608 Hz, the resonance frequency of the rubidium atom (^{87}Rb), and use the rubidium frequency to control the frequency of a quartz oscillator. The Q of a rubidium oscillator is about 10^7. Stability ($\sigma_y(\tau)$, at $\tau = 1$ s) is typically 1×10^{-11}, and about 1×10^{-12} at one day. Frequency offset ranges from 5×10^{-10} to 5×10^{-12} after a warm-up period of a few minutes or hours, so they meet the accuracy and stability requirements of most applications without adjustment.

Cesium oscillators physically realize the SI second, since the second is defined on the basis of the resonance frequency of the cesium atom (^{133}Cs), which is 9 192 631 770 Hz. A cesium oscillator should stay close to its nominal frequency without adjustment, and there should be no frequency change due to aging. The Q of a commercial cesium standard is a few parts in 10^8. Stability ($\sigma_y(\tau)$, at $\tau = 1$ s) is typically 5×10^{-12}, and reaches a noise floor near 1×10^{-14} in about one day, extending to weeks or months. The frequency offset is typically less than 1×10^{-12} after a 30-min warm up.

1 TIME STANDARDS

Time measurements include time interval measurements, which determine the elapsed time between two events; and time synchronization measurements, which determine the time offset between the test signal and the Coordinated Universal Time (UTC) second. Time standards typically produce 1 pulse per second (pps) signals. The period of these signals is a standard second that serves as a time interval reference. If the 1-pps signal is 'on time', or synchronized to UTC, it can also serve as a time synchronization reference. If the 1-pps signal is labeled, or time tagged, it can be used to synchronize time-of-day clocks. Some devices produce time tags at frequencies higher than 1 pps, with resolutions measured in milliseconds (ms), in microseconds (μs), or in nanoseconds (ns).

The second is defined as 'The duration of 9 192 631 770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the cesium-133 atom.' This definition was added to the International System (SI) of units in 1967, and therefore the 1-pps output from a cesium oscillator serves as an internationally recognized time interval standard. Commercially available cesium standards (Figure 1 provides a block diagram) routinely replicate the SI second with uncertainties near 1×10^{-13}. Even so, it is interesting to note that the 1-pps output from a cesium oscillator is not on time unless it has been synchronized. Prior to synchronization, the cesium timing pulse could be fast or slow by as much as 0.5 s with respect to UTC.

Cesium oscillators are expensive, and can cost $50 000 (USD) or more. They are usually owned only by facilities with stringent measurement uncertainty requirements. A more commonly owned time standard is a disciplined oscillator that receives radio broadcasts containing UTC information. The received information is often used to discipline a local quartz or rubidium oscillator, display the time-of-day, and to synchronize a 1-pps signal to agree with UTC. By applying continuous time and frequency corrections to the local oscillator signal, often through the use of a phase-locked loop, these radio-controlled devices can sometimes meet or exceed cesium oscillator performance over averaging periods of more than 1 day.

2 CALIBRATION OF SHORT TIME INTERVAL SENSORS

Measurements of time intervals less than 1 s are often made with oscilloscopes. Since oscilloscopes allow us to view the pulse waveforms, it is possible to select the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
Published in 2005 by John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

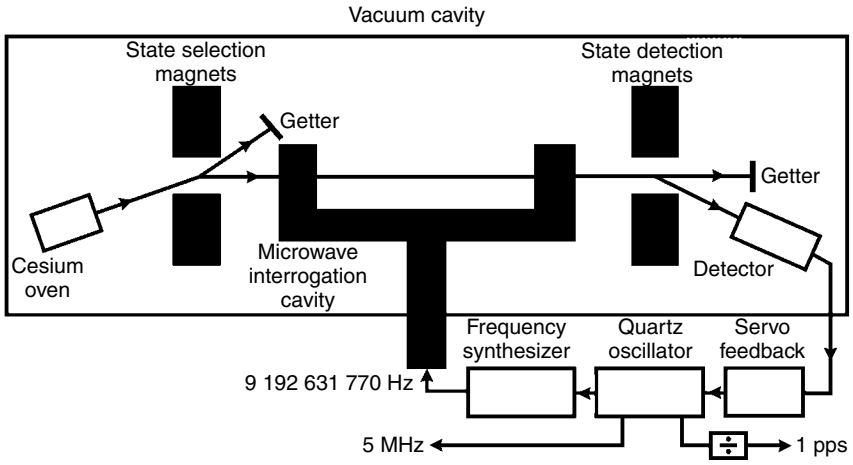

Figure 1. Block diagram of cesium oscillator.

precise start and end points that define a time interval, a major advantage when dealing with odd-shaped or noisy waveforms. Sometimes one pulse is displayed, while a different pulse is used to trigger the oscilloscope. Another method is to display both time pulses on a dual-trace oscilloscope. Triggering can be achieved from either of the two displayed pulses or from a third external pulse. The oscilloscope displayed in Figure 2 is triggering from channel A, and shows a 4-μs time interval between the A and B pulses.

The disadvantage of oscilloscopes for time interval measurements is lack of resolution and range. Oscilloscope range varies, and some models might be able to scale from 50 ps to 10 s per time division. However, the resolution

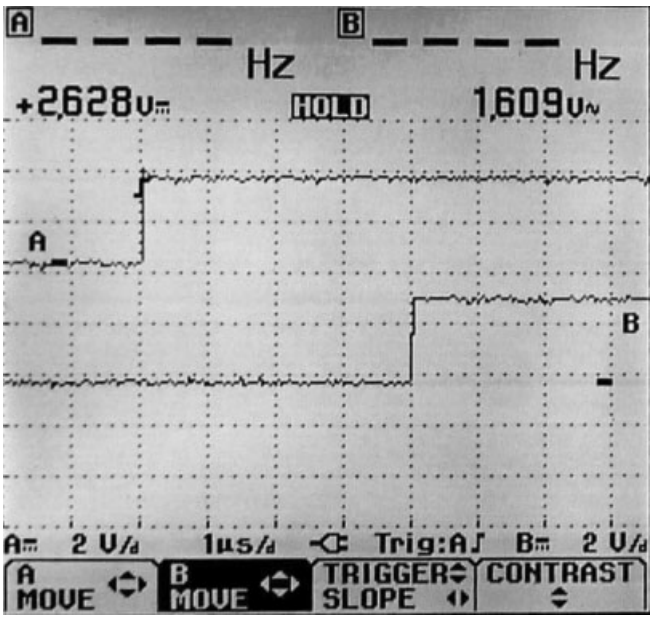

Figure 2. Measuring time interval with an oscilloscope.

of the time interval measurement is proportional to the length of the interval. If the time pulses are 10 ms apart, for instance, the best oscilloscopes can only resolve the interval to about ±1 μs. However, if the pulses are only 100 μs apart, the resolution is ±10 ns. In both cases, the relative uncertainty is 1×10^{-4}.

Time interval counters (TIC) are better suited for measuring all but the shortest time intervals. A start pulse gates the TIC (starts it counting) and a stop pulse stops the counting. While the gate is open (Figure 3), the counter counts zero crossings from time base oscillator cycle, and the resolution of the simplest TICs is equivalent to the period of a time base cycle (for example, 100 ns for a 10 MHz time base). However, many TICs use interpolation schemes to slice the cycle period into smaller parts. For example, slicing the 100-ns period into 5000 parts allows 20-ps resolution, a feat achieved by the best units. This translates to measurement uncertainties of a few parts in 10^{11} over a 1-s interval, often averaging down to parts in 10^{15} or 10^{16} after a few hours. Since these uncertainties are so low, TICs are routinely used for long-term comparisons between cesium oscillators.

The uncertainty of TIC measurements is, however, potentially limited by count ambiguity, trigger errors, or time base errors. A TIC generally has a +1 count or −1 count ambiguity in the least significant digit of its display. However, this ±1 count error usually averages out when multiple readings are taken, and is usually a problem only with single-shot measurements. Trigger errors are a more significant problem. They occur when the counter does not trigger at the expected voltage level on the input signal. Trigger errors can be caused by incorrectly set trigger levels or by input signals that are noisy (Figure 4), too large, or too small. Figure 4 illustrates that while triggering is desired on point a, noisy signals can cause triggering on points b or

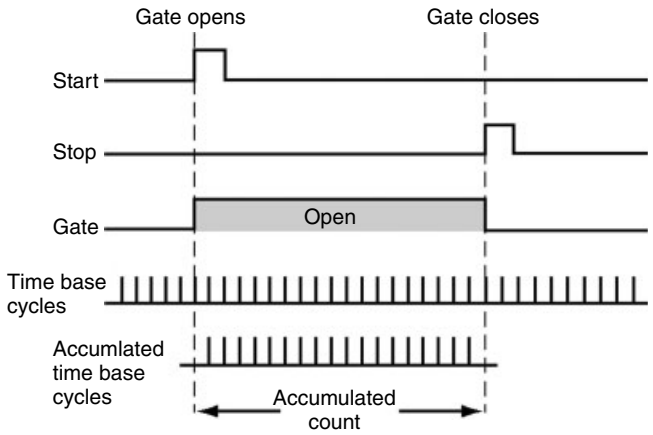

Figure 3. Gate and counting function of time interval counter.

c. This leads to incorrect measurements, so make sure the TIC is triggering at the proper point on both the start and stop waveforms (if necessary, view the waveforms on an oscilloscope). Time base errors are generally not a problem when measuring short time intervals. For example, consider a typical counter with 1-ns resolution and a time base stability of 1×10^{-8}. When a 1-ms interval is measured, the time base uncertainty is $10^{-3}\,\text{s}/10^{8} = 10^{-11}\,\text{s}$, or 10 ps. This is 100 times smaller than the 1-ns uncertainty contributed by the ± 1 count ambiguity. Even so, use the most stable oscillator available as an external time base, because time base errors are significant when measuring long time intervals.

Application notes are available for more detail, Agilent Technologies (2003a, b).

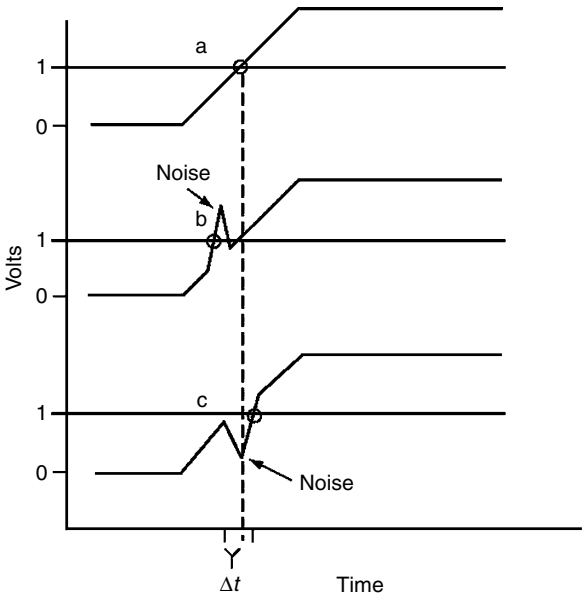

Figure 4. Potential effects of trigger errors on time interval measurements.

3 CALIBRATION OF MEDIUM AND LONG TIME INTERVAL SENSORS

A TIC is probably the best device for medium and long time interval measurements if it has the necessary range. For example, a TIC that counts 100 ns periods with a 32-bit counter will overflow after $2^{32} \times 100$ ns, or about 429 s. However, many TICs keep track of counter overflows, and some have the ability to measure intervals of about 1 day in time interval mode. If the TIC range is insufficient, most universal counters have a totalize mode that simply counts cycles from an external frequency source. Some commercial counters can count up to 10^{15} cycles. The period of the external gate frequency determines the resolution of this type of measurement. For example, if 1-μs resolution is desired, use a 1-MHz gate frequency. In this case, the time interval range would be $10^{15}/10^{6} = 10^{9}$ s, or nearly 32 years! In either time interval or totalize mode, a properly calibrated and triggered counter will probably exceed any measurement uncertainty requirements.

Low cost, simple timers are commonly used for coarse measurements of time intervals ranging from several seconds to many hours. These timers are typically found in manufacturing, industrial, medical, or laboratory facilities; or are sometimes used in commercial applications where consumers pay for services such as a ride in a taxicab or the use of a parking space. These timers are usually calibrated outside the laboratory, with field standard stopwatches. The stopwatches themselves require calibration, and this is often done by manually triggering the stopwatch while listening to an audio time signal. The legally required uncertainty for stopwatch calibrations is often 1 or 2 parts in 10^{4}, a large uncertainty limited mostly by human reaction time.

Stopwatch calibration methods exist that reduce or eliminate the problem of human reaction time. One method is to use a universal counter in totalize mode. Gate the counter with a signal from a calibrated signal generator. The gate frequency should have a period at least one order of magnitude smaller than the resolution of the stopwatch. For example, if the stopwatch has 0.01-s resolution (10 ms), use a 1-kHz frequency (1-ms period). This provides the counter with one more digit of resolution than that of the stopwatch. Start and stop the totalize counter by rapidly pressing the start–stop button of the stopwatch against the start–stop button on the counter. Then, compare the two readings and use the equation $\Delta t/T$ to get the results, where Δt is the difference between the counter and stopwatch displays and T is the length of the measurement run. For example, if $\Delta t = 100$ ms and $T = 1$ h, the time uncertainty is roughly 2.8×10^{-5}.

Table 1. Coordinated universal time (UTC) broadcast signals.

Station name or signal source	Nation responsible for signal	Coverage	Carrier frequency
JJY	Japan	Asian Pacific Rim	40 kHz 60 kHz
WWVB	United States	North America	60 kHz
MSF	United Kingdom	Europe	60 kHz
BPC	China	China	68.5 kHz
HBG	Switzerland	Europe	75 kHz
DCF77	Germany	Europe	77.5 kHz
WWV	United States	Worldwide[a]	2.5, 5, 10, 15, 20 MHz
WWVH	United States	Worldwide[a]	2.5, 5, 10, 15 MHz
CHU	Canada	Worldwide[a]	3.33, 7.335, 14.670 MHz
Indian National Satellite System (INSAT)	India	Indian subcontinent	2599.675 MHz
Global Navigation Satellite System (GLONASS)	Russia	Worldwide	1602.5625–1615 MHz (L1), 1240–1260 MHz (L2)
Global Positioning System (GPS)	United States	Worldwide	1575.41 MHz (L1) 1227.42 MHz (L2)

[a]Under optimal conditions.

A second method involves measuring the frequency offset of the stopwatch time base, and then converting the frequency offset to a time offset. Commercially available systems perform this measurement for both mechanical and electronic stopwatches (with 32.768 kHz or 4.19 MHz time bases). If an appropriate sensor is available (for example, an ultrasonic acoustic sensor for 32.768-kHz devices), this measurement can also be performed with a frequency counter. For example, if a 32.768-kHz time base has a 0.1-Hz frequency offset, the relative frequency offset ($0.1/32768 = 3 \times 10^{-5}$) translates to a time offset of about 108 ms in 1 h, or near the value for Δt in the previous example.

4 TIME SYNCHRONIZATION

Using the time interval measurement methods described above, a timing device can be synchronized by comparing it to a UTC reference, and by adjusting the time offset until it is as near zero as possible. Radio-controlled clocks are convenient UTC references. Models exist to receive signals scattered throughout the radio spectrum (Table 1), and they are commonly used for the synchronization of timing pulses and time-of-day clocks. The most common units receive low-frequency radio signals from stations such as WWVB (60 kHz) in the United States, MSF (60 kHz) in the United Kingdom, DCF77 (77.5 kHz) in Germany, or JJY (40 and 60 kHz) in Japan. The power levels from these broadcasts are large enough to cover their respective countries and a few neighboring countries, but no single broadcast is available internationally. The on-time pulse is delayed by the path between the transmitter and receiver, and if uncorrected for path delay, the synchronization uncertainty is often measured in milliseconds.

Better performance and true worldwide coverage can be obtained using a Global Positioning System (GPS) satellite receiver. Most GPS receivers receive the L1 carrier frequency (1575.42 MHz) broadcast by an orbiting constellation of at least 24 satellites. The long-term performance of a GPS receiver often meets or exceeds that of a cesium oscillator (2×10^{-13} uncertainty is typical at 1 day), and the 1-pps timing pulse of a calibrated receiver is usually within 100 ns of UTC. A properly operated GPS timing receiver is an excellent choice as a laboratory standard for time interval and time synchronization measurements.

1 INTRODUCTION

The output signal form to be measured in the majority of sensors will require the measurement of either a voltage (this article), a current (**Article 202, Current Measurement, Volume 3**), or a resistance/impedance (**Article 203, Resistance Measurement, Volume 3**). Thus, their explanation is fundamental to most measurements.

So far as voltage measuring devices are concerned, voltage measurement can be classified as

1. low-voltage measurements, such as those generated by sensors;
2. medium-voltage measurements, such as those that exist in the power mains, laboratories, and industrial operations;
3. high-voltage measurements, such as a rise in power generators, transmission lines, and with plasma effects.

Consequently, there is a wide range of voltage measuring techniques and devices in use. This article concentrates on medium-voltage and high-voltage measurements.

Low-voltage measurements for sensors require sophisticated signal processing schemes – *see* **Article 121, Signals in the Presence of Noise, Volume 2**; **Article 176, Signals and Signal-to-noise Ratio, Volume 3**; **Article 178, Noise Matching and Preamplifier Selection, Volume 3**; **Article 179, Input Connections; Grounding and Shielding, Volume 3**; and **Article 181, Amplitude Modulated Signals: The Lock-in Amplifier, Volume 3**.

Common to all techniques are three major aspects that characterize the measurements:

1. *Amplitude*: If the voltage is smaller than a few millivolts, we may need to use suitable electronic components to amplify the signals. If the voltage is large, in the kilovolts and megavolts region, we may need to attenuate the magnitude in order to bring it to manageable levels.
2. *Frequency*: The frequency of a voltage signal plays an important role in configuring the appropriate components of a voltage measuring device. The frequency of interest can range from DC to a few gigahertz. If digital techniques of measuring are used, sampling of the voltage signals must conform to the Nyquist sampling criteria. The signal frequency waveform also needs careful consideration lest errors be generated.
3. *Duration*: The duration of a signal is significant in determining the appropriate technique to use for the measurement. Duration may vary from continuous signals; as in the case of power supplies, to impulses appearing for a few microseconds; as in the cases of surges, and corona effects in power transmission and distribution.

2 BASIC THEORY

Voltage measurement is essential in electrical engineering as well as in many other disciplines of engineering and science. Voltage measurement involves determination of the electric potential difference between two points. The potential difference is the amount of work needed to move a unit charge located in an electric field from a reference point to another point. Hence, the potential difference is always relative to some reference point such as the Earth.

The potential difference is taken as the work per unit charge and the volt is related to the unit of work (joule – J) and the unit of charge (coulomb – C) by

$$1\text{volt} = \frac{1\,\text{joule}}{\text{coulomb}} \tag{1}$$

Although the concept of electric potential is useful in understanding electrical phenomena, it is worth noting that only the differences in potential energy are measurable. Therefore, it is commonly understood that the term *voltage* refers to potential differences. The measurement unit for the voltage is, in the International System of Units (SI), the volt (symbol: V).

Measurement of voltage is of utmost importance and extensively used in the electrical and electronic engineering, especially in the power industry. Moreover, when electronic devices for signal processing are involved, such as those used in telecommunication systems, control systems, and informatics, the majority of signals are in the voltage and current form. Therefore, voltage measurement constitutes an important area in industrial and scientific measurements, and in a diverse range of sensors of chemical, biological, and physical variables.

3 MEASURING NETWORKS

Since most common signals are in voltage form, there are many different techniques for processing the signals generated by a particular variable. However, some instruments called *voltmeters* are deliberately designed to measure voltages. There are five common types of voltmeters; these are

1. electromechanical instruments,
2. thermal type instruments,
3. electronic instruments,
4. Cathode Ray Oscilloscopes (CRO) or vacuum tube instruments (VTI),
5. virtual instruments.

1. *Electromechanical instruments*: These instruments are based on the mechanical interaction between various currents, between currents and magnetic fields, or between electrified conductors. Such interactions generate mechanical torque proportional to the voltage or to the square of the voltage under investigation. The generated torque is then balanced by a restraining torque, usually obtained by the use of suitably arranged mechanical springs. The balancing action causes the instrument pointer to be displaced by an angle proportional to the driving torque, and hence indicates the voltage to be measured. The value of the input voltage is therefore given by the reading of the pointer displacement on a graduated scale.
2. *Thermal type instruments*: These instruments are based on the thermal effects of a current flowing in a conductor. The reading is proportional to the square of the input voltage. These instruments are not used as widely as the others but are suitable for high frequency voltage measurement.
3. *Electronic instruments*: These instruments are based on purely electronic circuits, and attain the required measurement by processing the input signal by means of electronic semiconductor devices. The method employed to process the input signal can be either analog or digital. In the first case, analog electronic instruments are obtained, while in the second case digital electronic instruments are obtained.
4. *Oscilloscopes or vacuum tube instruments:* These instruments are basically voltmeters, and their main characteristic is to allow a graphic representation, on Cathode Ray Tubes (CRTs), or liquid crystal displays (LCDs). The time and amplitude characteristics of the signal can be determined directly from the displayed signal.
5. *Virtual instruments:* These are computer-based systems that can be programmed to function like voltmeters, ammeters, oscilloscopes, spectrum analyzers, and so on. They are equipped with Analog-Digital-Analog, converters – *see* **Article 139, Analog-to-Digital (A/D) Converters, Volume 3** and **Article 141, Digital-to-Analog (D/A) Converters, Volume 3** and are supported with software programs such as the LabView from National Instruments – *see* **Article 105, Modeling with LabVIEW™, Volume 2** and **Article 106, Virtual Instrumentation in Physics, Volume 2**.

These five basic types of voltmeters can be used for low-voltage, medium-voltage, and high-voltage measurements. In some cases, suitable arrangements such as amplification, attenuation, and conversions may be necessary to prepare the signals for measurement.

In addition, the voltage, current, resistance measurements can be made by a single instrument termed as *multimeters*

or *volt-ohm-multimeters*(VOMs). The VOM is a combination of the necessary circuits of a DC ammeter, DC voltmeter, AC ammeter, AC voltmeter, and a multirange ohmmeter. The typical DC voltage range of a common VOM is 0 to 1000 V, although with external resistor networks and voltage transformers, the range can be increased further, to say 5000 V. The DC current range is usually 10 A but with the use of external resistive shunt networks, or current transformers the range can be extended to much higher levels.

Particularly in power generation and transmission networks, precise, and adequate system measurements at the control centers are critical for high quality of operational decision making. The measurements taking place in remote locations are made available to the controllers by networks such as the Real Time Supervisory Control and Data Acquisition systems SCADA. The digital devices that collect the voltage measurements from the substation instruments and transducers are called *remote terminal units* (RTUs). The RTUs communicate with the SCADA over dedicated telephone lines, sometimes the transmission line itself and/or microwave channels.

The collection of analog measurements and the status of the circuit breakers from remotely monitored and controlled substations are telemetered by means of the cyclic scans of SCADA system. Typically, each scan lasts from 1 s to 10 s. This information has to be sufficient in number and evenly distributed across the network so that the observability of the system can be ensured.

4 VOLTAGE TRANSFORMERS

Transformers are extensively used in high-voltage measurements primarily to step the voltage down to a lower level that can be less expensively measured.

Transformers are devices that change the voltage level in the process of energy transfer from one AC system to another. The transformer has two coils, primary and secondary, both of which are wound on an iron core as shown in Figure 1.

The magnetic flux generated by the primary current links the secondary windings to generate a secondary voltage. Assuming 100% magnetic coupling, the ratio of the primary voltage (V_1) and secondary voltage (V_2) can be expressed by the turns ratio N_1 and N_2 as

$$\frac{V_1}{V_2} = \frac{N_1}{N_2} \tag{2}$$

This means the secondary voltage can be stepped up or down depending on the turns ratio. For example, if N_1 is 10 times greater than N_2, the secondary voltage is 10 times smaller than primary voltage.

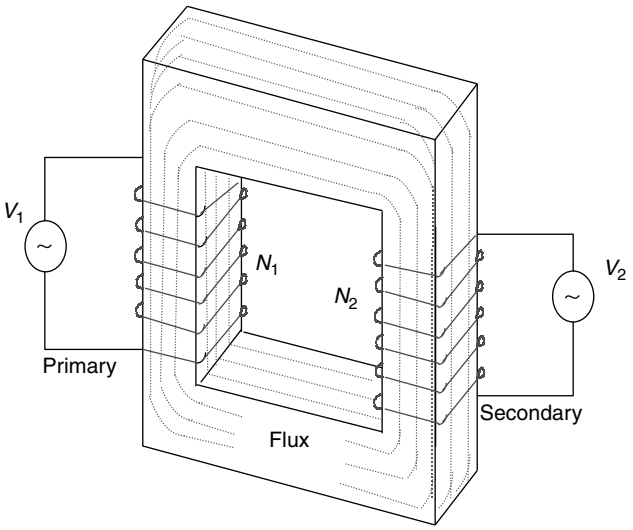

Figure 1. Transformer construction.

Voltage measurement instruments are used throughout the electric power system for monitoring and control purposes. Instrumentation components required to accomplish the measurements are the transducers, signal conditioners, and the analysis and monitoring equipment. Voltage transducers convert the system voltage to an acceptable level needed as the input to the signal conditioning equipment. The transducers are required to produce a scaled down replica of the input voltage to the accuracy expected for a particular measurement. Commonly used transducers are electromagnetic voltage transformer (VT), capacitive voltage transformer (CVT), and the cascade voltage transformer.

Voltage measurement transformers need to be specially designed to ensure the ratio is constant. Voltage transformers are much like small power transformers but they need to operate with secondary winding operating close to open circuit. The winding voltage drops are made small, and the rated flux density in the core is designed to be well below saturation density. These conditions maintain the calibrated voltage ratio.

Measuring very high frequency components in the voltage requires either a capacitive divider, or pure resistive divider. Special-purpose capacitor dividers can be obtained for accurate characterization of transients and harmonics up to at least 1 MHz. A disadvantage of such dividers is that they do not provide electrical isolation between the high voltage and the measuring systems and so impose special conditions for their use.

The cost of the electromagnetic VT tends to increase at an exponential rate with the rated voltage increase. An

alternative, more economic solution has been found in the CVT. This combines a capacitive potential divider with an auxiliary electromagnetic voltage transformer. This combination enables the insulation requirements of the electromagnetic unit to be reduced with associated savings in cost.

The CVT was developed to reduce the high cost of conventional VT by compromising on the frequency and transient response. Another possible solution to the problem is to use the cascade VT that is formed by connecting two or more electromagnetic transformer units in cascade. The primary windings of these transformers are connected in series and in this way the primary voltage is broken down in several distinct and separate stages. This solves the insulation problem and reduces costs. The secondary winding consists of a single winding on the last stage only.

Optical voltage sensors are also under development as replacements for VTs. They lower the costs compared to conventional CTs and VTs when mass produced. However, questions remain about their stability, sensitivity, and linearity. The sensitivity of the optical sensors to vibration and temperature changes must be minimized by either design or signal processing. The long-term stability of these sensors is under study in field trials, but techniques for calibrating them in the field and in the test laboratory have yet to be developed.

An important branch of voltage measurement is the determination of harmonics of such parameters as the fundamental power-frequency voltage, voltage dips, spikes, surges and sags, and other transient behaviors.

Specific reasons for taking harmonic measurements include confirming the presence of harmonics, evaluating the severity of the problem relative to acceptable limits, establishing compliance with standards and guidelines, harmonic filter design, providing input data for harmonic software analysis program, and designing an analytical model of the problem.

Instruments and systems for power quality measurements can help identify the sources of power quality degradation and protect customer equipment. Many power quality monitoring instruments are designed for input voltages up to 600 V rms and current inputs up to 5 A rms. In measurements, appropriate voltage transducers must be selected to provide these signal levels.

5 POTENTIOMETERS

There are many applications in which voltage measurements must be performed without drawing any current from the circuit to which the measurement device is connected. A typical case is the measurement of the electromotive force (emf), or no-load voltage, of a source with high internal resistance.

An important device that is capable of measuring voltages without drawing currents is the potentiometer. This device is not actually an instrument, but a set of electrical networks that are suitably arranged for the purpose. This arrangement also includes a galvanometer or indicator. The main purpose of the potentiometer is to perform an accurate comparison of an unknown emf against a standard one. There are many different types of potentiometers that can suit the requirements of a particular measurement, such as the slide-wire DC, slide-wire AC, Gall–Tinsley AC, and Drysdale–Tinsley AC Potentiometers. Owing to limited space, as an example, only the slide-wire DC potentiometer will be explained here.

1. *The slide-wire DC potentiometer*: The principle of operation of a slide-wire potentiometer can best be described by the slide-wire variety illustrated in Figure 2. The description of the various terms employed in this figure is as follows: E is the supply battery emf; R is the regulating resistance; i is the slide-wire current at balance conditions; r is the resistance per unit length of slide-wire; E_1 is the battery emf to be measured; E_2 is the emf of standard battery; l_1 is the length of slide-wire at balance conditions with emf E_1; l_2 is the length of slide-wire at balance conditions with standard emf E_2.

A battery of unknown emf E_1 is inserted in the circuit at a point shown in Figure 2. The galvanometer switch S is closed and the contact B moved along the slide-wire until the balance condition (zero reading on the galvanometer) is achieved. In this condition, no current flows through the galvanometer circuit. The current i supplied by battery E flows through the slide-wire. By Ohm's Law:

$$E_1 = irl_1 \tag{3}$$

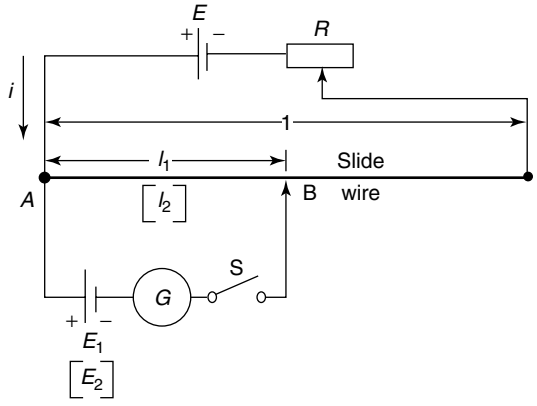

Figure 2. Slide-wire potentiometer.

Battery E_1 is replaced by a standard battery of known emf E_2. At the new balance condition, the following relationship can be written:

$$E_2 = irl_2 \tag{4}$$

From (3 and 4), the unknown emf can be obtained as

$$E_1 = \frac{l_1}{l_2} E_2 \tag{5}$$

A variable resistance is usually connected in series with the galvanometer to protect it against high currents during initial adjustments. This resistance is reduced to zero as balance is reached.

The simplest form of potentiometer consists of a supply battery E, a regulating resistor R and a slide-wire of uniform cross-section made of manganin, an alloy with a negligible temperature coefficient of resistance. The supply battery, usually of large capacity, provides the current in the slide-wire. The regulating resistance limits the value of this current to a reasonable quantity.

The many other forms of potentiometers are based on this simple form. The theory involved is akin to that of electrical Wheatstone bridges – *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**; and **Article 127, Unbalanced DC Bridges, Volume 2**.

6 CONVERTERS

In many applications, conversion of voltage to another electrical parameter is essential in order to process the signals. In some, the voltages are already converted to meet the process needs, and the measurement of voltages is necessary to assure sound operation. Voltage conversion can be divided into groups:

1. *Voltage-to-voltage conversion of signals*: These may be amplifiers, attenuators, analog-to-digital converters, digital-to-analog converters, and so on. Voltage-to-voltage conversion of signals can be achieved by passive resistor networks, transistor circuits, operational amplifiers, and dedicated integrated circuits (ICs).
2. *Voltage-to-frequency conversion of signals*: These are special electronic devices that convert voltages into frequencies for the convenience of processing.
3. *Voltage-to-voltage conversion by power circuits*: These converters are essential in many domestic, laboratory, and industrial applications, for example, the electrical power drive. Conversion can be achieved by using power electronic components such as Darlington Transistors, power field-effect-transistors (FETs), silicon-control-rectifiers (SCRs), thyristor, triacs, and so on.

Voltage converters are the major subject of many books (see Further Reading section provided). Voltage-to-voltage conversion by power circuits are given here as examples.

AC-to-AC converters are used in many power-engineering applications. The conversion can be realized by a diverse range of equipment based on different operational methods. Some of these methods are

- phase controlled AC voltage controllers,
- pulse width modulation (PWM) AC voltage controllers (AC choppers),
- cycloconverters,
- matrix converters, and so on.

Basically, AC voltage controllers allow adjustment of the rms value of the output voltage. They are based on antiparallel connected power switches such as thyristors, triacs, diodes, and so on. There are two basic types:

1. Single-phase devices generally used in domestic and light load industrial applications.
2. Polyphase devices that are used in motor control, heating, and other applications.

Figure 3 illustrates a single-phase thyristor-based AC voltage controller. In this arrangement, one SCR conducts at a time, therefore, input and output currents are equal. S_1 is fired at an angle α and S_2 is fired at $(\pi - \alpha)$. The minimum firing angle must be equal to or greater than the load angle. If α_e is the extinction angle, using half symmetry, the rms value of output voltage for a sinusoidal input can be shown to be

$$V_{O_{rms}} = \sqrt{\frac{1}{\pi} \int_{\alpha}^{\alpha_e} [V_m \sin(\omega t)]^2 \, d\omega t} \tag{6}$$

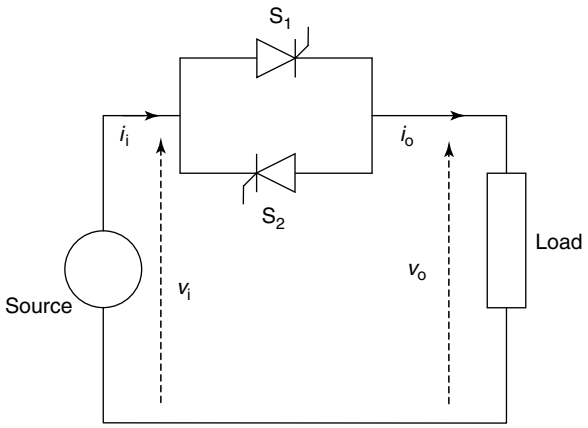

Figure 3. Single-phase voltage controller.

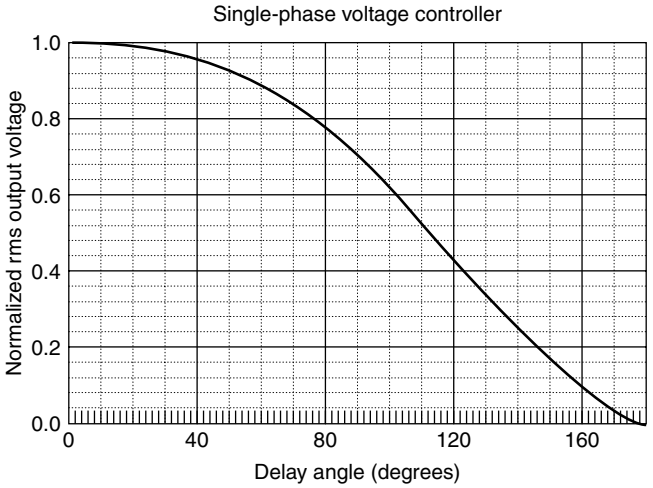

Figure 4. Normalized voltage versus delay (firing) angle.

With purely resistive load, from (6), the rms value output voltage can be determined to be

$$V_{o_{rms}} = V_m \sqrt{\frac{1}{2} - \frac{\alpha}{2\pi} + \frac{\sin 2\alpha}{4\pi}} \tag{7}$$

Equation (7) indicates that the output voltage is a function of the firing angle of the thyristors. The normalized rms load voltage versus firing angle for a single-phase controller is illustrated in Figure 4.

7 RECTIFIERS

For AC measurements, most instruments contain AC-to-DC conversion (or rectification), which are made from germanium or silicon diodes so that the voltages can be expressed in rms values. Depending on the signals, the rectification can be performed by transistor or operational amplifier circuits or by the SCRs.

AC/DC converters (rectifiers) operate on similar principles as the voltage controllers. These rectifiers can be configured in uncontrolled, semicontrolled, or fully controlled forms. Some of the configurations are

- single-phase half-wave rectifiers,
- single-phase full-wave rectifiers,
- polyphase half-wave rectifiers,
- polyphase full-wave rectifiers.

Rectifiers can be configured by using center-tapped transformer arrangements or by bridge forms. Since there are a variety of techniques available, here, as an example, we will give a single-phase rectifier using thyristors, as illustrated in Figure 5.

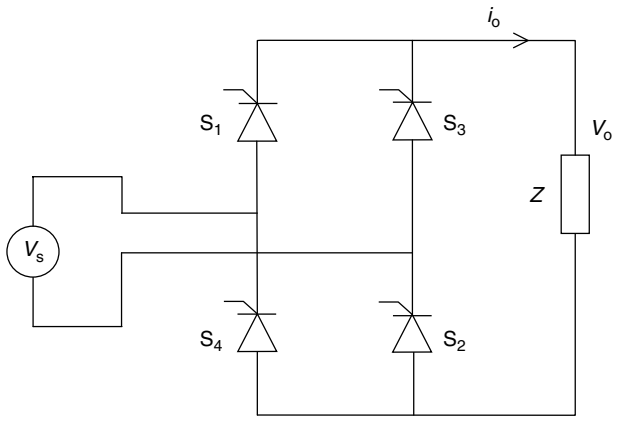

Figure 5. Single-phase fully controlled bridge rectifier.

The current flowing in the load impedance Z can be continuous or discontinuous. In the case of continuous currents, the mathematical analysis for currents and voltages uses Fourier series to show

$$V_o(\omega t) = V_o + \sum_{n=1}^{\infty} V_n \cos(n\omega t + \theta_n) \tag{8}$$

The DC average value is then

$$V_o = \frac{1}{\pi} \int_{\alpha}^{\alpha+\pi} V_m \sin(\omega t)\, \mathrm{d}(\omega t) = \frac{2V_m}{\pi} \cos\alpha \tag{9}$$

The amplitude of the AC terms can be calculated from

$$V_n = \sqrt{a_n^2 + b_n^2} \tag{10}$$

where

$$a_n = \frac{2V_m}{\pi}\left[\frac{\cos(n+1)\alpha}{n+1} - \frac{\cos(n-1)\alpha}{n-1}\right]$$

$$b_n = \frac{2V_m}{\pi}\left[\frac{\sin(n+1)\alpha}{n+1} - \frac{\sin(n-1)\alpha}{n-1}\right] \text{ for } n = 2, 4, 6\ldots$$

The Fourier series for the current is determined by superposition

$$I_{\text{rms}} = \sqrt{i_o^2 + \sum_{n=2,4,6\ldots}^{\infty} \left(\frac{I_n}{\sqrt{2}}\right)^2} \tag{11}$$

where

$$I_o = \frac{V_o}{R} \text{ and } I_n = \frac{V_n}{Z_n} = \frac{V_n}{|R + \mathrm{j}n\omega_0 L|}$$

The outputs of the controlled rectifiers can be improved by suitable arrangements of capacitive–inductive (L-C) filters.

8 INDICATORS

Indicators are electromechanical voltmeters that are based on the mechanical interaction between currents and magnetic fields, or between electrified conductors. Electromechanical instruments provide readings in analog form, by moving a pointer that indicates the measured value on a scale. The pointer can be real or virtual, usually a light beam reflected on a graduated ruler by a moving mirror. The scale is a linear scale if the pointer displacement is proportional to the measured quantity or a square-law scale if the pointer displacement is proportional to the square of the measured quantity. These instruments are classified according to their deflecting movements as

1. the moving-coil electromagnetic voltmeters (D'Arsonval Galvanometer);
2. the moving-iron electromagnetic voltmeters;
3. the electrodynamic voltmeters;
4. the electrostatic voltmeters;
5. electromechanical multimeters or VOMs.

Electromechanical instruments involve electromechanical forces. The controlling forces are either from the spring or from the force of gravity. They are aimed at balancing the deflecting forces so that the final pointer displacement is proportional to the measured quantity, or its squared value.

The spring control is achieved by the use of a spring arrangement, which is usually made from a phosphor–bronze spiral spring. The spring is attached to the moving system to provide a controlling torque that counterbalances the deflecting torque. It also provides the reading on the scale. An explanatory drawing is shown in Figure 6.

The spring has a large number of turns greatly reducing the deformation per unit length and giving an angle of deflection (θ) directly proportional to the deflecting torque. Occasionally, a long helical spring replaces the spiral spring. In some instruments, a single strip of phosphor–bronze provides the necessary spring control. Often two springs, wound in opposite directions are employed. This method is employed in order to reduce the reading errors.

Although the electromechanical instruments represent older technology in comparison to the electronic techniques, and the digital ones, in particular, they are still extensively used in many areas such as panel displays in industry, dashboard displays in motor vehicles, general-purpose low cost measurements and laboratories.

9 DIGITAL VOLTMETERS

The basic structure of a digital voltmeter (DVM) consists of the following three main stages:

1. analog signal processing,
2. analog-to-digital (A/D) converter,
3. digital signal processor (DSP).

The first stage of the device conditions the input signal, adapting it to the dynamics of the A/D. The A/D converter is responsible for sampling of the input signal and converting each sampled value into a digital form. The sequence of digital values obtained after the sampling and conversion operations is stored into the memory of the DSP and processed in order to attain the desired measured values. The detailed structure of a digital multimeter is given in Figure 7.

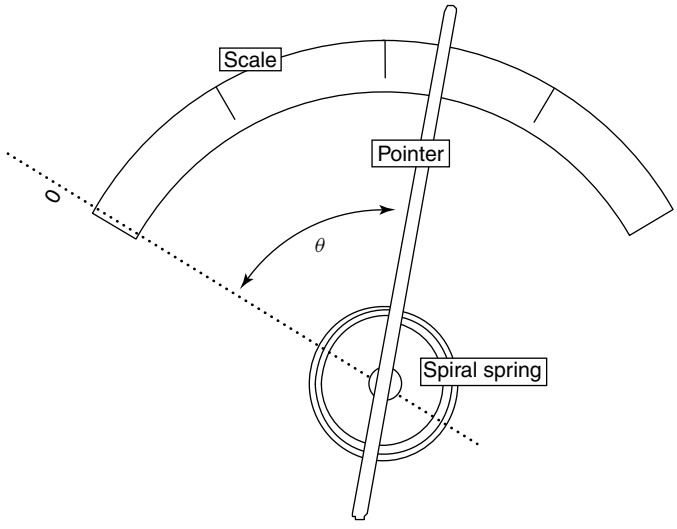

Figure 6. Schematic of a spring controlled voltage indicator.

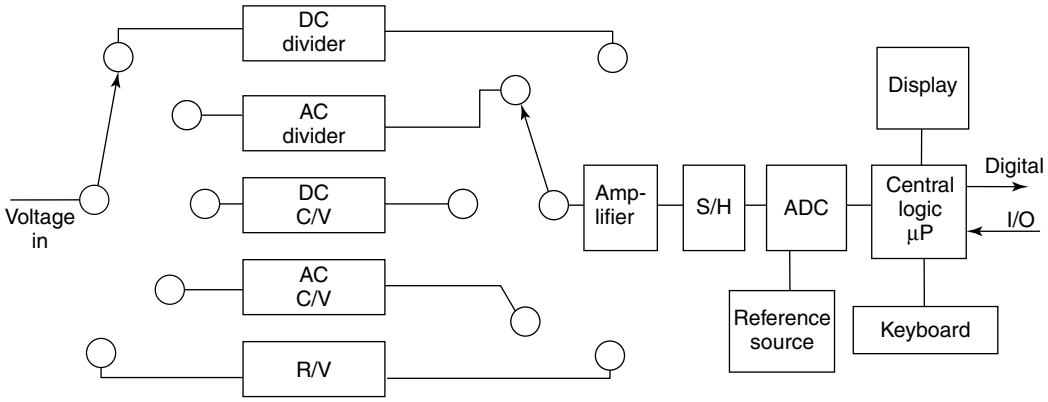

Figure 7. Block diagram of a typical digital multimeter.

DVMs may differ from each other in the following ways:

- number of measurement ranges,
- number of digits,
- accuracy,
- speed of readings,
- operating principles.

In a modern DVM, the basic measurement ranges to obtain full-scale values are as low as 0.1 μV. If an appropriate voltage divider is used, it is also possible to obtain full-scale values as high as 1000 V. The DVM, with a suitable input stage, can be used as an ammeter having very broad measurement ranges from 1 nA to 10 A.

When the measurement result is displayed on the instrument front panel, it is usually presented in decimal numbers, with a number of digits that typically range from 3 to 6. When the measurement result is sent to a DSP system, its representation takes the form of a binary-coded output signal. The number of bits of this representation typically ranges from 8 to 16, though 18-bit and 24-bit A/D converters are available.

The accuracy of a DVM is usually correlated to its resolution. This is quite obvious, since assigning an uncertainty lower than 0.1% of the range to a three-digit DVM makes no sense, since this is the displayed resolution of the instrument. Similarly, a poorer accuracy makes the three-digit resolution quite useless. Presently, a six-digit DVM can feature an uncertainty, for short periods of time in controlled environment, as low as the 0.0015% of reading or 0.0002% of the full range.

The speed of reading of a DVM can be as high as 1000 readings per second. When the A/D conversion is considered, the conversion rate is taken into account instead of the speed of reading. Presently, the conversion rate for 12-bit, successive approximation A/D can be as high as nominally 10 MHz. The conversion rate can be on the order of 1 GHz for lower resolutions when flash A/D converters are used – *see* **Article 139, Analog-to-Digital (A/D) Converters, Volume 3**.

10 VOLTAGE AND VOLTAGE MEASUREMENT STANDARDS

Voltage is an important property in electrical engineering and measurement technology. Hence, strict standards are developed in two major areas:

1. Voltage itself is governed by its own standards such as the Josephson junction standard – *see* **Article 43, Units, Volume 1**.
2. Voltage determination techniques are standardized to suit specific areas of application, such as the IEEE Std 1122 for digital recorders, IEC 60060 for high-voltage impulse calibrations.

The primary voltage standard is, today, the Josephson junction standard. Other voltage standards are nevertheless employed in the metrological laboratories as they are more convenient and, for example, are the time honored standard cells, although their accuracy is lower than that of the Josephson junction.

The Josephson junction standard describes the quantum standard of voltage. A Josephson junction consists of two super conductors separated by a thin insulation barrier. The junction is supercooled in helium cryostat and when it is irradiated by microwave energy (in the frequency range 10–100 GHz), the voltage–current characteristics get broken to the stepped form. The height of each voltage step can be found from

$$V = \frac{hf}{2e} \tag{12}$$

where h is the Plank constant, f is the frequency at which the junction is irradiated, and e is the electron charge.

Because only the irradiation frequency is a variable in the equation, the standard volt is related to the standard of time/frequency. The step voltages can be detected by the use of null detectors or resistors. The accuracy of this method is better than 1 part in 10^8. The uncertainty in the measurements is less than 1 part in 10^7.

The *standard cells* are made from saturated electrochemical Weston cells, which consist of electrodes of mercury (positive) and mercury cadmium amalgam (negative) placed in an electrolyte of saturated cadmium sulfate solution contained in an H-shaped glass container. There are two types of Weston cells – the saturated cell and the unsaturated cell.

The saturated cell has a voltage variation of approximately $-40\,\mu V$ per 1 K, whereas the unsaturated cell has a negligible temperature coefficient at normal room temperatures.

By using precision potentiometers, the standard-cell voltage can be compared with better than 1 part in 10^7 accuracy. However, the saturated cells are very sensitive to environmental conditions and the current they supply introduces further uncertainty in calibrations.

The various national standard laboratories refer to the Josephson junction standard as their primary standard for voltage. However, since the standard cells are much easier to employ, they also maintain a number of saturated cells, referred to by the Josephson junction standard, as the primary standards for voltage. Cells are kept in an oil bath to control their temperature within ± 0.01 K. The voltage of the Weston saturated cell at 293.5 K is 1.01858 V. They remain satisfactory as voltage standards for a period of 15 to 20 years with a drift voltage of about $1\,\mu V$ per year.

Electronic voltage standards, also known as the *transfer standards*, are based on electronic components such as diodes. When the voltage across a diode rises above a certain level, a current starts flowing (e.g. Zener breakdown) through it and the diode acts as a constant voltage device. When these diodes are fed by well-stabilized sources, they can provide a reference voltage that is stable by 1 part in 10^6. Often, they are used together with other electronic components such as transistors, operational amplifiers, and integrated circuits for stability and compensation of the environmental factors like temperature. They are widely used since they are not affected by environmental conditions, as is the case with standard cells.

Numerous standards define the procedures and methods for voltage determinations, particularly in power circuits. Some of these standards are

- IEC Std 60060-2 standard for high-voltage impulse calibrations;
- IEEE Std 519-1992 standard for harmonic control in electrical power systems;
- IEEE Std 4-1995 standard for high-voltage testing;
- IEEE Std 181-2003 standard for transition, pulses, and related waveforms;
- IEEE Std 1122 standard for digital recorders used with measurements in high-voltage impulse tests;
- IEEE Std 1451-1999 standard for smart sensors;
- IEEE Std 1459-2000 standard for the Measurement of Electric Power Quantities Under Sinusoidal, Nonsinusoidal, Balanced, or Unbalanced Conditions.

1 INTRODUCTION

Knowledge of the voltage located at the terminal of each circuit element as well as the current flowing in each element gives full knowledge of the circuit behavior. Moreover, when electronic devices for signal processing are involved, such as those used in measuring systems, telecommunication systems, control systems, and informatics, the majority of involved signals are in the voltage and current forms. Therefore, the voltage and current measurements constitute an important area in industrial and laboratory measurements, sensors, and systems.

Electrical currents can be measured in many different ways. Once the current is converted to voltage form, the oscilloscope (strictly a voltage measuring device) is a typical device that can be used to measure currents. There are many analog and digital ammeters and multimeters that are offered by many vendors. In some applications, special current measurement techniques may have to be designed by using carefully selected transducers to meet the particular characteristics and specifications of the process. In this article, the operation of ammeters and multimeters is explained, current transducers are discussed, and examples are given.

2 BASIC THEORY

A charged body in an electric field is subject to a force. If the body is not restrained, it will start moving in the electric field. The result of the movement of charged bodies from one point to another point in the space is the electric current. In the metallic conductors used in the electric circuits, the charged bodies that can flow through the conductors are the electrons. A basic property of an electron is its charge (1.603×10^{-19} C).

Electric current is the rate of charge flowing in a cross-section of the conducting element in a second and its measurement unit is, in the SI, the ampere (symbol: A).

Since the current is taken as the charge flow per unit time, its measurement unit is related to the unit of charge and the unit of time (second s) by

$$1 \text{ ampere} = 1 \text{ coulomb/second} \tag{1}$$

A current will flow in any medium in which there are free charges to move. These conduction charges may be electrons, positively charged 'holes', or positive or negative ions, depending on the material. They are in continuous random motion and collide with each other and with the atomic structure of the material. When a conducting material is placed in an electric field, the conducting charges are accelerated in the direction of the field. The velocity acquired is small compared with the average value of the random velocity (typically in the order of 10^6 m s^{-1}).

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

The current flowing through a circuit element is related to the properties of the circuit element and to the voltage across its terminals by the well-known Ohm's law:

$$V = R\,I \tag{2}$$

where R is a quantity representing the electric behavior of the circuit element. Under DC conditions this quantity is called resistance and its measurement unit is, in the SI, the ohm (Ω).

In most of the usually met applications of electrical and electronic engineering, voltages and currents exist in continuous forms. This means that a generic voltage v and a generic current i can be represented as functions of time t:

$$v = v(t) \quad \text{and} \quad i = i(t) \tag{3}$$

In the DC systems, voltages and currents are constant, that is

$$v = v(t) = V_{\mathrm{DC}},\ \text{const.} \quad \text{and} \quad i = i(t) = I_{\mathrm{DC}},\ \text{const.} \tag{4}$$

The voltmeters and ammeters for DC systems are realized in order to measure V_{DC} and I_{DC} respectively.

In AC systems, the voltage and current are defined with respect to time as

$$v(t) = V_{\max} \sin(\omega t + \alpha) \tag{5}$$

where $V_{\max}$ is the maximal value of the sinusoidal voltage and α is the phase angle of the voltage:

$$i(t) = I_{\max} \sin(\omega t + \beta) \tag{6}$$

where $I_{\max}$ is the maximal value of the sinusoidal current and β is the phase angle of the current. ω represents angular frequency and t is time in (5) and (6). Quantities that are used to characterize sinusoidal voltage and current are

- maximal value
- average value
- root mean square value (rms).

The average and rms values are defined as follows:

$$\begin{aligned} V_{\mathrm{av}} &= \frac{1}{T}\int_0^T v(t)\,\mathrm{d}t = \frac{2}{\pi}V_{\max}, \\ I_{\mathrm{av}} &= \frac{1}{T}\int_0^T i(t)\,\mathrm{d}t = \frac{2}{\pi}I_{\max} \\ V &= \sqrt{\frac{1}{T}\int_0^T v(t)^2\,\mathrm{d}t} = \frac{1}{\sqrt{2}}V_{\max}, \end{aligned} \tag{7}$$

$$I = \sqrt{\frac{1}{T}\int_0^T i(t)^2\,\mathrm{d}t} = \frac{1}{\sqrt{2}}I_{\max} \tag{8}$$

where T is the period.

In the case of a circuit containing only a resistive load, the single frequency current wave is entirely symmetrical with the voltage wave. The current wave lags behind the voltage wave in the case of inductive loads. In a purely capacitive load, the current wave leads the voltage wave. In general, circuits contain elements of resistance, inductance, and capacitance in varying amounts and they must, therefore, assume some intermediate condition of phase angle between voltage and current.

Ammeters for AC systems are realized primarily by using AC-to-DC conversion techniques or by using suitable transducers, both of which will be explained in the following sections.

Different kinds of signals, such as pulse, random, and discrete signals can also be found in nature, especially at the atomic scale. Such signals, however, require measurement with different kinds of instruments, which are not covered here.

3 MEASURING NETWORKS

There exists a diverse range of methods and instruments available for current measurements, and some of these are

- electromechanical ammeters
- thermal type ammeters
- multimeters
- oscilloscopes
- virtual instruments.

Electromechanical ammeters provide readings in analog form by moving a pointer that indicates the measured value on a scale. The scale is a linear scale if the pointer displacement is proportional to the measured quantity. The energy required to displace the pointer is taken directly from the circuit to which the instrument is connected. This energy is the so-called instrument self-consumption and, in electromechanical instruments, can be nonnegligible. Electromechanical ammeters can be classified according to their deflecting movements as

1. moving-iron electromagnetic ammeters,
2. electrodynamic ammeters,
3. moving-coil electromagnetic ammeters (D'Arsonval galvanometers),
4. electromechanical multimeters or VOM.

Although electromechanical ammeters still find extensive applications, they are not used as much as their electronic counterparts, so they will not be explained further. However, because of its special features, the D'Arsonval galvanometers will be visited in Section 8 of this article.

Thermal type ammeters are based on the thermal effect produced by a current flowing in a conductor. These ammeters are also known as the *thermo-instruments* or *true rms devices*. Irrespective of the shape of the input signal waveform, the active power dissipated in the heated conductor is equal to the heat generated and is proportional to the true rms value of the input current.

A simplified construction of this kind of ammeters, also called the '*hot-wire instrument*' is shown in Figure 1. The heated element has a negligible temperature coefficient of resistance (that is, its resistance will remain essentially constant over its operating range) and a constant temperature coefficient of expansion. Since the heating effect is proportional to the square of the current, accurate effective (rms) values of AC currents are measurable irrespective of frequency and waveform. Also, since no magnetism is involved in providing scale deflection, stray magnetic fields have no effect on the operation.

The hot-wire element is made of platinum-iridium, which has a constant resistance and temperature coefficient of expansion over its operating range. The element is about 0.1 mm in diameter. Platinum-iridium has the added benefit of being able to withstand high temperatures without oxidation. Attached to the hot wire is a phosphor-bronze 'magnifying' wire. A silk thread, connected to the magnifying wire, passes around a pulley before being fixed to a spring, which keeps the system under tension. When the hot-wire element expands, its slack and that in the magnifying wire is taken up by the tension in the spring and the silk thread causing the pulley to rotate and the pointer to deflect on the scale.

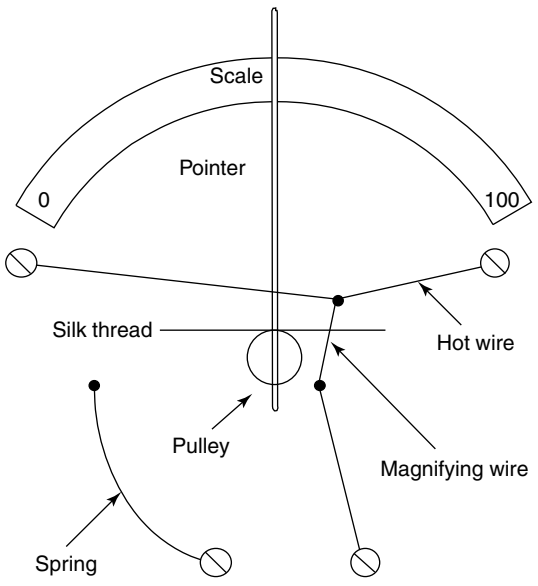

Figure 1. A hot-wire voltmeter.

Multimeters are instruments that can measure voltages, currents, and resistances. These instruments are also known as *volt-ohm-multimeters* (VOMs). The VOM is a combination of a DC ammeter, a DC voltmeter, an AC ammeter, an AC voltmeter, and a multirange ohmmeter with a switch to select the one to use. The DC voltage range of a common VOM is 0 to 1000 V, although with an external resistor the range can be increased to 5000 V. The DC current range is usually up to 10 A, although with an external shunt it can be extended to 20 A or more.

For AC measurements, the instrument contains a rectifying circuit made from germanium or silicon diodes. Because of the inertia of the moving coil, the meter indicates a steady deflection proportional to the average value of the current. Since AC currents and voltages are expressed in rms values, the meter is scaled to read the rms values of sinusoidal voltages through the form factor $\pi/2\sqrt{2}$. The indicated reading of a nonsinusoidal voltage may be erroneous, since its average value may differ considerably from the average value of a pure sinusoidal voltage.

Owing to the fact that the internal structure of the VOM cannot be optimized for a single measurement, the temperature and frequency ranges can be limiting factors. For example, a deterioration of 0.5% in the readings may be expected for every 1-kHz rise in frequency.

Further information on multimeters is provided in Section 8.

Oscilloscopes are probably the most versatile instruments for all forms of physical investigation, since almost any physical phenomenon can be converted into a corresponding electric voltage and the oscilloscope makes the waveform versus time visible for human observation. Measurements are performed on the horizontal axis and vertical axis since the screen features a graduated grid. Nowadays, digital storage oscilloscopes DSO are commonly used in voltage and current measurements. They sample the input signal and convert it into a sequence of data, which are stored in the DSO memory and displayed on cathode-ray tubes CRT or liquid-crystal displays (LCD). A typical structure of a digital oscilloscope is shown in Figure 2.

Virtual instruments use computers, interface electronics, and software to emulate the operational features of most traditional instruments. In this technology, plug-in data acquisition (DAQ) boards, PCMIA cards, and parallel port I/O devices are used to interface sensors and transducers of the system under investigation with computers. Once the signal is interfaced, the computer can be programmed to act just like a stand-alone instrument; but it can also

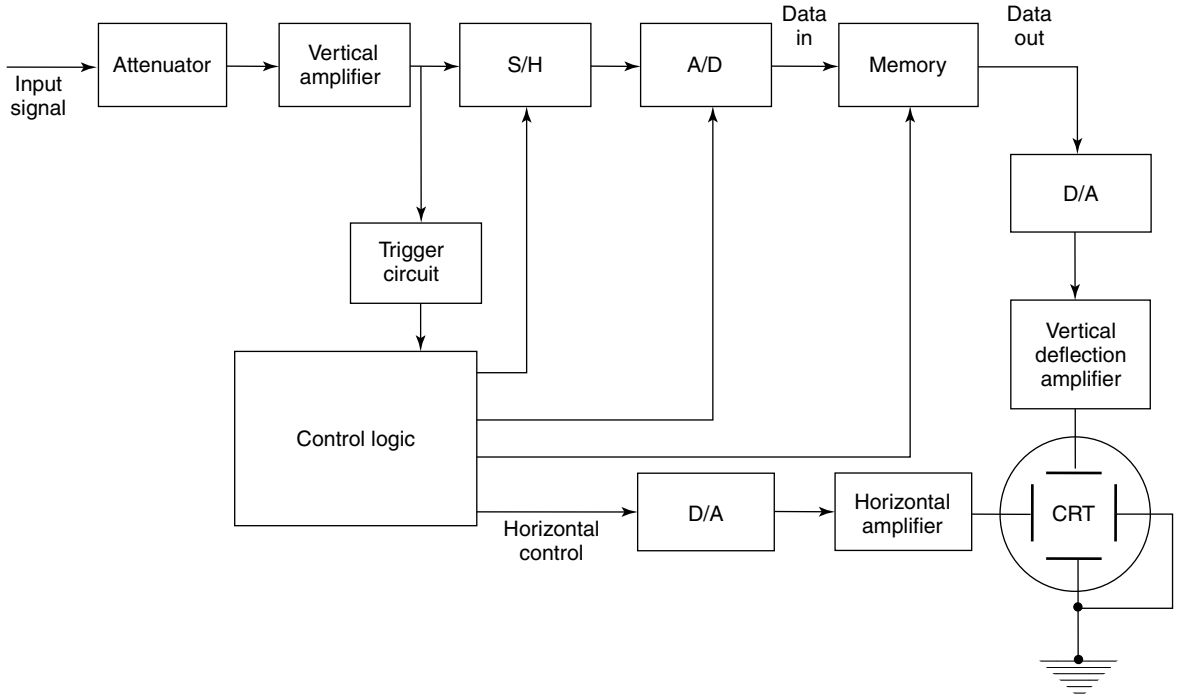

Figure 2. Structure of a digital storage oscilloscope.

offer the additional benefits of a computer by allowing flexibility in signal processing, reconfiguration of front panel displays, and providing extensive storage facilities. In virtual instruments, data can be saved or loaded in memory to be processed in popular spreadsheet programs and word processors, and a report generation capability complements the raw data storage by adding timestamps, measurements, user name, and comments.

4 CURRENT TRANSDUCERS

A transformer is an electrical device, which converts one AC alternating current into another one of the same frequency and having, in general, different characteristics in terms of voltage and current. It consists of two or more electric circuits coupled by a common magnetic circuit for the purpose of transferring electrical energy.

For current measurements in many circuits, it is not practical to allow primary current to flow directly through an instrument. One method is to divert a small current through a resistive shunt. A disadvantage of such a device is that, unlike transformers, they do not provide any insulation between the high-voltage side and measuring system. More commonly used transducers are

- current transformers (CT),
- Hall-effect transducers, and
- Rogowski Coils,
- optical current transducers (OCTs), and
- current shunts (explained in detail in Section 4).

Current transformers have two windings, designated as primary and secondary, which are insulated from each other. The primary winding is connected in series with the circuit carrying the line current to be measured, and the secondary winding is connected to instruments or protective devices. The secondary winding supplies a secondary current in direct proportion to the primary current almost without any difference in phase angle. Hence, the CT transforms line current into values suitable for measuring instruments, meters, protective relays, and other similar apparatus. CT also isolates the instruments and the relays from line voltages. The four common types of CT design are

- wound type
- bar type
- window type
- bushing type.

The current in any system changes more often and with greater magnitude than the voltage. Hence, selecting proper transducer for currents could be difficult. The right CT current rating and turns ratio to be used depends on the measurement objective.

In the case of disturbance recorders or protective devices, where fault or inrush currents are of concern, the CT

must be sized in the range of 20 to 30 times of normal load current. This will result in low resolution of the load currents and inability to accurately characterize load current harmonics.

Conventional current transformers are designed to operate within a frequency range from 15 to 100 Hz. With the need to measure harmonic content of the primary current, the frequency response of current transformers is essential to the measurement process. The frequency response of current transformers is effectively determined by the capacitance present in the transformer and its relationship with the transformer inductance. The standard metering class CT is generally adequate for frequencies up to 2 kHz. Phase angle shift between primary and secondary currents may start to become significant when the frequency is close to 2 kHz. For higher frequencies than 2 kHz, a window-type CT with a high ratio should be used. Desirable attributes for a CT, when harmonics are measured, include large ratio, small remanent flux, large core area (the more steel used in the core, the better the frequency response of the CT), secondary winding resistance and leakage impedance (as small as possible).

Rogowski Coils are more specialized transducers usually used for the measurements of very large currents, which last for a very short duration (hundreds of kiloamperes in less than a microsecond). The Rogowski Coils is a solenoid air core winding of a small cross-section looped around a conductor carrying the large primary current. The voltage induced on the terminals of the coil is proportional to the derivative of the primary transient current and number of turns. The coil is connected to an integrator. Integrated induced voltage gives a measure of the current in the primary conductor. The Rogowski Coils have the advantage of being free from saturation problems and have fast response time.

Hall-effect sensors operate on voltage difference across a thin conductor carrying current. The current depends on the intensity of the magnetic field applied perpendicular to the direction of current flow, as shown in Figure 3. An electron moving through a magnetic field experiences Lorentz force perpendicular to the direction of motion and to the direction of the field. The response of electrons to the Lorentz force creates a voltage known as the *Hall voltage*. If a current I flows through the sensor, the Hall voltage can mathematically be found by

$$V = R_H I B / t \tag{9}$$

where R_H is the Hall coefficient (cubic meters per degree of Celsius), B is the flux density (Tesla), and t is the thickness of the sensor (meters).

The value of R_H depends on the material used, temperature, and field magnitude. Its characteristics can be controlled to a certain extent by doping the base material with some impurities. For example, doping germanium with arsenic can reduce the temperature dependence at the expense of magnitude.

Semiconductor materials, such as gallium arsenide (GaAs), indium antimonide (InSb), and indium arsenide (InAs), produce the highest and most stable Hall coefficients. Because of its combined low temperature coefficient of sensitivity ($<0.1\%/^{\circ}$C), low resistance and relatively good sensitivity, InAs is the material favored by commercial manufacturers of Hall-effect devices.

Optical transducers represent one possible solution to the need for reliable and economical sensors in high-voltage measurement systems. Conventional transducers for voltage and current are expensive and require large volumes of electrical insulation when used on high-voltage lines. Optical current transducers are designed with all solid insulating materials and are therefore intrinsically safe. Because OCT is an electronic device, it differs fundamentally from CT with respect to the signal power involved. In a CT, the secondary signal has a power level of several watts, while power in the OCT secondary signal is typically a few microwatts.

A number of quite different OCTs are available. Diversity is present in all elements of the system. The sensor may be optical or electronic. The insulator may be ceramic or polymer and it may be used to support OCT or it may be suspended from it. All types of OCT use optics to isolate a high-voltage part of the system from a secondary side that carries information. The current being measured by an OCT is represented as modulated light. Typically, the link between sensor and user device (measuring instrument) is an optical fiber.

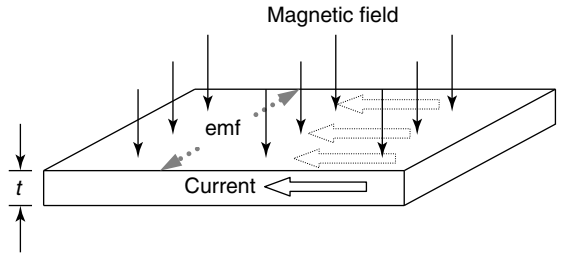

Figure 3. A Hall-effect sensor.

5 CURRENT SHUNTS

Apart from current transformers, CTs, and Hall-effect sensors, current shunts are a most common and cost-effective form of transducers that are used for current sensing.

It consists of a low-value resistor connected to the current path of the circuit, as shown in Figure 4. The waveform

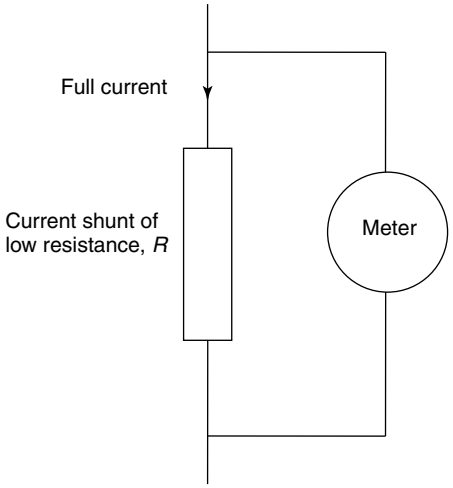

Figure 4. Current shunt arrangement.

of the voltage across the resistor is the replica of the current flowing through the shunt resistor. This voltage is then processed as a representative of the current through the circuit.

Shunt resistors are manufactured in various types and shapes to cater to the application needs. They can be divided into various groups:

- Sleeve shunts can be used for measuring impulse currents up to 500 A. The ohmic value of shunts can be changed by replacement of the active parts.
- Cage shunts can be used for currents up to 10 kA. The housing is usually filled with special sand to enhance operations and thermal characteristics.
- Tubular coaxial shunts can handle currents up to 100 kA for short durations.
- Special high current shunts are used for high currents in high-voltage applications, such as the arrestor testing.

Another way of using a current shunt is for rescaling of a meter. A suitable shunt resistor is connected across the meter. In this arrangement, majority of current flows through the shunt, but the full scale–deflection FSD of the meter is scaled to read the total current.

Shunt resistors usually have low resistance values, as low as 0.001 Ω giving a ratio 1/1000, that is, every 1/1000 (0.001) voltage drop across its length equals 1 A of current. A range of current shunts from 1 to 10 000 A with accuracy from 0.2 to 3% are available in compact flat plates, wires, strips, or brass-ended designs. Shunt resistors are manufactured by using Nichrome, copper, or similar materials of low resistivity. Mechanically, the current shunt is robust and can withstand both over-current and mechanical stress. NIST/NPL traceable calibration test certificates and certificates of conformance are available.

In applications where current shunts are selected for current measurements, attention must be paid to the inductive effects on shunts, terminal resistances of connections, and the types of leads used. This is especially so as the frequency content of the signal rises.

6 CONVERTERS

In many applications, signals are deliberately converted to currents for transmission of information (e.g. the 4–20 mA transmission method) to be connected back to voltage at the receiving end. Voltage-to-current (V–I) and current-to-voltage (I–V) converters are used extensively in the process industry to transmit information from one location to another. Current transmission is convenient because of its good immunity to electromagnetic interference and noise.

Figures 5(a) and (b) show how such converters are implemented using op-amp circuits. In the case of a V–I converter, the output is a current I_0 proportional to the input voltage V_i. Note that the portion of circuit between points A and B acts as a current source controlled by the input voltage V_i. In the case of the I–V converter, the output is a voltage V_0 proportional to the input current I_i. Also, note that whatever the load resistor placed at the output, the entire input current I_i will flow through resistor R_1. Thus, the portion of the circuit between point S and ground acts as a voltage source controlled by the input current I_i.

In some applications, it is important to note that the current-to-voltage converter can simply be a suitable terminating resistor that makes use of Ohm's Law to generate a voltage.

7 RECTIFIERS

In many applications, AC voltages and currents are measured by means of DC voltmeters and ammeters with an addition of a rectifying circuit in the input stage. Rectifiers

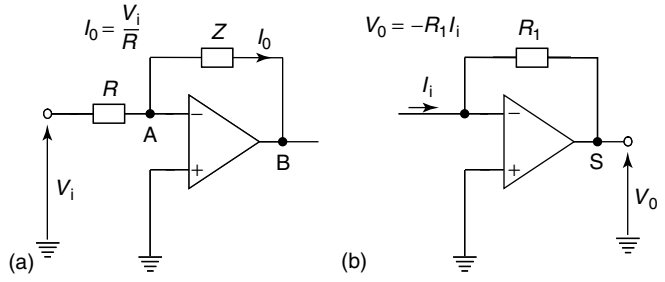

Figure 5. (a) Voltage and (b) current converters based on operational amplifiers.

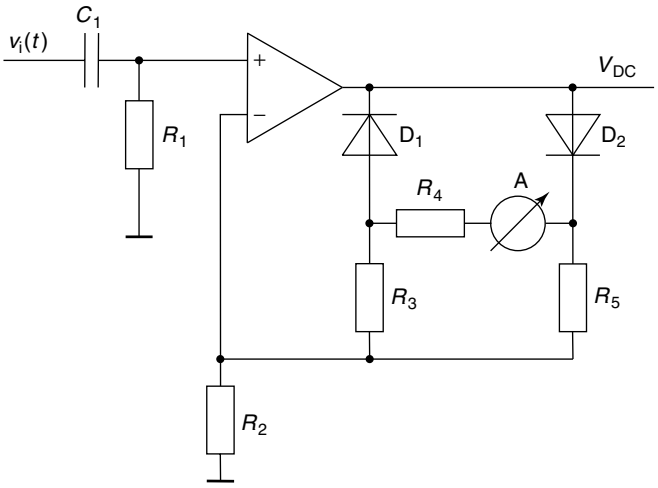

Figure 6. Rectifier-based AC ammeter.

can be classified as controlled or uncontrolled rectifiers, the majority of which are controlled types, which are obtained using thyristors and triacs.

Controlled rectifiers can vary the average value of the voltage applied to the load. They are suitable for use in rectification of single-phase or three-phase voltages and currents from constant AC supplies. A typical basic structure for a rectifier used in ammeters is shown in Figure 6.

The realized meter becomes an average voltage detector that can be used as an rms ammeter by labeling the scale to measure currents, provided that the input signal is a sinewave.

8 INDICATORS

Indicators are based on electromagnetic ammeter principles; one typical example is the D'Arsonval galvanometer. This galvanometer is an instrument specially designed for the measurement of very low currents (in the order of 10^{-8} A) and is therefore employed as null indicator in a majority of balance measurement methods (like the bridge and potentiometer methods). Because of the internal resistance of its coil, it can be also used to measure very low voltages, in the order of 10^{-7} V or even less.

The galvanometer structure comprises a rectangular coil of fine copper wire suspended between the pole faces of a permanent magnet. The magnet pole faces are curved to provide a radial flux. A fixed cylindrical iron core provides continuity of the magnetic circuit. The amplitude of the air gap between the fixed cylindrical iron core and the permanent magnet is about 3 mm. Each coil side lies halfway

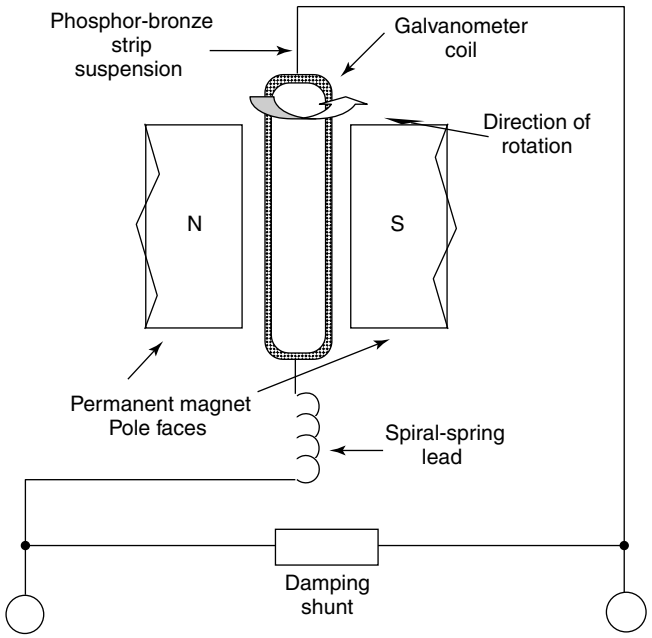

Figure 7. D'Arsonval galvanometer structure.

between the core and corresponding pole face. The suspension is a single fine strip of phosphor bronze and serves as a lead to the upper end of the coil. The lower end is connected to a lead consisting of a spiral spring. In the most accurate executions, the restraining torque is given by the torsion of the suspension strip. In this way, the friction torque is also practically removed. A small mirror, fixed to the suspension, reflects a narrow beam of light through a glass window in the outer case surrounding the galvanometer on to a scale placed a meter away, on which the deflection is measured. Simply winding the coil on aluminium frame provides eddy current damping. Resistive damping may also be obtained by connecting a variable resistor in parallel with the deflection coil. Proper adjustment of this resistance gives critical damping, thereby reducing measurement time. A typical galvanometer structure is shown in Figure 7.

9 DIGITAL INSTRUMENTS

Digital ammeters (multimeters) obtain the required measurements by converting the analog input signal into a sequence of digital samples uniformly spaced in time in the early stages of the signal processing. The input signals are therefore processed in the discrete-time domain and the measurement results are displayed in a digital form. It is worthwhile to note that the distinction between analog and digital meters is not because of the way the measurement results are displayed, but because of

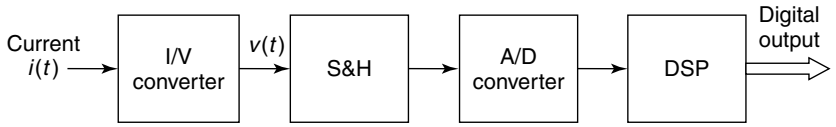

Figure 8. Structure of a modern digital meter.

the domain (continuous-time or discrete-time domain) in which the input signals are processed in the main body of the devices.

A more modern approach to this type of measurement exploits the capability of a fully digital structure as shown in Figure 8 that represents a voltmeter. The same structure can be adapted to an ammeter operation, provided that a current-to-voltage conversion input stage is inserted.

This structure samples the input signal $v_i(t)$ at constant sampling rate f_s and converts each sampled value into a digital code. The whole sequence of converted codes is stored in the memory of the DSP and then processed for the evaluation of information.

Assume that the input signal is periodic, with period T, and that the frequency spectrum is upper-limited by the harmonic component of order N. Digital signal processing theory, and in particular the sampling theorem, ensures that the information associated with the input signal can be totally retrieved from the sequence of the sampled data if at least $(2N + 1)$ samples are taken over a period T in such a way that $(2N + 1)T_s = T$, where the sampling period T_s being $T_s = 1/f_s$.

If $v_i(kT_s)$ is the kth sample, the rms value of the input signal is given by

$$V = \sqrt{\frac{1}{2N+1}\sum_{k=0}^{2N} v_i^2(kT_s)} \qquad (10)$$

As an example, a true rms AC ammeter based on this approach can feature an uncertainty as low as the 0.1% of the full-scale value with a 12-bit resolution analog-to-digital converter (ADC). According to the sampling theorem, the instrument bandwidth is limited to half the sampling frequency. This means that a 500-kHz bandwidth can be attained with modern devices. Although wider bandwidths can be obtained, this is paid for in terms of a lower resolution of the ADC devices.

In many cases, such as current measurements in high-voltage and power quality applications, special arrangements can be made by using appropriate current transducers and supporting equipment. In these cases, careful consideration is needed when sizing the transducers (e.g. CTs) required so that they take advantage of the full resolution of the instrument without clipping or distorting the measured signal. To obtain the most accurate representation of the signal being monitored, it is important to use as much of the full range of the ADC as possible.

10 STANDARDS

The unit of current is defined as, 'the ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} Newton per meter of length'.

There is no defined standard for electrical current as such as it is mainly derived from existing electrical standards of resistance and voltage, which are based on the quantum Hall effect and the Josephson effect respectively.

However, there exist numerous document standards for the current generation, harmonic contents, durations of currents in high-voltage applications, electrical and electronic circuits, batteries, grounding and safety aspects, circuit breakers and fuses, and so on. Some examples are

- IEEE C37.09–1979 for circuit breakers;
- ASTM D495-99 for test method for high-voltage, low-current, dry arc resistance of solid electrical insulation;
- IEC 60255-8 for high-voltage current-limiting fuses;
- AS 2024-1991 for high-voltage AC switchgear.

1 CHARACTERISTICS OF RESISTANCE

Resistance can be defined as the element in an electrical circuit that limits the flow of current in that circuit. Resistance of a material varies inversely proportional to the cross-sectional area of the material and directly proportional with its length and resistivity. Electrical energy flowing in a circuit containing resistance is converted to heat as the square of the current flowing through the resistance.

Materials that have low resistance are known as *conductors* and those that have very high resistance are known as *insulators*. At very low and specific temperatures, some materials exhibit zero resistance, a phenomenon termed *superconductivity*.

Resistance is one of the basic properties of electrical circuits and manufactured components called *resistors*. Although the primary function of resistors is to restrict current, they also find many other uses, such as pull-up, pull-down, impedance matching, voltage division, gain control, bias set, and so on.

The resistance of a resistor varies with manufacturing tolerances, temperature humidity, and voltage stress. Tolerances arise owing to manufacturing techniques, trimming of the material for the desired value, packaging, and soldering of the leads to resistive parts. The percentage variation of resistances quoted by the manufacturers is typically 20, 10, 5, and 1%. Precision resistors can have tolerance less than 1% but they are much more expensive.

Although resistors are manufactured in set values with some degree of tolerance, in many cases the exact values must be known. There are many methods of measuring resistances, as will be discussed in detail in this article. However, during measurements, careful consideration may be necessary due to numerous pitfalls. For example, when the resistance to be measured is small, then the resistance of the leads can cause a significant source of error. To deal with this problem, appropriate leads must be selected and the connection resistances must be minimized.

Apart from the direct measurement of the resistance of resistors and circuits, many sensors have resistive properties, thus requiring employment of appropriate signal processing techniques to monitor minute variations in resistances.

An example is the resistance temperature detector (RTD), which is based on the changes in electrical resistance with respect to temperature – *see* **Article 197, Metallic Resistance Temperature Detectors (RTDs), Volume 3**.

Another example is the strain gauge displacement sensor, which is based on resistance properties of electrical conductors – *see* **Article 192, Strain Sensors, Volume 3**. In this case, as the conductor is stretched or compressed,

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

its resistance alters owing to dimensional changes in the metal-film types.

Commercially available resistance measuring devices can be divided into three main groups: low-resistance meters, medium-resistance meters, and high-resistance meters. Many manufacturers supply meters ranging from few nano ohms to hundreds of tera ohms.

2 BASIC THEORY OF RESISTANCE

Resistance is related to current, voltage, and physical properties of materials. Current can flow in any medium in which there are conduction charges free to move. The conduction charges may be electrons, positively charged 'holes', or positive or negative ions, depending on the material. During current flow, the charges exhibit continuous random motion, colliding with each other as well as with atomic structure of the material.

When a conducting material is placed in an electric field, the conducting charges are accelerated in the direction of the field. The field adds a small average drift velocity to the random velocity. The magnitude of the drift velocity, v_d, is related to the strength of the field E by

$$v_d = \mu E \tag{1}$$

where μ is known as the *mobility* of the charge carriers.

The rate of flow of electric charge across a unit area of a plane normal to the direction of v_d is the current density, J, is given by

$$J = nqv_d \tag{2}$$

where n is the density of charge carriers and q is the charge of each particle. For electronic conductors, the electron charge, $e = q = 1.6 \times 10^{-19}$ C. Combining (1) and (2) gives

$$J = nq\mu E = \sigma E \tag{3}$$

where σ is the conductivity of the material, in Siemens per meter and J is the current density in coulombs per square meter per second. The inverse of conductivity is called the *resistivity* (ρ), which is measured in $\mathrm{VmA^{-1}}$ or Ωm. While the range of conductivity is somewhat arbitrary, it is very low in insulators, $\sigma < 10^{-15}\,\mathrm{S\,cm^{-1}}$, intermediate in semiconductors, $\sigma = 10^{-5}$ to $10^{3}\,\mathrm{S\,cm^{-1}}$, very high in conductors, $\sigma = 10^{4}$ to $10^{6}\,\mathrm{S\,cm^{-1}}$, and infinite in superconductors.

The mobility, μ, usually decreases with increasing temperature due to collisions between the moving electrons, that is, lattice vibrations. The number of charge carriers, n, remains constant for metallic conductors with increasing temperature, but increases exponentially for semiconductors and insulators. Thus, at very high temperatures some insulators become semiconducting, while at low temperatures some semiconductors become insulators.

Equations (1), (2), and (3) may be linked to basic electrical circuit theory by considering the flow of electric current in a section of a wire having a cross-sectional area of A and length l. Assuming a current I is uniformly distributed across the cross-section, the current density can be expressed as

$$J = \frac{I}{A} \tag{4}$$

Expressing the relationship between the electric field in the wire and the potential difference between its ends gives

$$E = \frac{V}{l} \tag{5}$$

Thus, from (3), (4), and (5), the relation between voltage and current becomes

$$V = \left(\frac{\rho l}{A}\right) I = RI \tag{6}$$

Therefore, the resistance R of a material can be expressed as

$$R = \frac{\rho l}{A} \tag{7}$$

R is a quantity representing the electric behavior of the circuit element under DC conditions. When a sinusoidal voltage is applied, the behavior of other circuit elements, such as capacitors and inductors, becomes significant.

In sinusoidal operation, the current flowing is determined by the reactance of the components of the circuit. Reactance is the ratio of the applied voltage to the applied current.

Inductors have inductive reactance $X_L = 2\pi f L\,\Omega$, where f is the frequency in Hz and L is the inductance in Henrys. Capacitance has capacitive reactance $X_C = (1/2\pi fC)\,\Omega$, where C is the capacitance in Farads.

The total effect of combined resistance and reactance in an AC circuit is called the *impedance*, Z, and its unit is ohm. Impedance is the vector sum of the resistance and reactance in the circuit. Impedance can be expressed in the vector form as

$$Z = R + j(X_L - X_C) \tag{8}$$

It can be seen in (8) that measurement of resistance may not be all that easy in circuits as the circuits will often contain some degree of inductive and capacitive properties, these often being the unpreventable imperfections of real systems.

In addition, resistors themselves may exhibit inductive and capacitive properties, which may have significant reactive properties at certain frequencies.

The impedance properties of circuits may be significant in many applications; hence, numerous measurement techniques have been developed. However, in this article, we will primarily concentrate on the measurement of resistance.

Thus, it can be seen that the simple resistance element is actually a complex component when its precise measurement is needed.

3 RESISTANCE MEASURING NETWORKS

Impedance in the AC, and resistance in the DC circuits are important parameters that characterize the circuit behavior, components, and materials used to make these components. In order to measure impedance, it is necessary to measure at least two values since it is a complex quantity, as expressed by 8. There are many modern impedance-measuring instruments that determine the total impedance and then determine the real and imaginary part for resistive and reactive components.

There exist many resistance and impedance measurement methods, each of which has advantages and disadvantages. Some of these methods are

- bridge method
- I-V method
- constant current source method
- network analysis method
- resonant method and more.

3.1 Bridge method

The unknown resistance or impedance forms one of the arms of an electrical bridge – *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**. When no current flows through the detector, the value of the unknown component can be expressed from the relationship with the other bridge elements. The electrical bridge method is used extensively in resistance measurements; hence, Section 4 is dedicated to this method. This method gives typical accuracies of 0.1% and is applicable for a frequency range of DC to 300 MHz.

3.2 I-V method

The unknown impedance or resistance is calculated from the measured voltage and current values. Current is calculated using the voltage measurement across an accurately known resistor. In some cases, low-loss transformers are used to prevent the effects caused by the use of low-value resistor in the circuit. This is the most suitable for probe-type tests and the frequency range is typically from 10 KHz to 100 MHz.

3.3 Constant current source method

This is the method employed in most multimeters to measure resistances. The resistance measurements are made using a current source and a normal voltage input. The current flows through the unknown resistance and the voltage drop across the resistance is measured. For example, a 1-mA current source will provide a voltage of 100 mV across the 100 Ω of a Pt100 temperature measuring device at 0 °C. This method is applicable in the laboratory environment for a wide range of resistances.

3.4 Network analysis method

In AC applications, the reflection coefficient from the unknown impedance or resistance is obtained by measuring the ratio of the incident signal and the reflected signal. A directional coupler or bridge is used to detect the reflected signal and a network analyzer is used to supply and measure the signals. This is mainly used in high-frequency applications from 300 kHz and above. It gives good results when the unknown impedance is close to the characteristic impedance.

3.5 Resonant method

When a circuit is adjusted to resonance by tuning capacitors, the unknown impedance can be determined from the frequency, capacitance value, and Q-factor. The Q-factor can directly be measured by using a voltmeter across the tuning capacitor. It is accurate in low-impedance measurements in the range of 10 kHz to 70 MHz.

Some of these methods will be explained in greater detail in the sections to follow.

4 BRIDGES FOR RESISTANCE MEASUREMENTS

Bridges are commonly used to measure basic electrical quantities such as resistance, capacitance, inductance, impedance, and admittance. There are two groups of bridges, the AC bridge and the DC bridge. In each type, there exist numerous configurations such as the Wheatstone,

and Kelvin DC bridges, and Schering, Maxwell, Hay, and Owen AC bridges.

Bridges are essentially two-port networks in which the component to be measured is connected to one of the branches of the network. For a detailed explanation of electrical bridges, refer to **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2** and **Article 127, Unbalanced DC Bridges, Volume 2**.

In a particular instrument, the selection of the bridge to be employed and the determination of values and tolerances of its components are very important. A typical example of an AC bridge, a series RC bridge, is given in Figure 1. We also offer some analysis briefly to illustrate their typical principles of operation.

From Figure 1, at balance when the detector D shows zero:

$$Z_1 Z_3 = Z_2 Z_x \tag{9}$$

Substitution of impedance values to this gives

$$\left(\frac{R_1 - j}{\omega C_1}\right) R_3 = \left(\frac{R_x - j}{\omega C_x}\right) R_2 \tag{10}$$

Equating the real and imaginary terms gives the values of unknown components as

$$R_x = \frac{R_1 R_3}{R_2} \tag{11}$$

and

$$C_x = \frac{C_1 R_2}{R_3} \tag{12}$$

Bridges can also be used in a deflection, or a null-balanced mode. A deflection bridge, known as the *unbalanced bridge*, is based on the detecting voltage across the bridge diagonal as illustrated in Figure 2. This figure also symbolizes a typical bridge amplifier. There are many other configurations of bridge amplifiers, depending on the grounding and the availability of grounded or floating reference voltages.

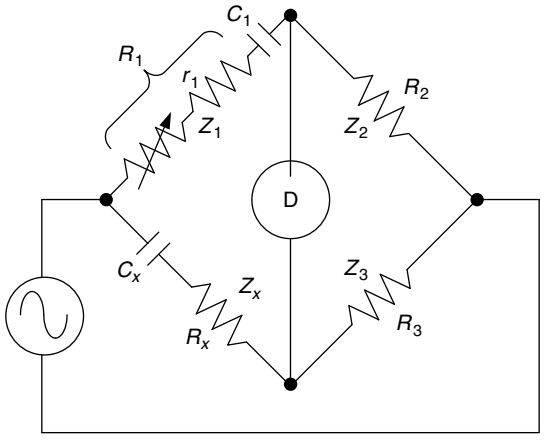

Figure 1. A series RC bridge.

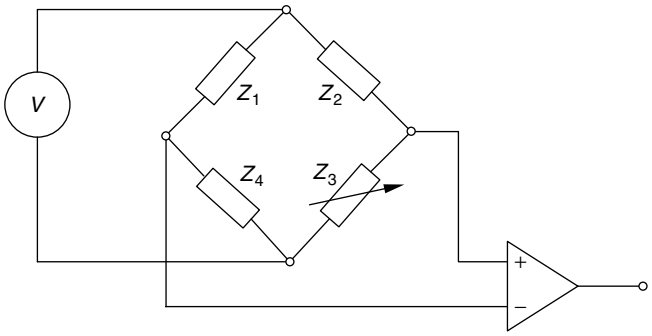

Figure 2. A deflection bridge.

In Figure 2, the output of the bridge is a nonlinear function of unbalance. In small ranges of measurements, the nonlinearity may be considered to be quasi-linear, but must be linearized by suitable techniques for large ranges.

The null-bridge requires it to be balanced at all times. This is achieved by adjusting one of the arms in response to variations in the other arm that carries the sensor. Null bridges have superior linearization characteristics compared to deflection bridges.

Wheatstone bridges, either in null or deflection modes, are commonly used for the conditioning of signals of the outputs of many sensors.

In some applications, the use of incorrect leads between the sensing elements and the signal conditioning circuits can result in severe errors. If care is not taken, some of these leads may have resistance values comparable to the resistances of the sensing elements thus resulting in poor stability. In such cases, a three-lead circuit, as shown in Figure 3, can be used.

In the three-lead circuits, the sensing elements are connected to the bridge using three wires made from the same

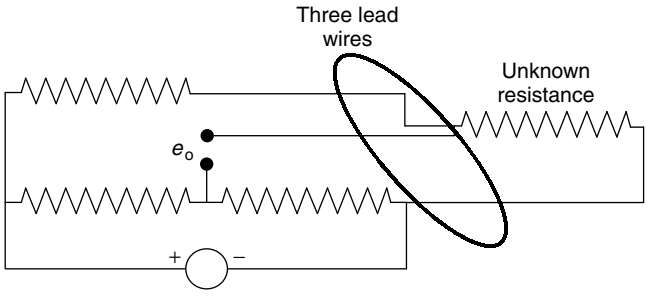

Figure 3. Three-lead configuration.

material and having identical lengths. Although the temperature changes the values of the resistances of the connecting wires, the effects of the one arm is canceled by the changes in the other arm. The third wire represents an additional resistance in series with the reading device and does not affect the measurements.

When very high accuracy is required, a four-wire or six-wire scheme can be adopted. In these cases, a voltage source excites the sensing device, and the corresponding output voltage is measured by a potentiometer. This device can be characterized by a virtual infinite input resistance. Neither the resistance of the connecting wires nor its variations can now affect the measurement results.

5 INDICATORS FOR USE WITH BRIDGES

Indicators for the bridge outputs can be simple voltmeters and galvanometers as well as sophisticated digital devices. In auto-balancing bridges, for example, a current is supplied to maintain a zero potential at the terminals. A detector detects potential at the low terminal and controls both magnitude and phase of an oscillator to maintain the detected potential at zero. When the bridge is unbalanced, the null detector detects an error current and the phase detector separates the vector components of this current. After having been filtered, the resultant signal is used to adjust the error current to zero in the null detector. This balancing operation can be performed automatically over a wide range of frequencies.

Most of the commonly used indicators are based on the principles of voltmeters. Once the error voltage is detected, the signal is processed either in the analog or digital form for suitable displays. Conventional resistance meters use needle displays based on galvanometers. Nowadays, displays are in digital form using LED arrays or LCDs. Once the digital platform is selected, the results may be displayed on a computer screen as indicators or numbers.

6 SUBSTITUTION METHODS

In some measurements, external effects such as temperature must be seriously taken into account. The resistance variation because of temperature can be of the same order of magnitude as the sensor-induced variations, thus prompting the selection of suitable compensating circuits. Best solutions for temperature compensation are obtained by using a dummy gauge as well as active gauges in the opposite legs of a Wheatstone bridge, as shown in Figure 4 (the so-called half bridge configuration). The bridge is balanced under the no-load condition and the sensors are mounted in such a way as to experience the same temperature fluctuations

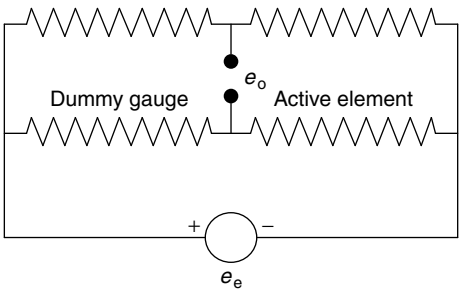

Figure 4. Wheatstone bridge by using dummy elements.

and hence undergo similar changes in resistance values. This assures that the bridge equilibrium is not altered due to temperature. In this arrangement, the sensor acts exclusively on the active gauge and the unbalance of the bridge becomes a factor of sensor resistance only.

The maximum value of the excitation voltage in Figure 4 is set by the self-heating phenomenon of the circuit owing to the currents flowing through the bridge arms. In fact, self-heating could destroy the sensing element and cause a series of alterations in the resistances.

7 VARIABLE RESISTANCE USE

Variable resistors, trimmers, and potentiometers find frequent use in all types of circuits including balancing of bridges. In electronic circuits, they are used for trimming op-amps, tapping reference voltages, setting trip points, adjustments voltages, currents, and frequencies, and so on. In electrical circuits, they are used to limit currents, and to adjust power flow in and out of the circuits. Variable resistors are available in carbon-composition and wire-wound types. Variable resistors tend to have good temperature stability. Nevertheless, they can be a source of externally induced noise, so it is advisable to provide good shielding for any possible electromagnetic interference (EMI).

Variable resistors are basically mechanical devices having inertia, friction, and their associated limitations. The sliding electrical contacts can be prone to oxidization and thus variable contact resistance as they move. In general, they can be sensitive to moisture, dirt, and wear and tear, and should be avoided whenever possible. Fixed resistors with the desired settings are preferable for precision operation.

Resistive potentiometers are basically resistance elements that have a movable arm that transform mechanical displacements into voltage forms. A simple potentiometer is illustrated in Figure 5.

In this Figure 5, e_e is the excitation voltage and $e_o(t)$ is the output voltage. The input signal is proportional to

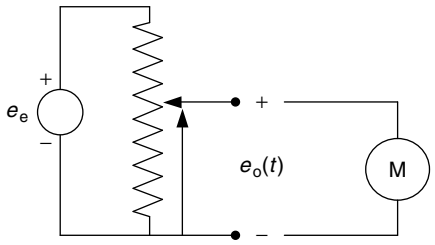

Figure 5. Schematic representation of a potentiometer.

the displacement $x(t)$ of the wiper. Under the no-load conditions, the output voltage is a linear function of the displacement. However, when a user device is connected to the output $e_o(t)$, a loading effect occurs that can make the device nonlinear. There are a number of techniques available to minimize the loading effects.

8 ACCURACY AND LOADING EFFECTS

For real measurements, it is reasonable to assume that results always contain some errors. Typical errors are

- loading effect
- instrument inaccuracies, such as DC biasing
- residuals in test fixtures and cables
- noise.

8.1 Loading effect

If the resistance of the measuring device shown in Figure 5 is comparable in size with the unknown resistance under investigation, the current drawn by the meter can distort the readings. One of the solutions to this problem is to select a high input–impedance meter that is at least 50 to 100 times higher than the impedance of the load. If loading effect is unavoidable, mathematical techniques can be used to make corrections.

8.2 Instrument inaccuracies

There may be many reasons for instrument inaccuracies. Many manufacturers design and produce precision instruments to measure high-resistances (called *Megger*) and low-resistances.

8.3 Residuals in test fixtures and cables

Typical examples are parasitic effects, cable impedances, test signal levels, guarding, contact resistances, and so on.

8.4 Noise

This is a discussion topic in its own right in such measurements. Noise can be generated by the measuring equipment, by the sample under test or imposed externally by means of electromagnetic interference – see the Section on **Noise and Interference**.

In applications in which sensitivity and precision are required, adequate compensation techniques and specially designed cables must be employed in highly controlled environments.

9 POWER RATING OF RESISTORS

The power absorbed (in the form of heat) by a resistor is a product of resistance and square of the current through it (i.e. $P = I^2R$). Therefore, the size, surface area, thermal properties, and composition of resistance are important for it to be able to dissipate the generated heat without changing its electrical properties, especially in the long term. Resistors, therefore, are manufactured for specific applications. The selection of an appropriate resistor for an application must meet the requirements of the circuit.

In electronic applications, resistors can be viewed under six different groups, these are: carbon-composition, carbon-film, thin-film, metal-film, wire-wound, and foil resistors.

9.1 Carbon-composition resistors

These are made from graphite, ceramic, and resin compressed at high temperatures. These resistors have poor temperature coefficients, stability, and shelf life. Carbon-film resistors generally are used in low power and higher-resistance applications, above 1 MΩ. They have low-noise properties.

9.2 Metal-film resistors

These are formed by sputtering metal onto ceramic tubes. They have good accuracy and low variability, therefore are most suitable for long term and continual use. Their noise figures are much lower than the carbon-composition resistors. Metal-film resistors have very low temperature coefficients and are suitable for linear circuits.

9.3 Thin-film resistors

These are made from tantalum nitrate sputtered and etched on a silicon substrate. They have low temperature coefficients and are suitable for resistance networks and surface-mount technology.

Table 1. Properties of resistor types.

	Carbon composition	Carbon-film	Metal-film	Thin film	Wire wound	Foil
Accuracy (±ppm)	10 000	5000	100	50	20	5
Maximum resistance (MΩ)	22	50	10	1	1	0.25
Temperature coefficient (±ppm/°C)	1200	1000	100	100	10	2
Maximum voltage (V)	500	500	350	200	1000	500
Humidity effects (%)	15	3	0.5	0.5	0.5	0.02
Power range	Low	Low	Low	Low	Any	Low
Noise	Low	Low	High	Low	Low	Low
Long-term stability	Poor	Low	Fair	Fair	Excellent	Excellent
Price	Very low	Low	Moderate	Moderate	High	High

9.4 Wire-wound resistors

These are made from nickel-chromium wire wound on a beryllium oxide core. They have excellent temperature coefficients. Wire-wound resistors find applications particularly in high-power circuits where accuracy is of prime importance. One drawback of the wire-wound resistors is that they may have substantial inductances, which can make them unsuitable in high-frequency applications (say above 50 kHz).

9.5 Foil resistors

These are made from nickel-chromium bonded onto a ceramic substrate and laser trimmed for accuracy. They have the best temperature coefficients and have very high precision. Foil resistors have low inductive and capacitive properties. They are good for high-frequency applications.

General-purpose, high-quality resistors are available in DIP packages, which look like ICs. They are used in many applications, particularly in digital circuits as pull-up or pull-down resistors.

The properties of the various kinds of resistors are summarized in Table 1.

It is worth noting that resistors for applications in electronic circuits are much smaller compared to their electrical and power applications counterparts, but their composition and thermal properties are similar.

10 STANDARDS OF RESISTANCE

The most accurate resistance standard presently available is based on the Hall-effect – *see* **Article 43, Units, Volume 1**. This is a quantum effect that takes place in a bidimensional electronic gas (that can be obtained on a very thin layer of semiconductor materials like the Si MOSFETs and GaAs thin structures) in the presence of a very high magnetic–induction field ($B \cong 10\,\mathrm{T}$) and at very low temperatures ($T \cong 1\,\mathrm{K}$). Under these conditions, the Hall resistance takes discrete values:

$$R_{\mathrm{H}} = \frac{h}{ie^2} \tag{13}$$

Where i is an integer, h is the Plank constant and e is the electron charge.

The quantity h/e^2 is called *von Klitzing constant* and has a value of 25812.807 Ω, known with a relative uncertainty of 2×10^{-7}. Moreover, experiments that lead to the determination of this constant has a reproducibility of about 10^{-9}. However, experiments require strict environmental conditions (low temperature, high magnetic–induction field) that can be obtained only by a few National Standard Organizations. For this reason, resistance standards are obtained by means of stable, low temperature–coefficient alloys that are usually maintained in the laboratories with these standard resistors being offered by many vendors. The resistance values of standard resistors are referred to as *Hall-effect-based standard for calibration*.

There are many standards for determining resistance under specific applications, such as

- IEEE 81-1983 *Measuring Earth Resistivity, Ground Impedance, and Earth Surface Potentials of a Ground System (Part 1)*
- IEEE 81.2-1991 *Measurement of Impedance and Safety Characteristics of Large Extended or Interconnected Grounding Systems (Part 2)*
- IEEE 118-1978 *Test Code for Resistance Measurements*

1 MEASURING NETWORKS

There are many techniques for the measurement of capacitance and inductance. General principles and examples are dealt with in texts such as Osvàth (1992), Coombs (1995), and Morrison (1993); the most used ones can be grouped in the following categories:

- Current–voltage methods
- Resonance methods
- Time constant methods
- Bridge methods
- Reflection methods.

To choose the most appropriate method for a specific application some factors, such as frequency coverage, measurement range, measurement accuracy, and ease of operation must be taken into account, but it is necessary to make tradeoffs between them since there is not a single measurement method that completely fulfills all measurement needs. Background for the measurement of voltage is found in **Article 201, Voltage Measurement, Volume 3**, current in **Article 202, Current Measurement, Volume 3**, and resistance in **Article 203, Resistance Measurement, Volume 3**.

1.1 Current–voltage methods

A sinusoidal current, of pulsation $\omega = 2\pi \mathrm{f}$, is forced through the unknown component. The capacitance/inductance value is derived from the voltage and current measurements. Usually, the current that flows through the component is obtained from the voltage measurement across a known low-value resistor, R, as reported in Figure 1.

1.2 Resonance methods

These methods use the fact that a combination of inductance and capacitance resonates at certain frequencies. In particular, the component to be measured is placed in a tuned circuit with known components and the resonance frequency is measured. In Figure 2, a simplified circuit for the inductance measurement is reported: the resonance is attained by adjusting the tuning capacitor, C, and the unknown inductance value is evaluated from the test frequency, f, and the C value.

1.3 Time constant methods

The unknown component is placed in a resistive circuit and the time constant of the obtained circuit is evaluated.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

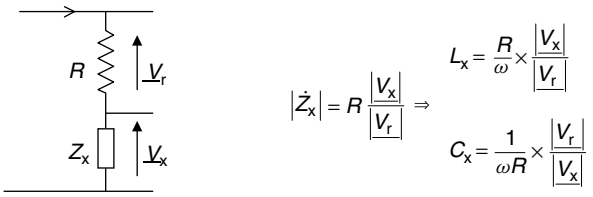

Figure 1. Current–voltage technique for impedance measurement.

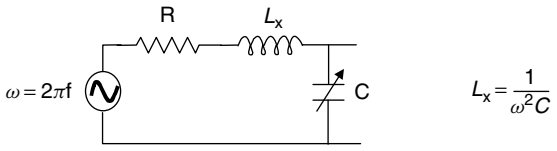

Figure 2. Example of inductance measurement with the resonance method.

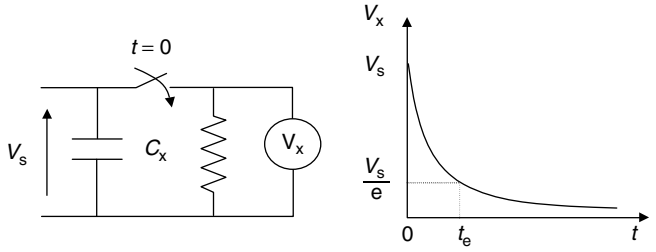

Figure 3. Example of capacitance measurement with the time constant method.

Figure 3 shows a measuring network for capacitance measurements. At time instant $t = 0$, the capacitor C_x, charged with voltage V_s, is shunted with the resistor R. Then the voltage across C_x becomes:

$$V_x = V_s e^{-\frac{t}{C_x R}} = V_s e^{-\frac{t}{\tau}} \tag{1}$$

The time constant, τ equal to the elapsed time from $t = 0$ to the time instant when V_x becomes equal to V_s/e, is measured, and the C_x value is obtained from it: $C_x = \tau/R$.

1.4 Bridge methods

The schematic of a 4-arm AC bridge network is reported in Figure 4. The voltage source is typically a sinusoidal oscillator whose frequency is adjusted to the required value.

Z_x is the component under measurement and the other three arms contain fixed and/or variable standard elements. The variable elements are adjusted until the detector, D, senses zero voltage across it (no current flows through it). In this condition, the value of the measurand can be obtained

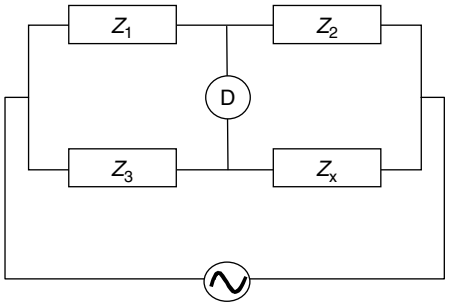

Figure 4. Schematic of impedance bridge.

by its relationship with the other bridge elements:

$$\dot{Z}_x = \frac{\dot{Z}_2 \times \dot{Z}_3}{\dot{Z}_1} \tag{2}$$

Bridges are used to make accurate measurements of unknown capacitances and of associated losses in terms of some known external capacitances and resistances.

Various types of bridge circuits, employing combinations of L, C, and R components as bridge elements, are used for various applications. In the following, the Schering and the Maxwell–Wien bridges used for capacitance and inductance measurement respectively are described as examples.

In the Schering bridge (see Figure 5), the unknown capacitance is modeled with the series equivalent circuit; the variable elements can be the reference capacitors (C_1, C_2), and this allows the use of the bridge in high frequency, or the resistance and the capacitance R_1 and C_1; this solution is preferred in high voltage measurements for safety reasons (the voltage drop on the variable components, adjusted by the operator, is low).

With these components, (2) becomes

$$C_x = C_2 \times \frac{R_1}{R_3}, \quad R_x = R_3 \times \frac{C_1}{C_2} \tag{3}$$

As you can see, the relationships are analytically independent of the frequency. It has to be noted that when both

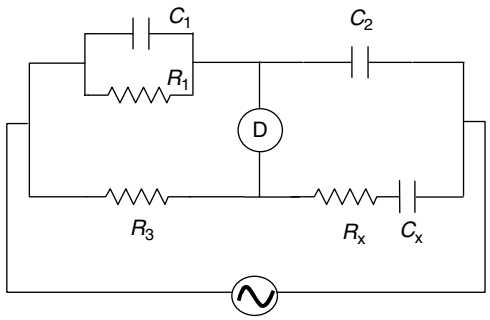

Figure 5. Shering bridge.

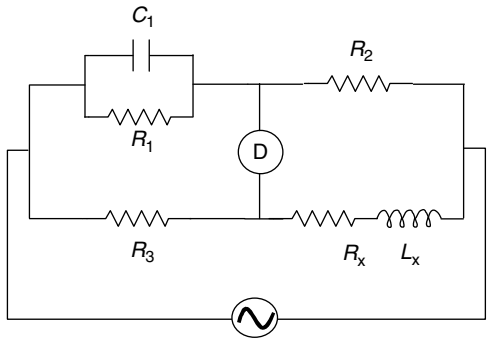

Figure 6. Maxwell–Wien bridge.

C_1 and C_2 are variable, the balancing procedure is difficult to achieve (sliding balance problem) since C_2 appears in both the C_x and R_x relationships. As you can see, the relationships are analytically independent of the frequency.

In the Maxwell–Wien bridge (see Figure 6), the unknown inductance is modeled with the series equivalent circuit and the equilibrium condition is obtained adjusting the R_1 and C_1 values. The relationships to obtain the unknown parameters are:

$$L_x = C_1 \times R_1 \times R_3,\ R_x = \frac{R_2 \times R_3}{R_1} \tag{4}$$

Also, this bridge is theoretically frequency independent and the balancing procedure is not affected by the sliding balance problem.

More detail in bridge design is found in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**; and **Article 127, Unbalanced DC Bridges, Volume 2**.

1.5 Reflection methods

The inductance or capacitance value is derived by a reflection coefficient measurement. A step signal is applied to the component under test and the reflected signal is analyzed: measuring the ratio of the incident signal to the reflected one, the reflection coefficient is obtained.

2 CAPACITANCE AND INDUCTANCE FORMS

Capacitance is defined as the capability of a system, circuit, or device for storing electric charge. Namely, the capacitance, C, is defined as the ratio of stored charge, Q, to the impressed potential difference, V:

$$C = \frac{Q}{V} \tag{5}$$

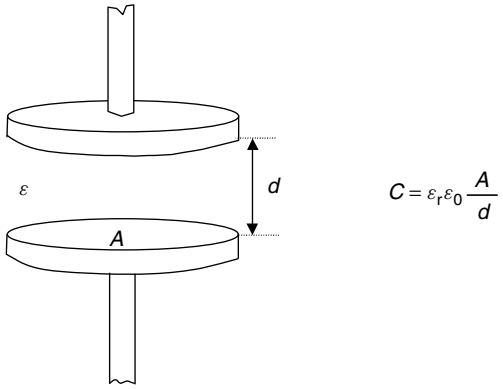

Figure 7. Example of a capacitor.

The device designed to store charge is called a *capacitor*. A simple capacitor (see Figure 7) consists of two plates made of an electrically conducting material and separated by a dielectric material, ε (e.g. mica, oil, paper, tantalum, or air).

Real capacitors present parasitics: dielectric absorption and leakage currents. Absorption introduces a time lag during the charging and discharging of capacitors. The leakage current prevents indefinite storage of energy in the capacitor.

In order to take into account these parasitics, a capacitor is represented with the equivalent circuit reported in Figure 8, where:

C is the capacitance;
R_s and L are the parasitics existing in the lead wires and electrodes;
R_p represents leakage between the two electrodes.

Usually, the simplified circuits shown in Figure 9 are used: the series circuit is chosen for low leakage capacitor (high R_p), while the parallel one is preferred for high leakage currents (low R_p). Measuring capacitor in series or parallel mode can provide different results, and how they differ depend on the quality of the capacitor.

Inductance is a quantity that measures the electromagnetic induction of an electric circuit component. The self-inductance, L, of a circuit component determines the

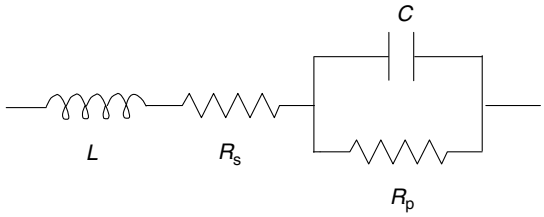

Figure 8. Equivalent circuit of a real capacitor.

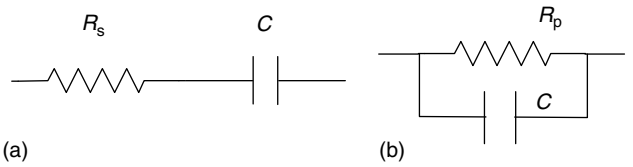

Figure 9. Simplified equivalent circuits of a capacitor: (a) series circuit and (b) parallel circuit.

magnitude of the electromagnetic force, V, induced in it as a result of a given rate of change of the current,

$$i, L = \frac{V}{\mathrm{d}i/\mathrm{d}t} \tag{6}$$

Similarly, the mutual inductance, M, of two components, determines the electromagnetic force that one of each may induce in the other for a given current change. An inductor consists of a wire, of good conducting materials, wound around a core. The simplest core material used is air, but for volumetric efficiency of the inductor, magnetic materials such as iron and ferrites are employed.

Real inductors include parasitic resistive proprieties, due to the resistance of the conductor used for the winds, and present distributed capacitance between turns and between layers of the winding, due to the imperfection of the insulation. The equivalent circuit of a real inductor is reported in Figure 10, where:

R_p represents the loss of the core;
R_s represents loss of the wire;
C is the distributed capacitance between the turns of the wire.

With DC and low frequencies, the effects of the latter two factors are negligible, and an inductor can be represented by the simple series circuit, as in Figure 11, where L is the inductance and R_s the resistance of the winding.

More details on the capacitance and inductance forms are presented in Eren and Goh (1999) and Kumar *et al*. (1999).

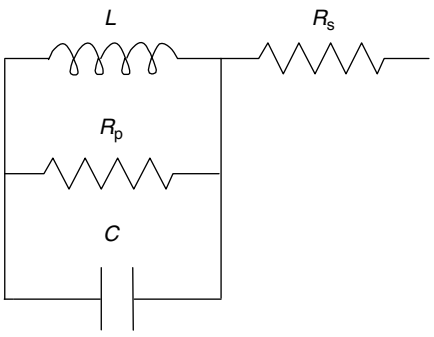

Figure 10. Equivalent circuit of a real inductor.

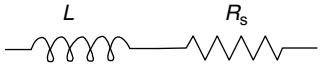

Figure 11. Simplified equivalent circuit of an inductor.

3 SELECTION OF TEST FREQUENCY

The actual value of capacitance and inductance takes into consideration the effects of the parasitic components; thus, it is frequency dependent. As an example, for a capacitor at high frequencies, the effects of lead inductance, series resistance, and leaking resistance become more pronounced. Consequently, in general, it can be said that the test frequency should be chosen close to the operating frequencies of the unknown component.

There are many measurement methods, see also Section 1, whose frequency range applicability is different.

3.1 Current–voltage methods

With this approach, the component reactance module is measured $Z = |V|/|I|$. Considering the components as ideal, because of the relationships between the reactance module and the test frequency (see Table 1), some considerations can be drawn. For low capacitance value (less than 100 pF), the supply frequency should be high enough, typical values ranging from 10 kHz to 100 MHz, in order to yield reasonable values for their impedances and vice versa for inductors.

3.2 Bridge methods

A class of bridges, the so-called resonance bridges (Wien), is structurally frequency dependent, namely, the relations involve the component reactance, and consequently the considerations for current–voltage methods are still valid.

Other kinds of bridges (e.g. Schering, Maxwell–Wien etc.) are theoretically frequency independent; but they are practically frequency dependent due to the presence of parasitics in the unknown device and in the bridge connections. In particular, at high frequencies the stray capacitance becomes a significant factor, while at low frequencies the magnetic effects have to be taken into account. Bridges

Table 1. Reactance of capacitance and inductance.

Component	Capacitance	Inductance
Reactance module	$\frac{1}{\omega C}$	ωL

are also dealt with in **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2**; and **Article 127, Unbalanced DC Bridges, Volume 2**.

3.3 Resonance methods

The value of the unknown quantity is obtained by tuning a standard and variable component in the measuring network and depends directly on the test frequency (e.g. $L = 1/\omega^2 C$). Since the range variability of the standard component is limited, at a given frequency only a small range of the unknown can be measured. In order to extend the input range, the test frequency is variable. In particular, the frequency value is determined as a function of the unknown component magnitude order, and then the standard component is regulated to obtain the resonance condition.

Moreover, it is necessary to underline that at a high frequency for a low-value inductor, measurement may be impossible, since the test cable capacitance can cause other resonances.

Problematic issues concerning the frequency selection are dealt with in texts such as Agilent Technologies Inc (2000) and Bartlett (1992).

4 MEASUREMENT OF LOSS ANGLE

In sinusoidal condition, using a phasor notation, an ideal capacitor, the voltage across it, V, lags the current trough, I, by 90° (see Figure 12(a)). For a real capacitor, at the capacitive current a resistive current (in phase with the voltage), owing to the loss in the dielectric, is added; consequently the current through the capacitor is not 90° out of phase with respect to the applied voltage (see Figure 12(b)). The angle, δ, between the resulting current, I, and the capacitive current, I_c, is called the *loss angle* and depends on the used dielectric characteristic and on the capacitor structure. In order to measure this angle, traditional phase

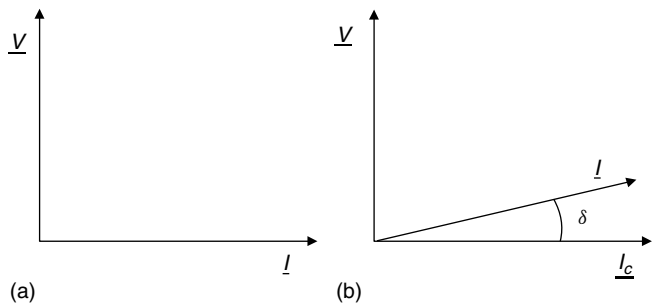

Figure 12. Current and voltage phasors for (a) ideal capacitor and (b) real capacitor.

measurement techniques (zero crossing, oscilloscope methods, three-voltmeters method etc.) can be employed; but since this angle is normally small the obtainable uncertainty is too high.

Often, in order to quantify the dielectric loss, the dissipation factor, (DF), also known as *loss tangent* is used, $DF = \tan(\delta)$ instead of the loss angle of course, for a good capacitor (small δ), the loss angle is approximately equal to the dissipation factor ($\delta \approx \tan(\delta)$).

The dissipation factor is defined also as the inverse of the quality factor and consequently can be obtained as the ratio between the energy lost and the energy stored in the capacitor

$$DF = \frac{energy\ lost}{energy\ storage} \tag{7}$$

Using a capacitor equivalent circuit, the relationships between the loss tangent and the equivalent capacitance and resistance can be determined analytically.

Considering a series equivalent circuit, (Figure 9(a)) we have:

$$\tan\delta = \frac{V_R I}{V_C I} = \frac{R_S I^2}{\frac{1}{\omega C_S} I^2} = \omega C_S R_S \tag{8}$$

For a parallel equivalent circuit (Figure 9(b)):

$$\tan\delta = \frac{V I_R}{V I_C} = \frac{\frac{V^2}{R_P}}{\frac{V^2}{\omega C_P}} = \frac{1}{\omega C_P R_P} \tag{9}$$

see also Krupka and Geyer (1999), and Eren (1999).

Consequently, in order to determine the dissipation factor/loss angle, impedance measurement methods (e.g. bridges, resonance techniques, LCR meter) that allow the value of both components of the capacitor equivalent model to be evaluated can be used.

Some digital instruments can directly display the loss angle of the component under measurement.

The loss angle depends on the frequency, but, normally, it is measured at 1 kHz.

5 STRESSES IMPOSED BY MEASUREMENT

In order to correctly measure inductance and capacitance, all the influence parameters have to be taken into account. In particular, the more typical dependency factors that affect measurement results are the following:

- Frequency
- Test signal level
- DC bias
- Physical environment.

The influence of these factors on the measurement process is explained in Agilent Technologies Inc (2000), Bartlett (1992), and Eren (1999).

5.1 Frequency

As said in Section 3, frequency dependency is common to all real-world components because of the existence of parasitics. Not all parasitics affect the measurement but the prominent ones that determine the component's frequency characteristics have to be quantified.

5.2 DC bias

Some capacitors are polarized; therefore, any applied alternating voltage should have a DC component that avoids any polarity violation. Furthermore, the capacitance of some types of dielectric ceramic capacitors varies depending on the DC bias voltage applied.

Analogously for cored-inductors, for which, owing to the magnetic flux saturation characteristics of the core material, the inductance varies according to the DC bias current flowing through the coil.

5.3 Test signal level

Since components are not completely linear, the test signal amplitude may affect measurement results and different considerations have to be made in the case of a capacitor or an inductor.

5.3.1 Capacitor

This dependency varies as a function of the dielectric constant used; consequently, the test signal level has to be chosen near to the working level. Furthermore, when the capacitor is subjected to high operating voltages, if the electric field in the dielectric exceeds the breakdown value, it damages the dielectric permanently. Usually, values of surge voltages are given to indicate the ability of capacitors to withstand high transients.

5.3.2 Inductor

Cored-inductors are current level dependent due to the electromagnetic hysteresis of the core material. This dependency is significant: in fact, when a high-level test signal is applied to an inductor, measurement may be impossible for a certain frequency range. This is because of the nonlinearity of the core material that causes harmonic distortion of the test signal current.

5.4 Physical environment

Physical environments, for example, humidity, magnetic fields, light, atmosphere, vibration, and time may affect the impedance value. Consequently, it is necessary to control these influence parameters.

6 SINGLE ARM MEASUREMENTS

The capacitor and inductor are two terminal components, but, depending on the value being measured, other configurations, allowing parasitic effects to be reduced, are used, namely, for low impedance (high-value capacitance or low-value inductance) measurement, lead resistance and lead inductance in the contact electrodes, test fixture, and cables must be minimized. Toward this aim a four-terminal or a four-terminal pair configuration has to be used to connect the unknown components to the measurement instrument (see Figure 13). The impedance value is defined as the ratio between the voltage across the voltage sensing points (PL, PH) and the current flowing in the supply leads when no current flows (IL, IH) in the voltage path.

Conversely, for high impedance (low-value capacitance or high-value inductance), stray capacitances become significant compared to the impedance under measurement. To constrain the effects of the stray capacitance, a three-terminal configuration is used. An electric shield enclosing the component constitutes the third terminal of the impedance. The effect of the shield is to keep the parasitic impedances constant in the presence of any change in its electric environment, but it does not reduce their values. There are several options available for the connection of the shield, as an example, the solution to Figure 14 is used, in order to prevent the flowing of the leakage current into the ammeter leads. As a consequence, parasitic effects do not influence the measured value.

The three-terminal and four-terminal connections can be combined resulting in a five-terminal connection. With

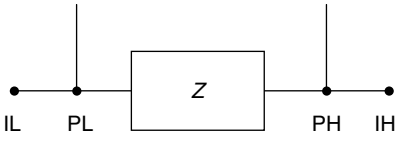

Figure 13. Four-terminal connection.

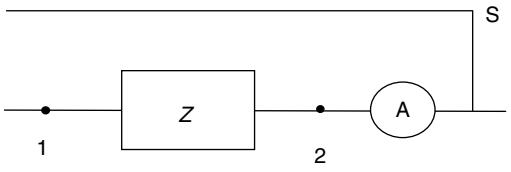

Figure 14. Three-terminal configuration.

this connection, benefits from both connections can be obtained.

For accurate measurements, open/short compensation should be properly performed, in order to compensate the effect of stray admittance and residual impedance respectively, namely, when the instrument input terminals are open, stray admittance is measured, whilst residual impedance is negligible; when the instrument input terminals are shorted, the measured impedance represents residual impedance. These measured parameters are used for correcting the unknown impedance measured value.

Useful suggestions can be found in Osvàth (1992), Coombs (1995), and Agilent Technologies Inc (2000).

7 DIFFERENTIAL MEASUREMENTS

Some capacitive and inductive sensors are differential: namely, the quantity to be measured determines a variation of the reactance value of the sensor. These sensors generally have three terminals; as an example, in some capacitive differential sensors, the central plate moves in response to a physical variable with respect to fixed plates. Consequently, for one measurand change, two capacitances vary: one increasing and one decreasing, obtaining a higher sensitivity (Webster and Pallas–Areny, 1991).

Normally, a bridge measurement configuration, *see also* **Article 127, Unbalanced DC Bridges, Volume 2**, is used with the two impedances placed in adjacent arms; the output from the central plate is zero at the central position and increases as it moves left or right. The major advantage of this configuration is the obtained linear relationships between the measured voltage and the impedance variations.

Considering the bridge of Figure 15, the measured voltage is equal to

$$V_m = \left[\frac{R_1}{R_1+R_2} - \frac{Z_1}{Z_1+Z_2}\right] \times E$$

$$= \left[\frac{R_1}{R_1+R_2} - \frac{\dfrac{1}{j\omega C_1}}{\dfrac{1}{j\omega C_1}+\dfrac{1}{j\omega C_2}}\right] \times E$$

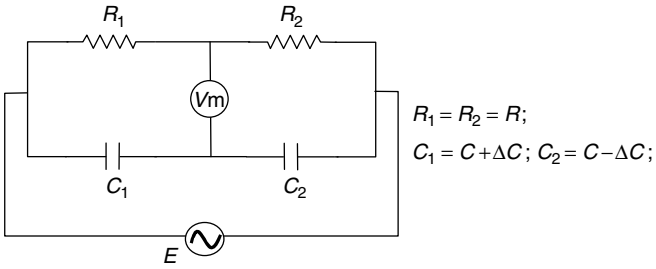

Figure 15. Example of bridge circuit for differential measurements.

$$= \left[\frac{R}{R+R} - \frac{j\omega C_2}{j\omega C_1 + j\omega C_2}\right] \times E$$

$$= \left[\frac{1}{2} - \frac{C+\Delta C}{2C}\right] \times E = \frac{\Delta C}{2C} \times E \qquad (10)$$

Consequently, the relationship between the measured voltage and the capacitance variation is linear. Moreover, all unwanted changes that simultaneously affect both sensors (e.g. change owing to temperature) are compensated thanks to the chosen mounting circuit. Similar circuits can be used for inductance sensors.

8 EXCITATION SOURCES

The methods used for capacitance and inductance measurement, both utilized in analog circuit and digital instruments, require sinusoidal (current/voltage, bridges, resonance) or step (time constant, reflection) excitation signal.

8.1 Sinusoidal test signal

Since the impedance value depends extrinsically and intrinsically on the test signal frequency, the first two requirements for the sinusoidal signal are the stability and accuracy of the selected frequency and the spectrum purity.

Quartz oscillators are normally used. Their oscillation frequency is stable but cannot be varied. Consequently, direct or indirect methods (see Figure 16) are used to implement a high precision frequency variation. Direct synthesis is accomplished by multiplying, dividing, and mixing the oscillator output; the indirect method derives its frequency from one or more phase locked voltage (PLL) tuned oscillators. The stability in both cases is derived from the reference source, but the indirect method allows a wider range of frequency and better accuracy to be obtained.

As for the signal purity, there are three principal contributors that degrade the ideal behavior (the signal spectrum constituted by a single line): harmonic distortion,

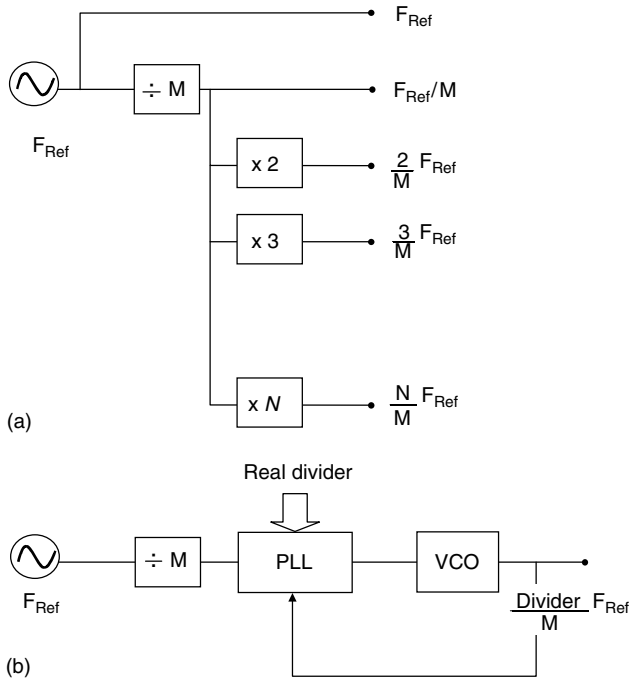

Figure 16. Oscillator: (a) direct synthesis and (b) indirect synthesis.

spurs, and phase noise. A 'harmonic' is a tone whose frequency is a multiple of the sine wave frequency: if harmonics are present, the resulting waveform is not sinusoidal. The harmonic distortion quantifies the harmonic presence (Figure 17(a)). There are several sources of spurs (nonharmonic tones). Examples are unwanted coupling among circuits, distortion produced in the mixer, and so on (Figure 17(b)). The phase noise refers to the sidebands present in the signal spectrum (Figure 17(c)).

A further requirement, for the signal source, is the possibility of adjusting its output power level. In fact, the signal level should be set as high as possible to obtain a good S/N ratio, since a high S/N ratio improves the accuracy and stability of the measurement; however, in some cases, the level should be decreased, such as when measuring cored-inductors. In addition, occasionally, to the AC test signal a DC voltage has to be added.

Generally, a frequency synthesizer is used to meet frequency accuracy, resolution, and stability needs. The amplitude of signal source output is adjusted for the desired test level by an output attenuator.

8.2 Step test signal

The main requirement for voltage step signal is a very low rise-time. In fact, the faster is the step signal, the finer will be the instrument resolution. Furthermore, a control on the output power and on the DC component allows more accurate measurement to be performed.

For more detail on signal generators, see books such as Doebelin (2003) and Coombs (1995).

9 DIGITAL INSTRUMENTS

There are a variety of digital instruments for impedance measurement, which provide the convenience of a direct digital readout and adequate accuracy (Agilent Technologies Inc, 2000; Bartlett, 1992). Moreover, almost all are able to evaluate the complex impedance (real and imaginary part) of the component. In addition, thanks to the presence of a processing unit, they can directly display the complex impedance, its module and phase, the dissipation factor, and the value of the series or parallel equivalent circuit components.

In the following section, the most used digital instruments, grouped on the basis of the measurement principle, are summarized.

9.1 Current/voltage methods

There are a number of instruments (e.g. LCR meter, impedance analyzer) based on the current/voltage method. All foresee the simultaneous sampling of both signals many times per cycle; but they differ on the technique used for the evaluation of the attenuation and the phase shift between current and voltage. Technique for the evaluation of the attenuation and the phase shift between current and voltage include sine correlation, phase sensitive detectors

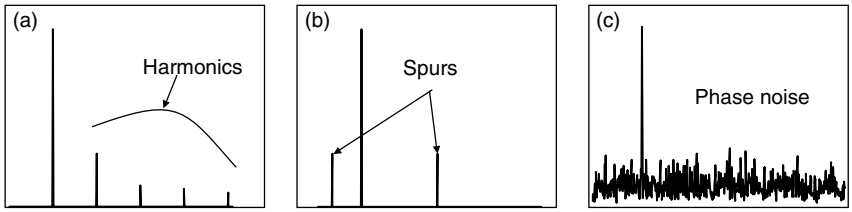

Figure 17. Sinusoidal signal impurities.

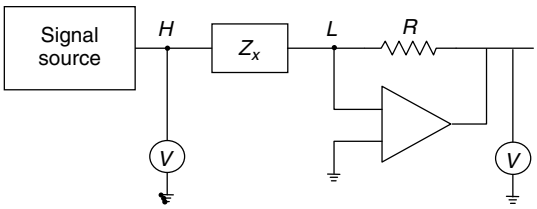

Figure 18. Block diagram of an autobalance bridge.

(lock-in amplifiers), fast Fourier transform FFT techniques, Lissajous figures, and so on.

The so-called auto balancing bridge method is commonly used in modern low frequency, usually within few hundreds of MHz, impedance measurement instruments. In Figure 18, a block diagram of a digital bridge is reported.

The current, flowing through the unknown component, Z_x, also flows through the resistor R. The potential at the L point is maintained at zero volts (thus called a *virtual ground*), because the current through R balances with the Z_x current by operation of the I-V converter amplifier. The unknown impedance is calculated using voltage measurement at the high terminal and that across R.

In practice, the configuration of the auto balancing bridge differs for each type of instrument. Generally, LCR meters in a low frequency range, typically below 100 kHz, employ a simple operational amplifier for its I-V converter. This type of instrument has a disadvantage in accuracy, at high frequencies, because of performance limits of the amplifier. Wideband LCR meters and impedance analyzers employ an I-V converter consisting of sophisticated null detector, phase detector, integrator (loop filter), and vector modulator to ensure a high accuracy for a broad frequency range over 1 MHz. This type of instrument can attain a maximum frequency of 110 MHz. *See also* **Article 202, Current Measurement, Volume 3** and **Article 201, Voltage Measurement, Volume 3**.

9.2 Time constant methods

A capacitance meter essentially measures the charge or discharge time of the capacitor under test. The capacitor is allowed to charge up to an accurate reference voltage, and a gate pulse is started when the capacitor begins to discharge to a lower accurate voltage level through an accurate known resistance. When the capacitor discharges to a lower accurate level, the gate signal is closed. The time interval of the gate voltage is a measure of the RC time constant of the unknown capacitor and the precision resistor. A clock frequency and counter circuit measure the time constant.

Many digital capacitor testers also have the ability to measure inductances. One of the digital L–C meters is unique in that inductances are measured by ringing the current wave shape. The number of cycles an inductor resistor circuit produces after being used is a measure of the inductance.

9.3 Reflection methods

The network analysis, based on reflection methods, is the most used solution at high frequency. A network analyzer can be divided into four main parts: a signal source; a signal separation device to separate the incident, reflected, and transmitted signals; a receiver to convert the microwave signal to a lower intermediate signal; and a signal processor unit to determine the impedance value starting from the measured signals.

10 STANDARDS

The term standard associated with a passive component refers to an object built to reproduce a physical quantity or parameter very accurately.

10.1 Capacitors

These capacitors are very stable, have very low dissipation factors, small temperature coefficients, and very little aging effect Eren (1999).

Standard capacitors can also be fixed or variable.

Fixed capacitors are constructed from interleaved metal plates. The area of the plates and the distance between them are determined and constructed with precision. National metrology institutes maintain a bank of primary standard air capacitors that can be used to calibrate secondary and working standards for laboratories and industry. Generally, smaller capacitance working standards are obtained from air capacitors, whereas larger working standards are made from solid dielectric materials (mica, polymeric, paper, and ceramic).

Variable capacitors are generally made of air or ceramic dielectric materials and consist of two assemblies of spaced plates positioned together by insulation members such that one set of plates can be rotated; usually they are available in decade units.

10.2 Inductors

There are two groups of inductance standards: namely, standards of self-inductance and those of mutual inductance; both types can be fixed or variable Krupka and Geyer (1999).

Standard inductors are made without iron cores and use glass, porcelain, marble, and wood impregnated with paraffin for the coil materials. They are nonmagnetic and provide good insulation and adequate stability. The basic coil forms are flat cylindrical coil of square winding cross-section and toroidal configuration.

Fixed mutual-inductance standards are similar to the self-inductance standards except that they consist of two windings instead of one.

Variable standards of single or mutual inductance are obtained by connecting in series some self-inductors or sections of the secondary winding of a mutual inductor. Furthermore, variometers/inductometers are realized to allow a continuous adjustment of the inductance.

1 DEFINITION OF VIBRATION

Vibration here is the oscillatory mechanical motion of an object. It is a dynamic state. Several other measurable parameters fit under the term vibration.

- Relative position
- Velocity
- Acceleration
- Jerk (the derivative of acceleration)
- Dynamic force.

For each parameter it may be the instantaneous value, average value, or some other descriptor that is needed.

Vibration, in the general sense, occurs as a periodic oscillation, a random movement, or as a transient motion, the latter more normally being referred to as *shock* when the transient is large in amplitude and brief in duration.

2 PHYSICAL FEATURES OF VIBRATION

Vibration can occur in linear or rotational forms of motion, the two being termed *translational* or *torsional vibrations* respectively. In many ways, the basic understanding of each is similar because a rotational system also concerns displacements in space. Translational forms are outlined in the following description. An equivalent rotational system usually exists for all arrangements described.

In vibration measurement, it is important to decide whether a mechanical sensor can be physically attached to the test object – called a *contacting* or *intrusive method*.

If mass cannot be added, then a noncontacting technique is necessary.

Detailed measurement of vibration can be a most complex measuring task. The basic requirement is to determine features of the motion of a point, or more practically an extended object in a three-dimensional space relative to a reference framework; see Figure 1.

A point in space has three degrees of freedom. It can translate in one or more of the three directions when referred to the x, y, z Cartesian coordinate system shown. Rotation has no meaning for a purely point measurement. To monitor free motion of a theoretical point object three measurement-sensing channels are required to capture all three motions so that the vector of direction can be reconstructed.

If the object of interest has significant physical size, it must be treated as an extended object in which the rotations about each of the three axes described above provide a further three rotational degrees of freedom. Thus, to monitor the free motion of a realistic object we may need up to six sensor channels, one for each degree of freedom. These may be built into a single sensor housing and processed to give absolute values.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

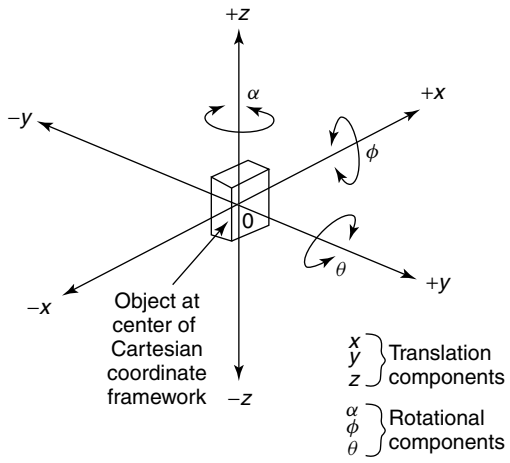

Figure 1. Possible motions of an extended object in space relative to a Cartesian framework.

In practice, some degrees of freedom can be nominally constrained (but are they really?) possibly eliminating the need for some of the six sensor channels. Practical installation should always contain a test that evaluates the degree of actual constraint possible because vibration sensors will usually produce some level of output for the directions of vibration they are not primarily seeking to measure. This is called their *cross-axis coupling*, transverse response, or some such terminology.

In many installations, the resultant direction of the motion vector might lie in a constant fixed direction with time. In such cases, in principle, only one sensor will be required provided it can be mounted to sense in exactly that direction. If not, as is often the case, more than one unit will be required, the collective signals then being combined to produce the single resultant.

The potentially available frequency spectrum of vibration parameters extends, as shown in Figure 2, from very slow motions through frequencies experienced in machine tools and similar mechanical structures to the supersonic megahertz frequencies of ultrasound.

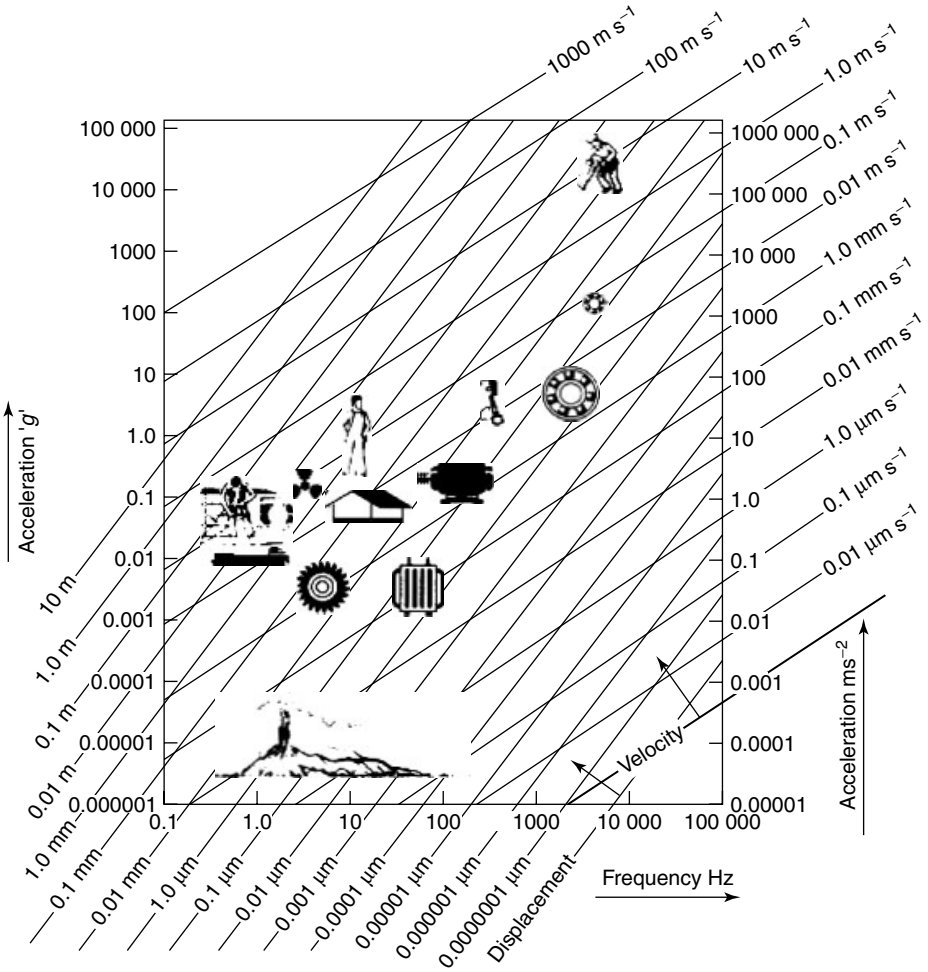

Figure 2. Frequency spectrum and magnitude of vibration parameters. (Reproduced by permission of Bruel & Kjaer.)

It is not possible to cover this range with a single general-purpose sensor. Each application will need careful consideration of its many parameters to decide which kind and model of sensor should be applied in order to make the needed measurement.

The complicating factor in vibration measurement is the distributed nature of mechanical systems that enables the energy causing a vibration to flow from a point. This leads to complex patterns of vibration, requiring care in the positioning of sensors.

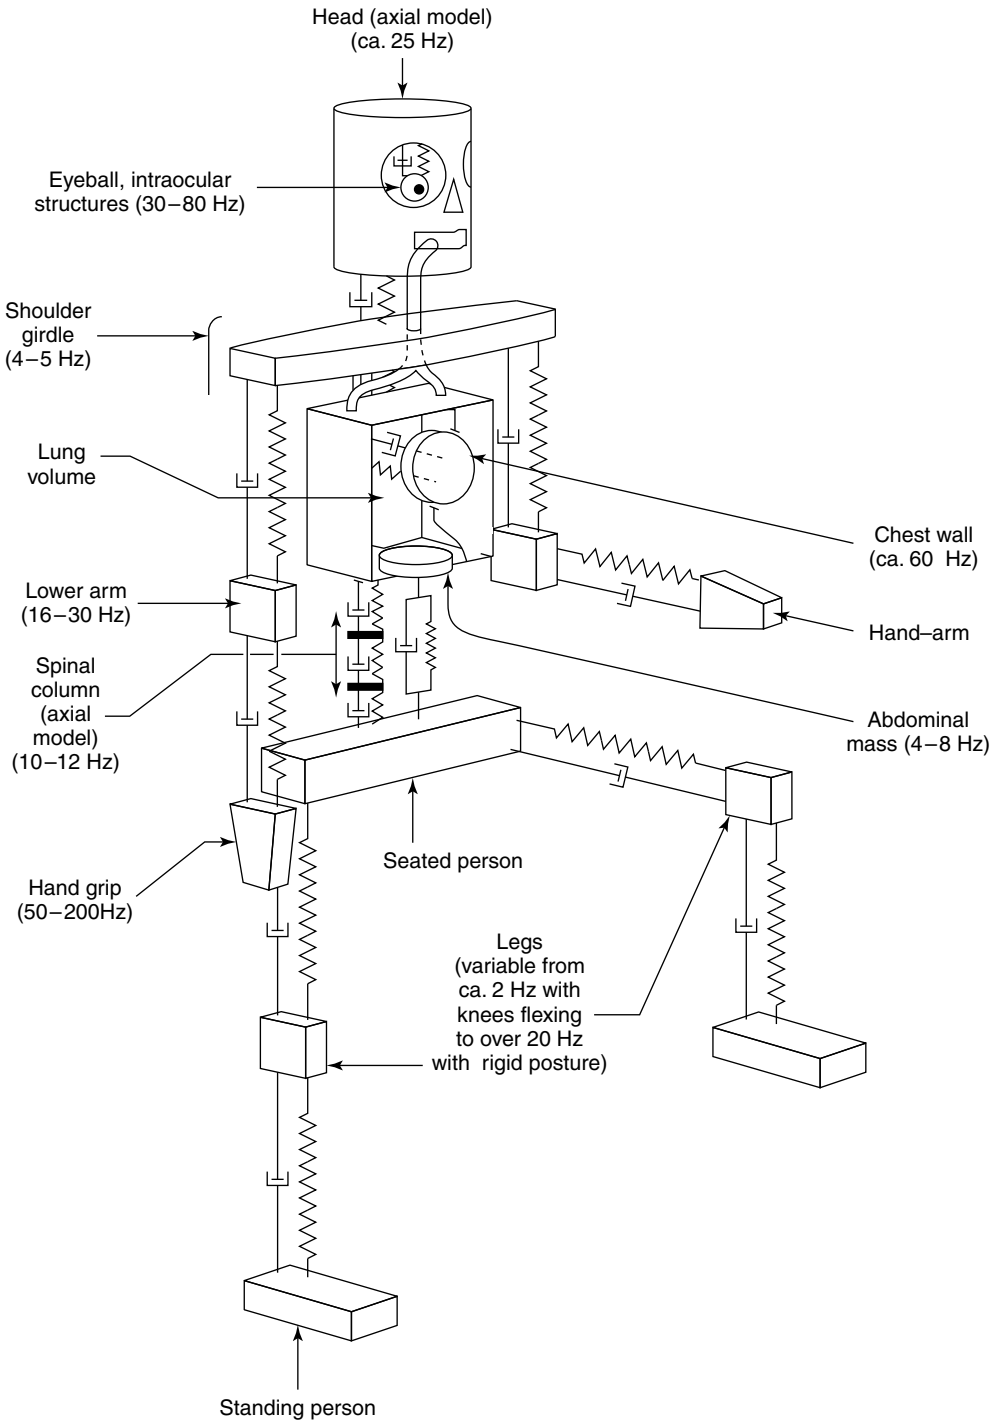

Figure 3. Mechanical systems can be modeled in terms of springs, masses, and dampers; model of the human body. (Reproduced by permission of Bruel & Kjaer.)

3 MATHEMATICAL DESCRIPTION

Mechanical systems, including the human body given as an example in Figure 3, comprise mass, spring compliance (or stiffness), and damping components.

In the simplest case, where only one degree of freedom exists, linear behavior of this combination can be well described using linear mathematical theory to model the time behavior as the result of continuous force excitation, or some initial position displacement – *see* **Article 60, Zero-order System Dynamics, Volume 1**; **Article 61, First-order System Dynamics, Volume 1**; **Article 62, Second-order System Dynamics, Volume 1** for a general analysis of linear motion.

Vibration can be measured by direct comparison of instantaneous dimensional parameters relative to some adequately fixed datum point in space. The fixed point can be on an independent measurement framework (fixed reference method) or can be a place that remains sufficiently stationary because of its high mechanical inertia (seismic system) that holds it relatively constant in position.

The accelerometer is the main vibration sensor – *see* **Article 207, Acceleration Measurement, Volume 3**. It is formed with a mass, and a spring having some damping. If operating in its linear range, it will exhibit a second-order linear system output response, q_o, that is related to an input function, q_i, by the generalized differential equation

$$\frac{a_2 \mathrm{d}^2 q_o}{\mathrm{d}t^2} + \frac{a_1 \mathrm{d}q_o}{\mathrm{d}t} + a_o q_o = q_i \tag{1}$$

For the specific mechanical vibratory system given in Figure 4, this becomes

$$\frac{m \mathrm{d}^2 x_0}{\mathrm{d}t^2} + \frac{c \mathrm{d}x_0}{\mathrm{d}t} - k_s x_0 = q_i \tag{2}$$

where m is the effective mass (which may need to include part of the mass of the spring element or be composed entirely of it), c the viscous damping factor, and k_s the spring compliance (expressed here as length change per unit of force applied).

In practice, these three components may be distributed to a varying extent across an object. Often, they can be adequately considered using the lumped model shown. Where the degree of distribution is significant, then analysis becomes much more complex and is studied using such computer-based methods as the Finite Element Method (FEM).

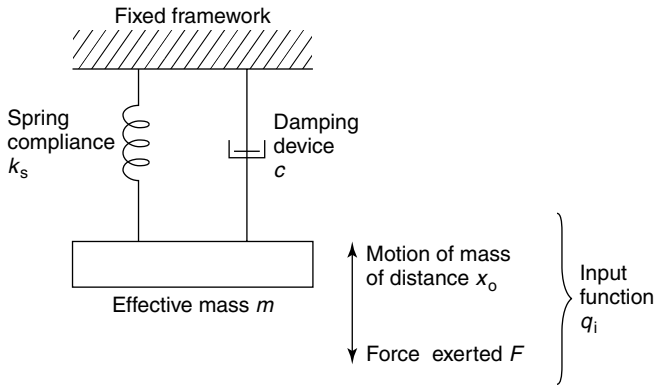

Figure 4. One degree of freedom, spring-mass-damper system model.

4 AMPLITUDE AND FREQUENCY OF VIBRATION

Where the damping effect is negligible, the system will have a frequency at which it will naturally vibrate if excited by a pulse input. This natural frequency ω_n is given by

$$\omega_n = \sqrt{\frac{k_s}{m}} \tag{3}$$

Presence of damping will alter this vibration frequency value, but as the damping rises the system is less able to provide continuous oscillation.

The static sensitivity is given by the spring constant, either as k_s, the spring compliance, or as its reciprocal term stiffness that is expressed as force per unit extension.

The influence of damping is readily described by a dimensionless number, called the *damping ratio*, given by

$$\xi = \frac{c}{2\sqrt{k_s \times m}} \tag{4}$$

It is usually quoted in a ratio form that relates its magnitude with respect to that at $\xi = 1$.

These three important parameters are features of a spring system as a whole formed from the object under test, plus any contributions from an added sensor, any protective cover, and its wiring. The parameters are independent of the input driving function.

Such systems have been extensively analyzed when excited by the commonly seen input forcing functions, the step, impulse, ramp, and sinusoid. A general theory for handling any input function other than these is also available.

In practice the step, impulse, and continuous sinusoidal responses are used in analyses, as they are reasonably easy to apply in theory and in practical use.

5 IMPORTANCE OF DAMPING

From the plots of different damping ratios for a step input given in Figure 5, it can be seen that as the damping factor ξ increases the response to a transient step force input (applied to the mass) can vary from a sinusoidal oscillation at one extreme (called *underdamped*) to a very sluggish climb to the final value (*overdamped*). The nominal value of $\xi = 0.7$ is called the *critical damping* state as this is the fastest rise to its final value.

In the case of a continuous sinusoidal force being applied to the input, the system frequency response varies as shown in Figure 6.

Note the resonance buildup point at ω_n, and that it is limited by the existing degree of damping. Thus, the damping of the system to be measured by addition of the sensor itself, if it is of the seismic kind, can be of importance as a modifier of likely system responses.

A well-known measurement error situation is where an oscillatory response is being plotted with a mechanical chart recorder. If the response of the chart drive mechanism (itself a second-order system) is not adequate, the record is attenuated as the oscillation frequency of the measured input rises. The same effect can arise with poorly set up vibration-measuring systems.

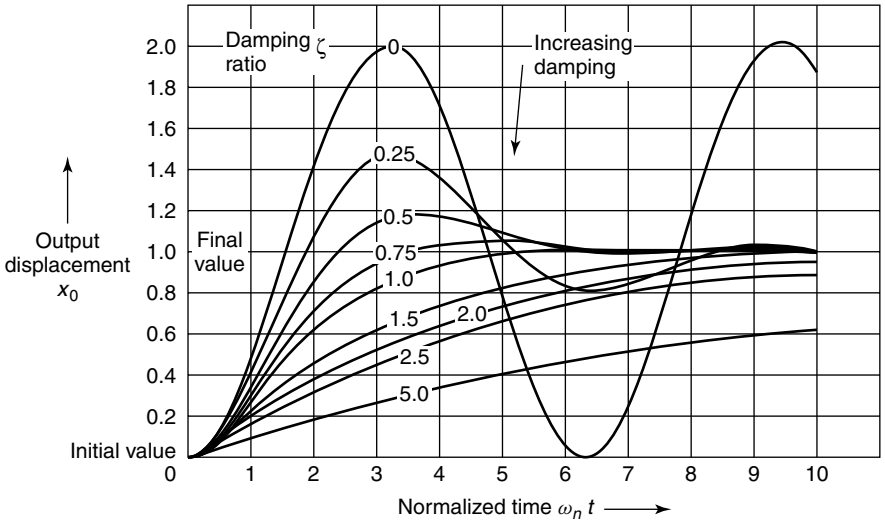

Figure 5. Displacement responses of a second-order system to an input force step.

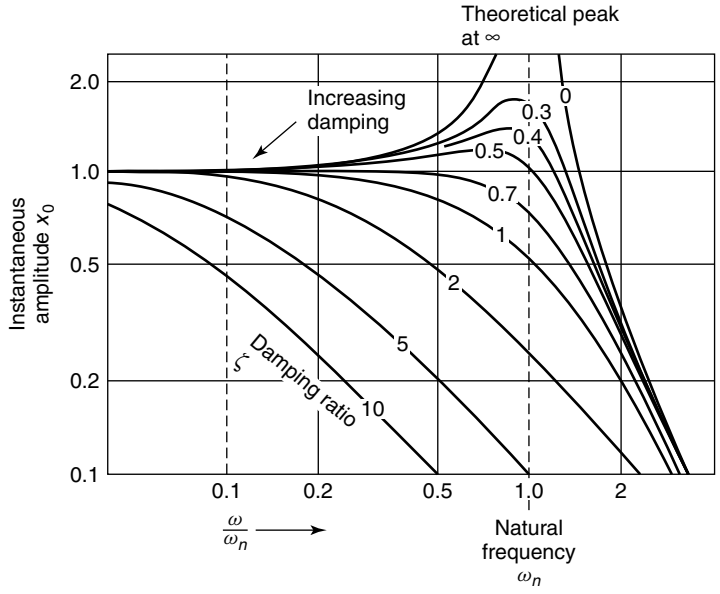

Figure 6. Displacement responses of a second-order system to a continuous sinusoidal force input.

As damping increases, the system response takes on the form of the lower first-order exponential response system, and it cannot oscillate.

The above discussion, with respect to vibration of the measurand is also the basis of understanding the operation of seismic vibration sensors – *see* **Article 208, Amplitude and Velocity Measurement, Volume 3**.

Second-order measuring systems, therefore, will have a natural frequency of vibration. This is the frequency at which they vibrate when given impulse energy that is not overridden by continuous forced vibrations. Thus, a sensing system that is second order and not damped will (because of noise energy inputs) produce outputs at its natural frequency that are not correlated with frequencies occurring in the system of interest. Use of vibration sensors must, therefore, recognize these limitations by selecting designs that position their resonant frequency correctly, and that possess the right degree of damping. Such issues are covered in **Article 206, Practice of Vibration Measurement, Volume 3**.

6 APPLICATION TO VIBRATION MEASUREMENT

In practice, it is also often more convenient to sense vibration by an indirect means and obtain the desired unit by mathematical processing. For example, accelerometers are conveniently used to obtain motional forces (from force = mass × acceleration) and hence stresses and strains. Acceleration signals can be twice integrated with respect to time to yield displacement. Sensors that operate as velocity transducers can yield displacement by single integration.

Integration of data is generally preferred to differentiation as the former averages random noise present to a smaller value compared to the signal, whereas the latter, in reverse, will deteriorate the signal-to-noise ratio.

7 DATA PROCESSING

Signals obtained in vibration measurements will take many forms depending on the vibration characteristics of the object under test. These will include

- repeating pulses,
- sine waves,
- complex waveforms,
- noise.

Their nature can be

- continuous, having the same signal waveform,
- varying waveforms with time,
- modulated amplitudes,
- modulated frequencies,
- short bursts,
- random.

The kinds of information to be extracted from the raw signal can

- be frequency and magnitude of an oscillation;
- be identification of the source of pulses and unwanted noises;
- impact behavior as objects collide or are deliberately impacted;
- be the frequency spectrum of a signal that establishes relative amplitudes and energy distributions; in vibration, spectral analysis is also taken on a spectrum;
- be a prediction of the future condition of equipment.

These signals are used to establish such things as

- wear in bearings,
- noise inside a vehicle,
- dangerous vibrations that can cause mechanical failure,
- response of loud speakers,
- where to attach balancing weights,
- machine health monitoring,
- earthquake research,
- building vibration in wind,
- where to apply noise dampening materials, and so on.

Thus, the signal processing of vibration signals often has to use the full power of signal processing in both the analog and digital domain.

The methods used for general analog and digital signal processing, in general, are applicable – *see* **Article 142, Z-transforms, Volume 3**; **Article 143, DFT and FFTs, Volume 3**; **Article 144, DSP Chip Sets, Volume 3**; and **Article 145, DSP Tools, Volume 3**.

Texts devoted to vibration measurement cover the special methods used, Harris and Piersol (2001), McConnell (1995), Thomsen (2003), and Wowk (1991).

Today, as much as possible this signal processing is carried out in the Digital Signal Processing, DSP domain. These methods are very powerful and make use of dedicated DSP chips and processors. Tool kits are commonly available and have become so widespread that many of the analysis tools are now routinely built into equipment, test sets, and into the vibration sensor system itself.

The sensor, however, is usually analog by nature so the extraction of signals in high noise environments is often essential – *see* **Article 176, Signals and Signal-to-noise Ratio, Volume 3**; **Article 178, Noise Matching and Preamplifier Selection, Volume 3**; **Article 180, Bandwidth Reduction of Baseband DC Signals, Volume 3**;

Article 181, Amplitude Modulated Signals: The Lock-in Amplifier, Volume 3; **Article 182, Boxcar and Signal Averagers, Volume 3**; **Article 183, Correlators in Signal Extraction, Volume 3**; and **Article 184, Photon Counting, Volume 3**.

8 THE LITERATURE ON VIBRATION

There exist many general books on the kinds of transducers that are used to measure the various vibration variables. Some of the titles published have become standard sources carrying forward considerable unchanging knowledge, Bruel and Kjaer (1982), Trampe-Broch (1980), and Harris and Piersol (2001).

Whereas the data processing has changed greatly over the past decades, the sensing principles and nature of vibration remain the same, making older works valid for many aspects of vibration.

Few general instrument reference texts, such as Webster (1999), Dyer (2001), address the subject of vibration as a distinct topic. Relevant material will be found there under such headings as velocity and acceleration measurement, accelerometers, position sensing, and piezoelectric systems.

There are, as would be expected, works entirely devoted to vibration and related measurands. The following will be of value to those who require more than the limited introduction that an article such as this can provide, Crandall (1959), Harris and Piersol (2001), Ling and Shabana (1996), McConnell (1995), Mobley (1999), Smith (1989), Steinberg (2000), Thomsen (2003), Timar (1989), and Trampe-Broch (1980).

The various trade houses that manufacture vibration-measuring and testing equipment often provide extensive literature and other forms of training aids to assist the uncertain user. Their application engineers also offer assistance in vibration system design and set up.

1 MASS-SPRING SENSORS

Many vibration measurements make use of the mass-spring, seismic, sensor system. The seismic sensor is mostly described in the literature as the accelerometer, but this use is not the general case.

Other methods of vibration measurement used include inductive, capacitive, and optical methods that are primarily noncontact displacement measuring methods having a fast response and small range capability – *see* **Article 191, Displacement and Angle Sensors Performance and Selection, Volume 3**. The strain gauge, a contact method of displacement measurement, is also able to deliver vibration data; this is discussed in **Article 192, Strain Sensors, Volume 3**.

Given the appropriate design of spring-mass-damping combination a seismic sensor attached to a vibrating surface can yield displacement, velocity, or acceleration data. The principles and theory of this kind of sensor are covered in **Article 205, Theory of Vibration Measurement, Volume 3**. Unfortunately, the conflicting response needs of the three do not enable a single design to be used for all three cases. It is, however, often possible to derive one variable from another by mathematical integration or differentiation of the data.

The design of vibration sensors can be most sophisticated. Fortunately, the user of vibration sensors rarely becomes involved in its design but must appreciate the design features in order to avoid incorrect use. Minor digressions from best practice can lead to metrological error that is not easy to detect.

Two forms of seismic sensor exist. The first, called the *open-loop sensor* makes use of the motion of a mass moving relative to the support case to operate either a displacement or a velocity sensing transducer. These possess some undesirable properties that often rule them out of practical use.

The second form closes the loop (and is, therefore, referred to as a *closed-loop* or *servo seismic sensor*) using the output signal to produce an internal force that retains the mass in the same relative position with respect to the case, the magnitude of the force needed to effect balance being a measure of the vibration parameter. As will be explained, this method while being more sophisticated is much more effective.

1.1 Open-loop sensors

The fundamental schematic arrangement of the open-loop seismic sensor form is as given in Figure 1. There the mass, spring, damper, and sensing element are clearly identified.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

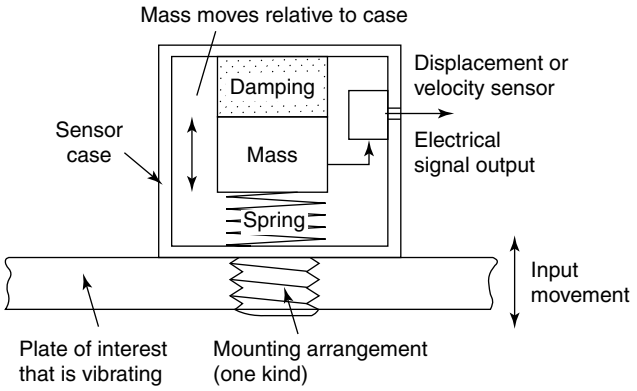

Figure 1. Schematic layout of open-loop, seismic form of vibration sensor.

In a real design, the case and the mass are also part of the system's stiffness and they have to be made adequately stiff. Actual construction can vary widely depending upon how the spring force and damping are provided and upon the form of the sensor used.

The spring element is sometimes produced as a distinct mechanical assembly. Figure 2 is an example made using a flexure-strip spring suspension. Alternatively, perforated membranes, helical coils, torsion strips, disks, helical springs, solid compliable pieces, and the like can be used, *see* **Article 85, Elastic Regime of Design – Design Principles, Volume 2**.

Often the compliance of the mass itself may be the spring element, for example, in the piezoelectric crystal, which also acts as the sensing element and contributes some of the damping needed.

Important design parameters of a spring element used for measurement are its

- compliance
- amplitude range
- fatigue life
- constancy of spring rate with time
- temperature
- influence effects
- suitability to be manufactured and packaged to produce a suitable sensor unit.

All masses have compliance to some extent. This has to be allowed for in the support packaging design or else the case can modify the measurement amplitudes obtained. Except for sensors with the higher natural frequencies, the masses used to form the support case can be regarded as completely rigid compared to the compliance of the spring element.

Design of these sensors uses the best of fine mechanical element design techniques as are covered in **Article 80, Principles of Fine Mechanics – Kinematic and Elastic Designs, Volume 2**; **Article 81, Principles of Fine Mechanics – Systems Considerations, Volume 2**; **Article 82, Kinematical Regime – Members and Linkages, Volume 2**; **Article 83, Kinematical Regime – Fasteners, Bearings, Volume 2**; **Article 84, Kinematical Regime – Rotary Motion, Volume 2**; **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 86, Elastic Regime of Design – Spring Systems, Volume 2**; **Article 87, Elastic Regime of Design – Plates and Bimorphs, Volume 2**; and **Article 88, Error Sources in Fine Mechanics, Volume 2**.

Rotary equivalent forms of the linear arrangement shown in Figure 1 are also available.

Sensing methods that have been used in vibration sensors include the electrical-resistance sliding potentiometer, variable inductance (see, for instance, Figure 2), variable reluctance, variable capacitance, metallic strain gauges (metallic bonded and also unbonded use as shown in Figure 3), semiconductor strain gauges, piezoelectric crystal and magnetostrictive elements, position-sensitive optical detectors,

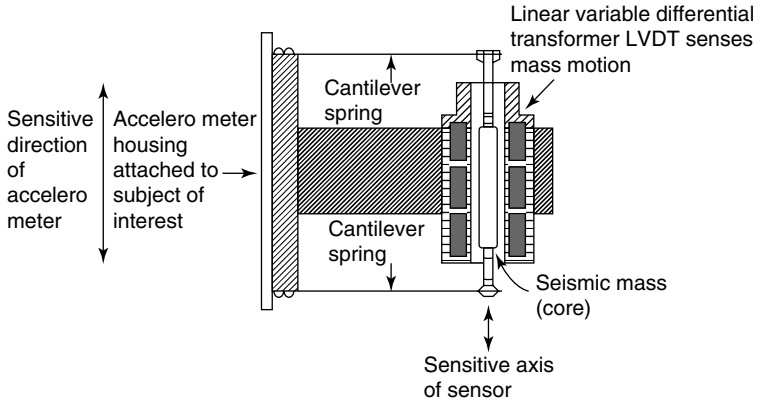

Figure 2. Spring vibration sensor using a parallel flexure-strip spring suspension and inductive sensor of mass displacement.

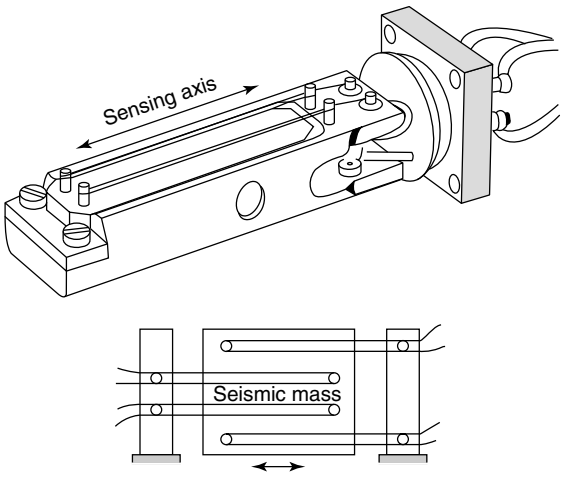

Figure 3. Displacement sensing of mass motion using unbonded strain gauges.

PSD, and electromagnetic principles that can provide direct velocity sensing.

Sensors of the mass-spring form are usually encapsulated and set up to be used as an accelerometer. The encapsulation takes many forms, ranging from miniature units of total weight around just 1 g through to 0.5 kg units where the sensing mass must be physically large to get the response down to low frequencies. Simultaneous measurements in two, or three, orthogonal directions are often required. To meet this need, seismic sensors are made that consist of two, or three, units that are mounted in different directions, as shown in Figure 4.

Temperature invariably affects the metrological performance of sensors and here also it changes, to a varying degree, the characteristics of the displacement sensing method, the spring rate, the damping coefficient, and

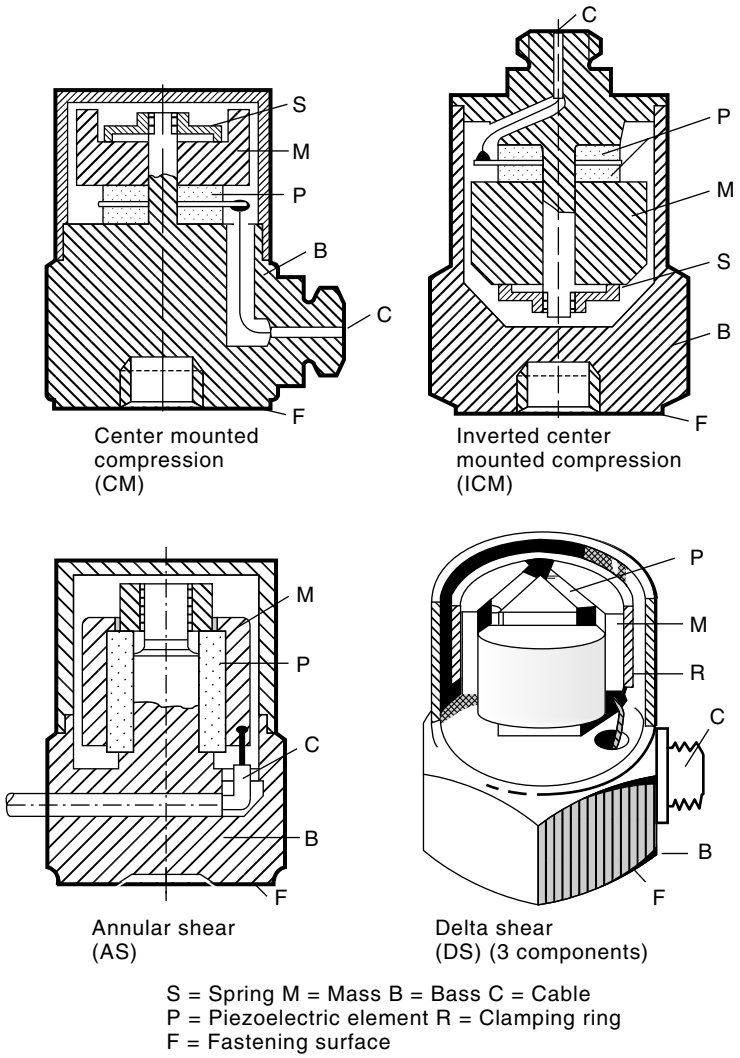

Figure 4. Examples of small size single- and three-axis accelerometers using piezoelectric displacement sensing. (Reproduced by permission of Bruel & Kjaer.)

the case dimensions. Effective design – *see* **Article 85, Elastic Regime of Design – Design Principles, Volume 2** and **Article 88, Error Sources in Fine Mechanics, Volume 2** – can reduce these effects considerably, but to get the best from a design of high performance vibration sensors can require compensation for temperature change.

This is either performed in the electronic circuitry as a correction to the data using a temperature sensor placed accordingly or by incorporating some form of thermomechanical device into the spring-layout to reduce the error at source.

1.2 Servo vibration sensors

The performance of open-loop seismic sensors can be improved with respect to their sensitivity, accuracy, bandwidth, and output signal amplitude by forming the design into a closed-loop operation.

Figure 5 gives the schematic diagram of a simple form of closed-loop system, which is based upon a moving-coil actuator and a capacitance position sensor. This particular kind is described here, as the elements of the closed-loop system are clearly evident.

The inertial mass upon which the acceleration is to be exerted is able to rotate on the end of a freely supported arm. This is attached to the electrical coil placed in the permanent magnetic field supplied by the magnet assembly. Acceleration applied to the mass attempts to rotate the arm thereby causing displacement of the arm. This unbalances the capacitive displacement sensor monitoring the relative position of the pendulous mass. The displacement signal produces an input to the difference-sensing amplifier. The amplifier drives a corresponding electric current into the coil, causing the arm to rotate back to the null displacement position. Provided the loop response is rapid enough, the mass will be retained in a nearly constant place relative to the displacement sensor. Acceleration variations are, thereby, converted to variations in coil current.

In this way, the displacement sensor is used in the preferred null-balance mode – *see* **Article 126, Electrical Bridge Circuits – Basic Information, Volume 2** and **Article 127, Unbalanced DC Bridges, Volume 2** – wherein error of linearity and temperature shift are much reduced. In this design, only the more easily achieved proportionality between coil current and force is important. Servo instruments are further described in **Article 113,**

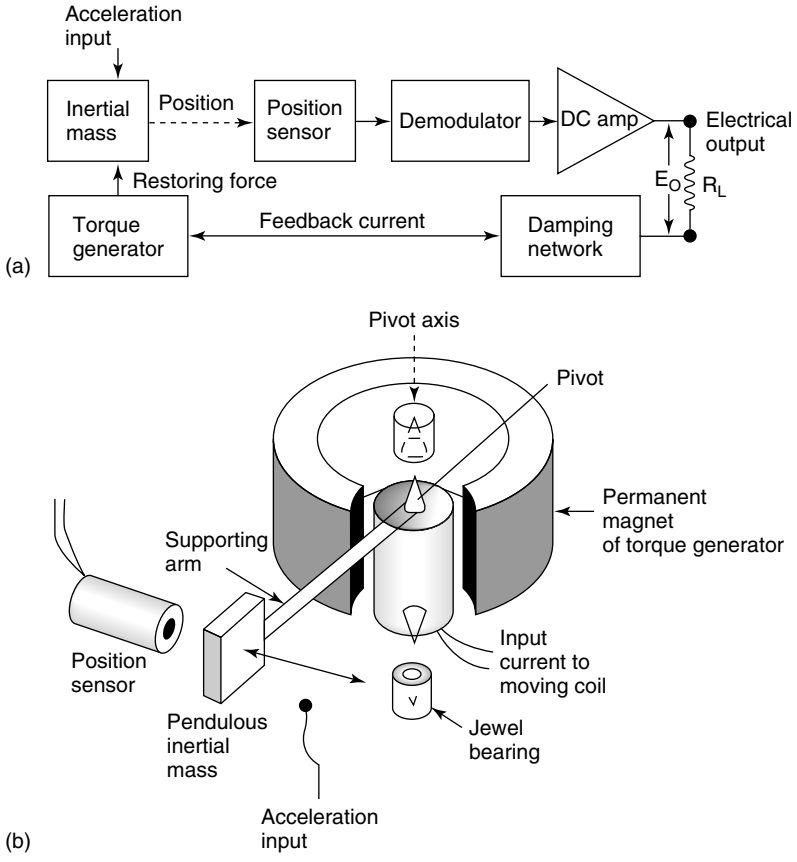

Figure 5. Component layout of a simple form of closed-loop accelerometer.

Force-feedback Sensors, Volume 2, in Jones (1982), and sections in Webster (1999).

Microminiaturization has provided considerable scope to form mass-spring systems in microelectro mechanical systems (MEMS) devices – *see* **Article 85, Elastic Regime of Design – Design Principles, Volume 2**; **Article 163, Uses and Benefits of MEMS, Volume 3**; and **Article 164, Principles of MEMS Actuators, Volume 3**. The complete seismic spring system can be formed at micrometer dimensions, meaning that the mass is very much less than constructions formed of mixed materials as shown in Figure 4.

The spring element is made in many forms – cantilever, double-ended supported beam, vibrating strings, and disks. With such small masses, these are able to operate at much higher vibration frequencies and shock rates than traditional forms.

They are used in many applications such as airbag sensors and also in accelerometer sensors for general-purpose use. Solid-state manufacture, however, is not able to fully compete with the performance of the best traditional forms of sensor because of production variations and parameter drift over time.

2 AREAS OF APPLICATION

When searching for information about a measurement technique, it is often helpful to have an appreciation of the allied fields that use the same equipment. Vibration will be of interest in many different applications, but some can be singled out as the main areas to which commercial marketing forces have been directed to enhance certain sensor characteristics.

2.1 Machine health monitoring

A significant field of interest is that of machine health monitoring, or condition monitoring. Failures in machines can often be avoided by 'listening' to the sounds and vibrations made by the system and making changes early enough. An example is shown in Figure 6, where the position of vibration sensors and their typical frequency spectra are given. Vibration and other forms of sensor are applied to the operating system, first while running in its early life to provide a base calibration for ongoing comparison, and then at periodic intervals during life.

If the frequency/amplitude data (the so-called signature) has changed from the baseline shape, then this can provide diagnostic information, suggesting which component is beginning to fail and when it will reach that state. It can then be conveniently replaced before a major untimely break down occurs. Figure 7 shows the set of equipment commonly needed to set up one of these systems.

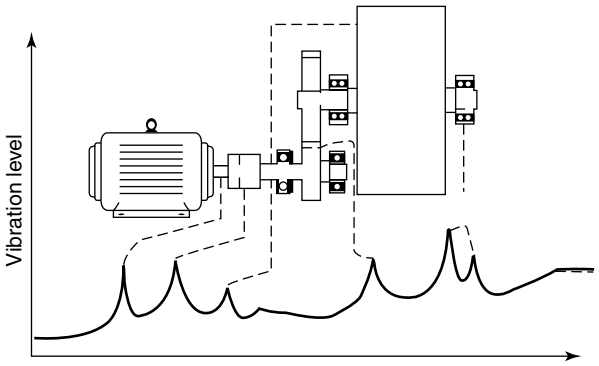

Figure 6. Vibration levels observed are recorded for comparison with a normal frequency spectrum signature.

Further information on machine health condition monitoring can be found in Reeves (1999), Rao (2000), and Mobley (2002).

2.2 Energy exploration

When a very robust sensor is needed, the energy exploration application field is a good place to start looking. The phrase Measurement While Drilling (MWD) has been coined for their in-process measurements.

For this market, ruggedized vibration sensors are needed to withstand the working conditions existing deep down drilling boreholes, wherein shock, high temperatures, and pressure demand much more protection than does a laboratory unit. There temperatures up to 185 °C and shock levels of 1000 g can arise in practice.

2.3 Space

In space navigation and control and inertial grade navigation, some key requirements are small in size and weight, high in reliability, and low in noise levels. As an example, one unit offered for this market has an RMS noise level up to 10 Hz of 0.6 μg.

3 CROSS COUPLING, CABLING, AND AMPLIFIERS

With vibration measurement, it is all too easy to produce incorrect data. This and the following section headings

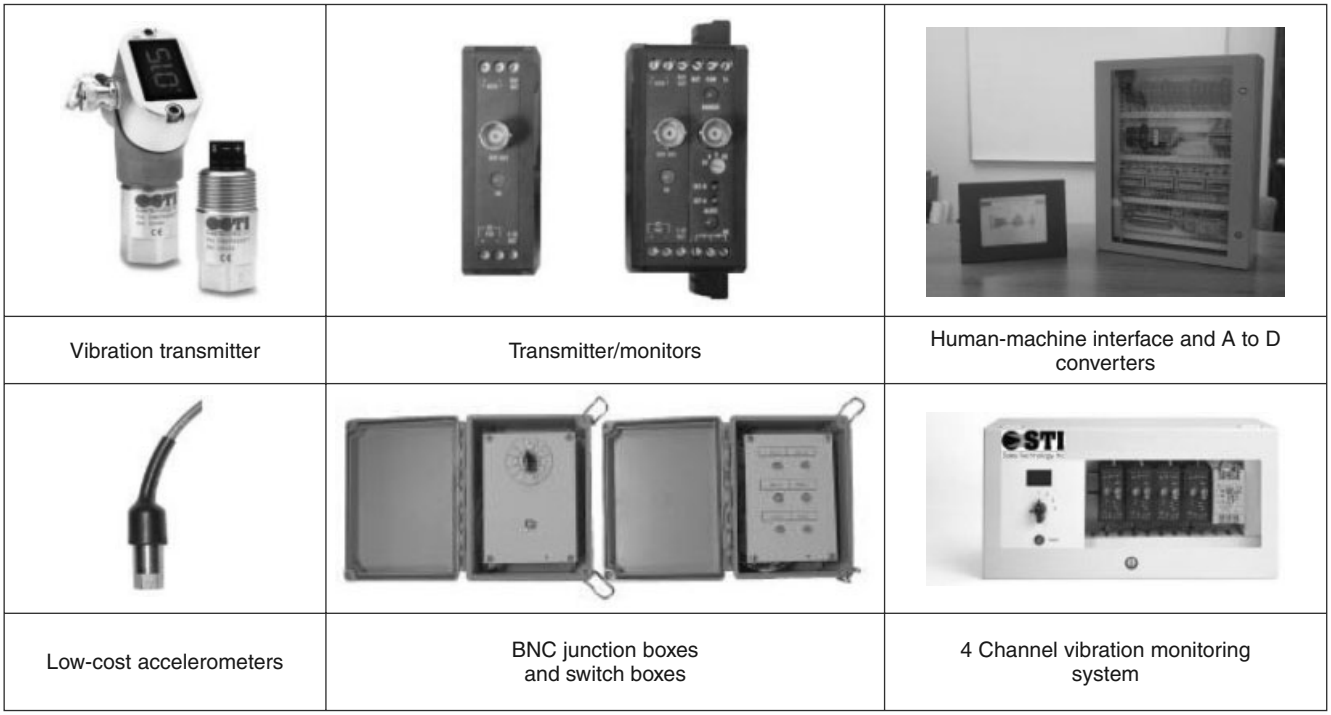

Figure 7. Range of equipment needed to instrument a machine health monitoring system. (Courtesy STI, Sales Technology Inc.)

address several important installation conditions that should be carefully studied for each new application.

3.1 Cross-coupling and cross-axis sensitivity

A vibration sensor is usually designed with one principal measuring axis that is perpendicular to its mounting surface.

Transducers will exhibit cross-axis coupling to some extent. This arises because the sensing system will also be partially sensitive to components of transverse motion. This means maximum sensitivity is not exactly aligned with the axis of symmetry of the mounting case but will be the resultant vector of the cross-axis sensitivity for two orthogonal planes through the center of the sensor.

Best practice measurements include a test that vibrates the sensor in a direction perpendicular to the direction of normal use.

Once the cross-axis sensitivity is established, a value judgment is needed to decide if this error exceeds the allowable limit for the application to hand; special care is needed where complex vibration is involved.

Rotational (torsional) sensitivity may also be important.

These tests can be avoided each time they are used if the sensors are precalibrated for this source of error and, of course, are still within calibration. An upper limit of 3 to 5% is offered by suppliers as the upper bound; most sensors will calibrate under this magnitude.

Sensors that have no cross-axis sensitivity quoted should not be used until it is established that it does not impact on the measurement needed. For example, conducting a comparison test of two objects placed into the same vibratory conditions will not be influenced much by any cross-axis sensitivity, unless its value is way above the 5% level, whereupon the signal could become saturated and thus limited.

In the case of a triaxial accelerometer (three units mounted together on each of the three-dimensional axes), any high magnitude cross-axis output sensitivity can corrupt data if the principal motion is at right angles to the base.

A quality sensor will be calibrated and usually marked on the sensor with a red spot placed at the point of maximum transverse sensitivity. A polar plot of the output might also be supplied that is tied into the position of the spot.

3.2 Coupling compliance

The compliance of the bond made between the sensor and the surface it is mounted on must be adequately stiff. If not, the surface and the sensor form a system that can vibrate in unpredictable ways. As an example, an insufficiently stiff

mounting can give results that produce much lower frequency components than truly exist. In extreme cases, the sensor can be shaken free as it builds up the unexpectedly low-resonance frequency of the joint to dangerous amplitude levels. As a guide, the joint should be at least ten times stiffer than the sensor mounting so that the resonant frequency of the joint is well above that of the sensor.

3.3 Cables and preamplifiers

Certain types of sensors, notably the piezoelectric (PZT) kind, are sensitive to spurious variations in capacitance and charge. Sources of such charges include the tribo-electric effect occurring in the bending motion of the vibrating connecting cables; mechanical stress in the material produces electrical signals as the cable bends. Special kinds of connecting cable are used that allow for movement of the cable.

Another source of potential error arises from any varying relative humidity, as this can alter electric field leakage; this becomes important when designing long-term installations.

The preamplifier stage is also important to get right for the PZT sensing element has very high output impedance. Such issues are largely overcome by integrating the preamp with the sensor unit.

4 INFLUENCE EFFECTS ON THE SENSOR

Ideally, the sensor should operate in a perfect environment wherein sources of external error, called *influence parameters*, are insignificant – *see* **Article 16, Reduction of Influence Factors, Volume 1**.

In vibration sensing, possible influence effect error sources include temperature variation of the sensor, possible magnetic field fluctuations (especially at radio frequency), and existing background acoustic noise vibrations. Each of these might induce erroneous signals.

A good test for influence parameters is to fully connect the sensor system, observing the output when the measurand of interest is known to be at zero level, such as by clamping it in a very stiff manner. The output will then comprise internal noise of the sensing channel and internal defects, such as system mains supply hum, plus contributions of any impacting influence effect. If the sensing noise is not observable, then more gain is needed to ensure the test is valid.

Where practical, the important error inputs can be systematically varied to see the sensor response. Many a vibration measurement has finally been seen to be worthless because some form of influence error turned out to be larger than the true signal from the measurand. Vibrations apparently occurring at electric mains frequency (50–60 Hz) and harmonics, thereof, are most suspect. Measurement of mechanical vibration at these frequencies is particularly difficult because of the need to separate true signal from influence error noise signals.

5 LOADING BY THE SENSOR

Vibration sensors contain mass. As this mass is made smaller, the sensitivity of the sensor usually will be reduced, so units with larger mass are more desirable. However, addition of mass to a vibrating system can load the mass of that system, causing shifts in frequency and amplitudes from the normal state of operation.

For this reason, manufacturers offer a wide range of attached type sensors. Provided the mass added is, say, 5% or less of the mass of interest, then the results will usually be acceptable.

Cables can reduce the overall mechanical compliance by forming a mechanical bridge from its holding down point to the sensor case. This can corrupt the true signal magnitude. They can also increase the damping, thereby shifting frequencies.

Where a system is particularly sensitive to external loading, the use of noncontact, fixed-reference methods may be the only way to make a satisfactory measurement.

6 DURATION OF USE OF SENSOR IN TESTS

When damping of a structure is very small, as in many mechanical structures, the time taken for a resonance to build up to its peak value is long. When using forced vibration frequency scanning to seek resonances, it is important not to sweep the excitation input frequency too rapidly.

As the Q Factor rises, the time to reach full amplitude of the resonance can take many minutes in large-size mechanical systems.

One often-used test is that for obtaining the vibration frequency spectrum of a machine tool as its tool post is excited, as it would be when machining metal. The time taken to sweep through the complete spectrum can take many tens of hours. The issue then is to be certain that the scanning and measuring equipment maintains its declared specifications over such long continuous periods of operation.

Some tests are best done in the time domain using an impulse or a step increase, the time domain data resulting being transformed into the frequency domain. Impulse tests need special care to avoid occurrence of zero shift and

ringing errors, caused by nonlinearities, in electrical aspects of amplifiers and the sensor for which residual mechanical strain can also arise if the spring element is overloaded during such shocks.

7 AMPLITUDE CALIBRATION

Here, attention is drawn to the issue of sensor calibration. Whereas the fixed-reference methods do have some relevance in the practical measurement of vibration, the need for a convenient fixed datum is very often not met.

Static amplitude (displacement) is easily calibrated using a standardized micrometer, displacement sensor, or optical interferometer. The motional element of the sensor is deflected a known amount and the output measured.

Note that some types of accelerometer, such as the PZT type, are not DC-connected and thus have zero static output at any position; there has to be motion present, at a relatively rapid rate, to generate an output.

Dynamic calibrations may be made either by comparison, using a technique of known accuracy and frequency response, or by using a calibrated vibration generator.

Dynamic amplitude of the non-DC-connected types requires use of a noncontacting method of measuring the

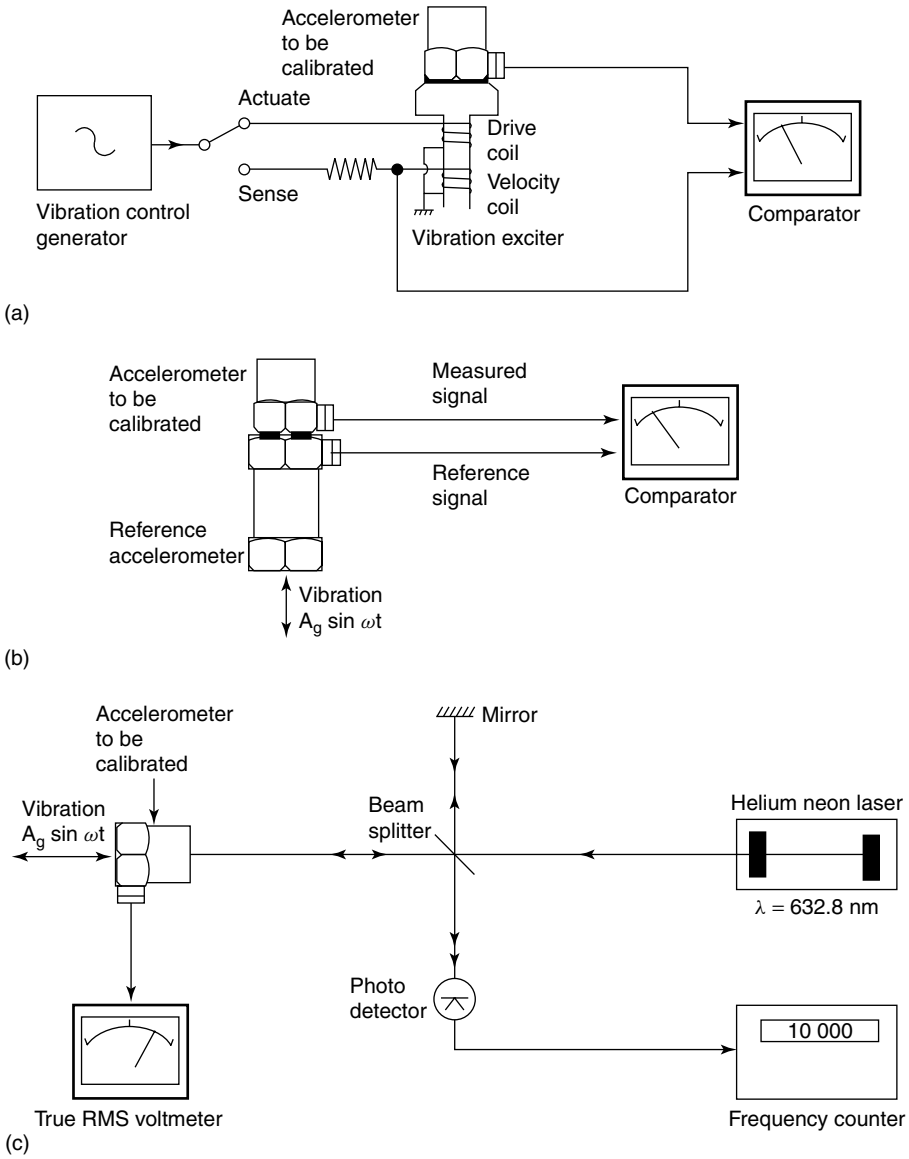

Figure 8. Calibrating accelerometers. (a) Calibrated vibration exciter shaking accelerometer at calibrated levels; reciprocity method. (b) Back-to-back calibration of a calibrated accelerometer against one to be calibrated; comparison method. (c) Absolute measurement using optical interferometry.

displacement taking place. This is viewed on a display screen along with the sensor output. Viewing the signal is recommended as this allows the wave shape to be checked. Once the nature of the signal has been validated, the data can be processed into more directly useful charts or numerical values.

8 ACCELEROMETER CALIBRATION

Figure 8 shows outlines of three methods of calibrating accelerometers and other vibration-measuring sensors. Calibration is normally performed at $500\,\mathrm{rad\,s^{-1}}$. Figure 8(a) is the reciprocity method. A calibrated vibration exciter shakes the accelerometer at calibrated levels. Figure 8(b) shows the comparison method. This uses back-to-back calibration of a calibrated accelerometer against the one to be calibrated. Figure 8(c) is a noncontact method using optical interferometry; this gives an absolute not relative determination.

Other methods that can be used are to subject the accelerometer to accelerations produced by the Earth's force. Simple pseudostatic rotation of an accelerometer in the vertical plane will produce accelerations in the 0 to ± 1 g range (g is used here for the Earth's acceleration value). Larger values can be obtained by whirling the accelerometer on the extremity of a rotating arm of a calibrating centrifuge. Alternatively, it can be mounted on the end of a hanging pendulum.

9 SHOCK CALIBRATION

Short-duration acceleration, as produced by impact, requires different approaches to calibration. Accelerations in such applications as explosive devices can exceed 10 000 g and last for only a few milliseconds.

A commonly used method is to produce a calibrated shock by allowing a steel ball to free-fall on to an anvil on which is mounted the sensor. This method provides an absolute calibration but, as with all of the methods described, has uncertainties associated with the practice of the method. In this case, one source of error is caused by the difficulty of releasing a ball to begin its downward path without imparting a small negative or positive velocity at time zero.

Another method uses a long pendulum carrying a large mass. This is allowed to swing down to impact on the object carrying the sensor under test. Physical consideration allows the rate of energy release to be calculated and thus the impact forces, but it is not that accurate. It is useful for relative calibrations where the sensor under test and a standardized unit are mounted in the same impacted object.

10 FORCE CALIBRATION

Static forces can be calibrated by applying dead weights to the force sensor, the weights being calibrated masses.

Dynamic forces arising in vibration can more easily be determined using the relationship force = mass × acceleration. A shaking table is used to produce known accelerations on a known mass. In this way, the forces exerted on the accelerometer can be determined along with the corresponding output voltage or current needed to produce transducer sensitivity constants.

At the completion of any calibration, the determination and support data about the method of calibration must be recorded according to the organizations policy. This ensures traceable results in the event of dispute arising later – *see* **Article 45, Calibration Process, Volume 1**. The period between calibrations is covered in **Article 46, Calibration Interval, Volume 1**.

Space does not permit greater explanation; detailed accounts of vibration sensors are available in the literature, Trampe-Broch (1980), Bruel and Kjaer (1982), Smith (1989), Timar (1989), Wowk (1991), McConnell (1995), Ling and Shabana (1996), Mobley (1999), Steinberg (2000), Dyer (2001), Harris and Piersol (2001).

1 USE OF SEISMIC SENSORS

Of the many measurands that appear under the heading of vibration – *see* **Article 205, Theory of Vibration Measurement, Volume 3** – the most measured is acceleration.

The fixed-reference method of measuring acceleration is rarely used, determinations being made more easily with the mass-spring, seismic form of sensor. This method uses the inertial mass as a short-term fixed reference: the test object moves whilst the mass stays sufficiently stationary in space for short periods of time.

For the seismic sensor system, the mass and the spring compliance are both fixed entities. Consideration of the $F = m \times a$ (force = mass × acceleration) law with spring compliance being linear shows that displacement of the mass relative to the sensor case is proportional to the acceleration of the case.

The curves, plotted in Figures 5 and 6 of **Article 205, Theory of Vibration Measurement, Volume 3** for sinusoidal input of force to a second-order system, are applicable for obtaining the output response curves of accelerometers using displacement sensing. In this case, the vertical axis is interpreted as the relative displacement of the mass for a given acceleration.

2 OPTIMAL USE OF SEISMIC SENSOR FOR ACCELERATION MEASUREMENT

The curves, Figure 6 in **Article 205, Theory of Vibration Measurement, Volume 3**, show that a seismic sensor will provide a relatively constant output sensitivity representing sensor acceleration from very low vibration frequencies up to around 0.5 of the natural frequency of the spring-mass arrangement used. Further, the damping ratio can be optimized at around 0.5–0.6 and electronic compensation added (if needed) to raise the upper limit a little further than the undamped resonance point.

At first sight it might, therefore, appear that a single, general-purpose design could be made having a very high resonant frequency. This, however, is not the case for the deflection of the spring (which is a major factor deciding the system output sensitivity) is proportional to $1/\omega_n^2$. In practice, this means that as the upper useful frequency limit is extended, the sensor sensitivity falls off rapidly. Electronic amplification allows low signal output to be used but with additional cost to the total measuring system. As the signal level falls, added amplification will also increase the noise level.

At the very low frequency end of the accelerometer response, the transducers become ineffective as

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

accelerometers because the accelerations produce too small a displacement to be observed against the background noise level. By increasing the mass, the units can be made to respond to lower frequencies – *see* **Article 208, Amplitude and Velocity Measurement, Volume 3**.

3 TYPICAL ACCELEROMETERS

As a guide to the range of capability available, one major manufacturer's catalog for traditional accelerometers not made in the more recent microminiature form, offers accelerometers with sensitivities ranging from a small $30\,\mu V\,ms^{-2}$ through to $1\,V\,ms^{-2}$ with corresponding sensor masses of 3 g and 500 g and useful frequency ranges of 1000 Hz and 0.2 Hz. As the mass increases, the frequency range falls or, conversely, to get low frequency response the mass has to increase. Sensors have been constructed for higher frequencies using the MEMS, microelectro mechanical system technology as is discussed in Section 7. A selection of traditional accelerometers is shown in Figure 1.

The many constraints placed upon the various performance parameters of a particular seismic sensor can be represented in numerical terms on a single chart, Figure 2, Harris and Crede (1976).

It is not always appreciated that all materials exhibit some degree of mechanical compliance and that the modulus of elasticity is a property of the material, not the way it is used. Elastic structures, such as helical springs, are used to increase the compliance to suit a particular task – *see* **Article 85, Elastic Regime of Design – Design Principles, Volume 2**.

To obtain the stiffness needed, accelerometer springs may occur as stamped rigid plates, as flat cusped spring washers, or even as a sufficiently compliant clamping bolt. In applications of piezo-sensitive materials, use is often made of the compliance of the material itself.

Figure 1. A range of accelerometers is required to cover the full needs of vibration measurement. (Courtesy, Honeywell Sensing and Control.)

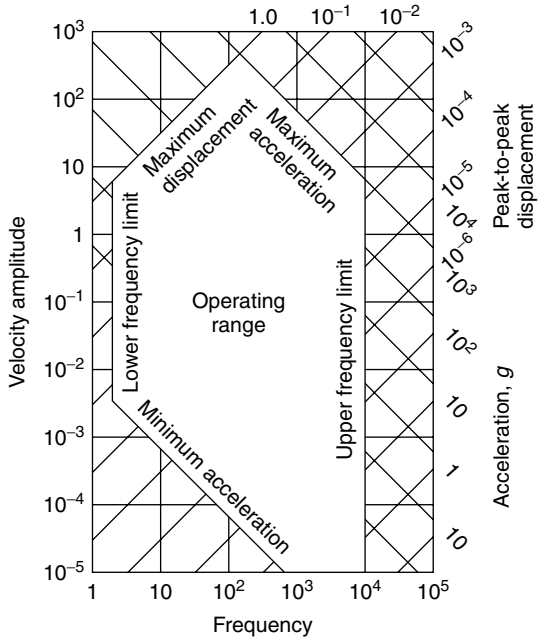

Figure 2. Useful linear operating range of an individual seismic vibration sensor can be characterized with this type of chart.

4 RESPONSE TO COMPLEX WAVEFORMS

The response curves given in Figures 5 and 6 of **Article 205, Theory of Vibration Measurement, Volume 3** relate to seismic sensors excited by sinusoidal signals. To predict the behavior of a certain sensor, such as an accelerometer, used to measure other kinds of continuous or discrete waveforms, it is first necessary to break down the waveform into its Fourier components – *see* **Article 29, Relationship Between Signals in the Time and Frequency Domain, Volume 1**. The response, in terms of amplitude and phase, to each of these is then added to form the resultant response.

It has been stated above that damping can be added to extend the useful bandwidth of a seismic sensor. However, where this is done it can increase the phase-shift variation with frequency; that is, the components are sensed with different phase shifts to the undamped case and thus the reconstructed signal is no longer a fully faithful replica of the original motion.

A signal comprising many frequencies will, therefore, produce an output that depends largely on the damping and natural frequency values of the sensor. A number of responses can be plotted, such as shown in Figure 3 from Harris and Crede (1976). Generally, the damping value for best all-round results is that near the critical damping value of 0.7.

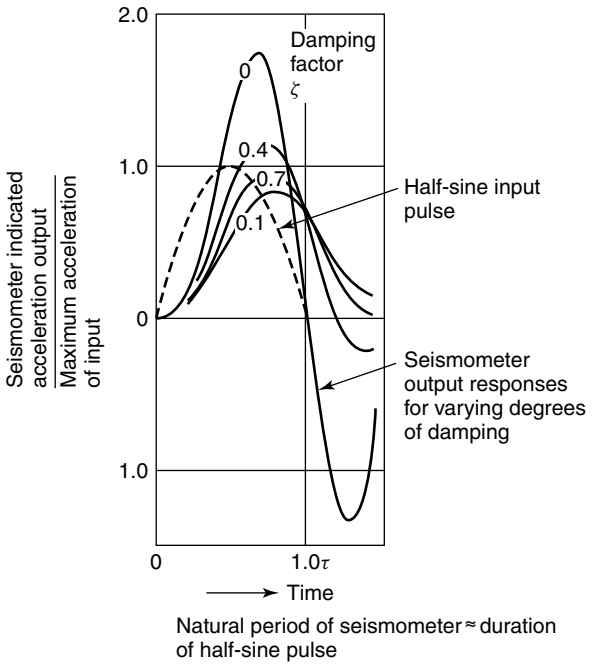

Figure 3. Example of response, at various damping-factor levels, of a seismic accelerometer to a complex forcing input-half-sine wave of similar period to that of the natural resonance period of the sensor.

5 THE PIEZOELECTRIC SENSOR

Numerous sensing methods have been devised to measure the motion of the mass in a seismic sensor. Discussed here is the most commonly used PZT, piezoelectric transducer method: others are described in Norton (1969), Oliver (1971), Webster (1999).

Force applied to certain crystalline substances such as quartz produces, between two surfaces of a suitably shaped crystal, an electric charge that is proportional to that force. This charge is contained in the internal electrical capacitance formed by the electrically insulating, high-dielectric material and its two conducting surfaces deposited on each face.

The first approximation descriptive mathematical relation for this effect is

$$q = a \times F \times K_s \tag{1}$$

where q is the electrical charge generated by force, F (in Newtons), applied across the faces of a piezoelectric device having a mechanical compliance of spring rate K_s (mN^{-1}) and a material constant a (of dimensions $C\,m^{-1}$).

The constant a, depends on many factors including the geometry of the crystal, position of electrodes, and material used. Typical materials now used (natural quartz is less sensitive and, therefore, less applicable) include barium titanate with controlled impurities, lead zirconate, lead niobate; many others are available but their composition is a trade secret.

The usual PZT sensing material is made from loose powder that, after shaping, is fired at a very high temperature. While cooling, the blocks are subject to an electric field that traps a polarization.

Sensitivity of PZT materials is temperature-dependent on the charge sensitivity and the capacitance value, both of which alter with temperature. These effects do not follow simple linear laws. Such materials have a critical temperature, called the *Curie point*. They must never be taken above it for it will then destroy the properties as calibrated.

The Curie point varies from 120 °C for the simpler barium titanate forms ranging up to values close to 600 °C. For the interested reader, detailed explanation can be found in **Article 118, Ultrasonic Sensors, Volume 2**, Bruel & Kjaer (1976), Endevco (1980), Harris and Crede (1976), Trampe-Broch (1980), and in the detailed information provided by the makers of PZT materials in application notes, and many Internet Web sites.

To read the charge of a PZT sensor as it is vibrated by the subject under test, an electronic amplifier is used that converts charge magnitude to a voltage equivalent. It is the nature of this sensing system that it provides no DC response; when stationary there will be no output other than system noise.

In practice, the PZT sensors used to measure acceleration can be operated down to around 0.1 Hz, dependent on the amplitude to be measured. With a natural resonant frequency that can be made relatively very high (up to 100 000 Hz in some designs), PZT sensors provide a useful frequency range that can cover most vibration needs. The system response, however, relies not only on the sensor but also upon the cables and the preamplifier used with the PZT unit – *see* **Article 206, Practice of Vibration Measurement, Volume 3**.

To produce the charge, the PZT material can be used in its pure compression, shear, or bending modes. This method of sensor design is amenable to the combination of three units giving the three translation components of vibration. Figure 4 in **Article 206, Practice of Vibration Measurement, Volume 3** gives some examples of commercially available PZT accelerometers.

The PZT material itself contributes only of the order of 0.03 of the required critical damping factor. Without additional damping being added, PZT transducers should not be used too close to their resonant frequency – see Figure 6 in **Article 205, Theory of Vibration Measurement, Volume 3** – or an error will arise.

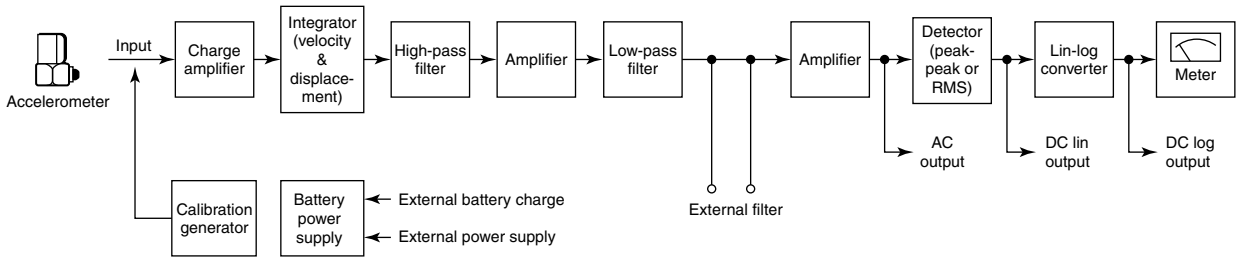

Figure 4. Block diagram of vibration measuring system showing functions that may be required. (Reproduced by permission of Bruel & Kjaer.)

Mounting arrangements within the case also can add additional damping. Some use an additional spring to pre-compress the PZT element so that it remains biased in compression under all working amplitudes: this makes for more linear operation.

Typical sensor element charge sensitivities range from 0.003 up to $1000\,\mathrm{pC\,m\,s^{-2}}$, implying that the following preamplifier units will also need to vary considerably.

6 AMPLIFIERS FOR PIEZOELECTRIC SENSORS

An amplifier for reading out the state of the PZT sensor is one that has very high input impedance, an adequate frequency response, and low output impedance. Adjustment of the gain, filtering action and integration time variously yield velocity and displacement sensing – *see* **Article 208, Amplitude and Velocity Measurement, Volume 3**.

Figure 4 is a typical analog conditioning system incorporating most features that might be needed. Some of the block functions often use digital processing methods, but the charge amplifier still needs to be analog.

The charge amplifier could be designed to see the sensor either as a voltage or a charge (current) source. The latter is preferred for, using modern electronic-feedback operational amplifier techniques, the effect of cable, sensor, and amplifier capacitances can be made negligible (which in the voltage-reading method, is not the case). Cable length is, therefore, of little consequence. This is justified as follows.

Figure 5 is the relevant equivalent circuit for a PZT accelerometer connected to an operational amplifier (the preamplifier) via a cable. It includes the dominant capacitances that arise in practice.

It can be shown (see Trampe-Broch (1980), for example) that the use of feedback in this way with a very high amplifier gain A gives

$$e_0 = \frac{S_q a}{C_f} \tag{2}$$

This shows that the user need only define the sensor charge sensitivity S_q and the feedback capacitance C_f in order to be able to relate output voltage from the preamplifier to the acceleration of the sensor.

If the preamplification shown here is carried out in the sensor housing, then a special connection cable having reduced triboelastic effect is not needed from the sensor to the fixed cable support. Many cases, however, cannot place the preamplifier in the sensor housing as that adds mass to the accelerometer, which may not be acceptable.

7 MICROACCELEROMETERS

Microelectronic forms of the accelerometer made by the MEMS technology – *see* **Article 162, Principles of MEMS, Volume 3**; **Article 163, Uses and Benefits of MEMS, Volume 3**; and **Article 164, Principles of MEMS Actuators, Volume 3** – can be remarkably small compared with traditional forms.

For example, one unit reported at the R&D stage by researchers at Seoul University, Kwang *et al*. (2003), has a proof mass of 15 μg that is $870 \times 1027 \times 50$-μm thick. The accelerometer's natural frequency at 14 kHz implies operation up to 7 kHz or a little more if compensation is used. The spring elements supporting the lateral capacitive comb type sensor are 4-μm thick and 250-μm long. The sensing gap is 3 μm.

Another development unit, Figure 6, shows one of the many forms of suspension used to support the proof mass, LLNL (2000).

8 SIGNAL CONDITIONING IN MICROACCELEROMETERS

The signal processing used in the MEMS forms of accelerometer can be very sophisticated as it allows integration of the system blocks needed to produce a ready to use robust output signal. These are

A good study, readily available to consult on the Internet is Kulah *et al*. (2004). Their account shows the intricacies and level of achievement possible with fully integrated MEMS units.

Further details of MEM systems are found in **Article 162, Principles of MEMS, Volume 3**; **Article 163, Uses and Benefits of MEMS, Volume 3**; and **Article 164, Principles of MEMS Actuators, Volume 3**.

Signal conditioning is covered in the Section on Data Acquisition Systems starting at **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**.

9 MEASUREMENT OF SHOCK

Shock is a sudden short impulse of applied force that can generate very large acceleration (100 000 g can arise) that is not recurrent. It can be regarded as a once-only occurrence

of a vibration waveform, although sometimes it is used to describe a short burst of oscillation. Examples are objects subject to explosions and impacts arising because of a collision.

Understanding the formalized behavior of a given vibration sensor to a shock situation requires Fourier analysis of its response to a truncated wave shape, that is, a discontinuous wave. The mathematics becomes more complex.

Theoretical considerations lead to the generalization that as the waveform becomes more like a single pulse of high magnitude and very short duration, the frequency band of the sensor must be widened if the delivered output is to be a satisfactory replica of the actual input vibration parameter.

Thus, the accelerometer used to measure shock must preferably possess sufficient flat bandwidth below its natural frequency point. Special DSP, digital signal processing methods allow measurement signal extraction beyond this criterion using advanced algorithms.

Fidelity of output increases as the period of the natural frequency of the sensor becomes shorter than the pulse length. An idea of the variation of responses with natural frequency and damping is available in graphs given in Harris and Crede (1961). An example can be found in Figure 3.

Here also the very large force exerted on the transducer (force = g × mass of sensor) requires a total design that recognizes the need to withstand large transient forces without altering the mechanical residual strains in the sensor system during measurement. Mounting circuitry on the sensor itself adds more room for induced shock error, for the silicon chips can be shock sensitive.

Well-designed shock sensors can accurately measure single half-sine-wave pulses as short as 5 μs. Some amount of ringing in the output is usually tolerated in order to provide measurement of very short duration shocks. Compensation to increase the bandwidth is also useful in extending the range of operation.

1 MEASUREMENT OF DISPLACEMENT WITH A SEISMIC FORM OF SENSOR

Where a fixed reference method is inconvenient, one of several forms of seismic sensor system can be employed as follows.

It is sometimes more convenient to mathematically integrate the signal from a velocity transducer making use of a fixed reference framework.

Integration is a sound process, for the noise present is reduced by the integration, averaging process. The integral of an acceleration measurement is velocity and the second integral is then displacement. Thus, an accelerometer can be used to measure displacement under certain conditions.

2 THEORY OF DISPLACEMENT MEASUREMENT USING A SEISMIC SENSOR

The second-order equations of motion, given in **Article 205, Theory of Vibration Measurement, Volume 3**, for a mass that is moving relative to a fixed reference frame (the mode for studying the movement of vibrating objects) can be reworked to provide response curves relating the displacement amplitude of the seismic mass to that of its case.

Figure 1 is the family of response curves showing the effects of different operating frequency and the degree of damping. Given that the case is moving in sympathy with the surface of interest, it can be seen, from the curves, that for input vibration frequencies that are at least twice the natural frequency of the seismic sensor, the measured output displacements will be a true indication (within a percent or so) of the movements of the surface. This form of seismic displacement sensor is also often called a *vibrometer*.

It is possible to lower the frequency of operation by using a damping factor with a nominal value of 0.5. This, however, does introduce more rapidly changing phase-shift error with frequency, which may be important. The lowest frequency of use above which the response remains virtually flat is seen to be where the various damping factor curves approach the horizontal line equal to unity ratio, to within the allowable signal tolerance.

Given that the chosen damping remains constant and that a system does follow the second-order response, it is also possible to provide electronic frequency compensation that can further lower the useful frequency of operation by a useful amount.

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

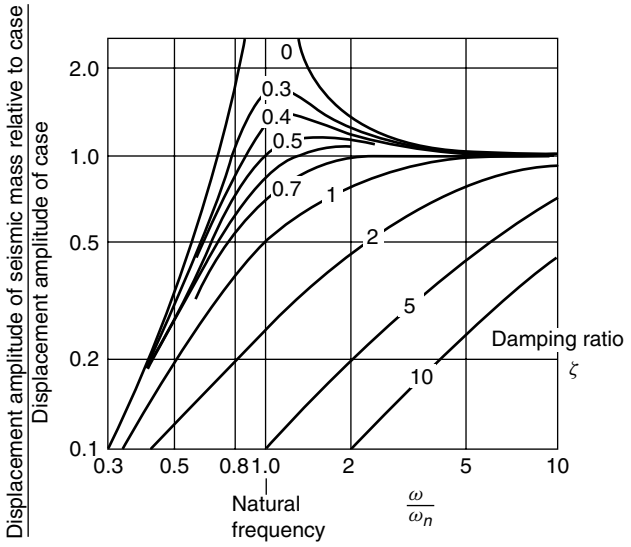

Figure 1. Responses relevant to displacement and velocity sensing with seismic sensors.

Thus, to directly measure displacement amplitudes with a seismic sensor, it must have a natural frequency set to be below the lowest frequency of interest in the subject's vibration spectrum. In this mode, the seismic mass virtually remains stationary in space acting as a fixed reference point. It is also clear that the seismic sensor cannot measure very low frequencies, for it is not possible to construct an economical system having a low enough resonant frequency, as that needs massive masses and very springy suspensions; these are the features of the large strong motion seismometers that measure ground and building motion and displacement during earthquakes.

3 PRACTICE OF DISPLACEMENT MEASUREMENT USING A SEISMIC SENSOR

The curves are theoretical perfections and would apparently indicate that the seismic sensor, in this case, will have flat response to infinite frequency. This is not the case in practice, for, as the frequency of vibration rises, the seismic sensor structure begins to resonate at other frequencies caused by such mechanisms as the spring vibrating in modes other than the fundamental of the system.

Given that the low frequency range of accelerometers can extend down to less than 1 Hz (*see* **Article 207, Acceleration Measurement, Volume 3**), it may often be more practical to twice integrate an accelerometer signal, in order to derive displacement amplitude, rather than to make use of a direct-reading displacement seismic sensor design.

4 MEASUREMENT OF VELOCITY

This section covers simple traditional forms of velocity sensor used to measure the short motions of solid objects that will possibly also need acceleration determination.

The many other forms for measuring velocity (i.e. flow speeds) of gases, liquids, solids, and mixed-phase flows are covered in the following articles:

- Laser Doppler velocimeters and other flowmeters – **Article 187, Flowmeter Selection and Application, Volume 3**
- Angular and displacement devices in general – **Article 191, Displacement and Angle Sensors Performance and Selection, Volume 3**; **Article 192, Strain Sensors, Volume 3**; **Article 193, Specialty Displacement and Angle Sensors, Volume 3**.

Other methods, such as digital encoders, Hall-effect toothed wheel sensing, tuning forks, magnetohydrodynamics, and optical correlation are variously covered in Webster (1999), Norton (1969), and Dyer (2001).

5 THEORY OF VELOCITY MEASUREMENT

The prime method used to generate a direct velocity signal makes use of the law of electromagnetic induction. This gives the electrical voltage e generated as N turns of an electric coil to cut magnetic flux ϕ over time t as

$$e = -N\frac{\mathrm{d}\phi}{\mathrm{d}t} \tag{1}$$

Velocity sensors are thus self-generating; they produce a voltage output that is proportional to the velocity at which a set of turns moves through a constant and uniform magnetic field.

Many forms of this kind of sensor exist. The commonly used, moving-coil arrangement comprises a cylindrical coil vibrating inside a magnetic field that is produced by a permanent electromagnet. A commonly seen arrangement, Figure 2(a), is that typified by the reversible-role, moving-coil, loudspeaker movement. For this form, the output voltage V_{out} is given by

$$V_{\text{out}} = -Blv \times 10^{-9} \tag{2}$$

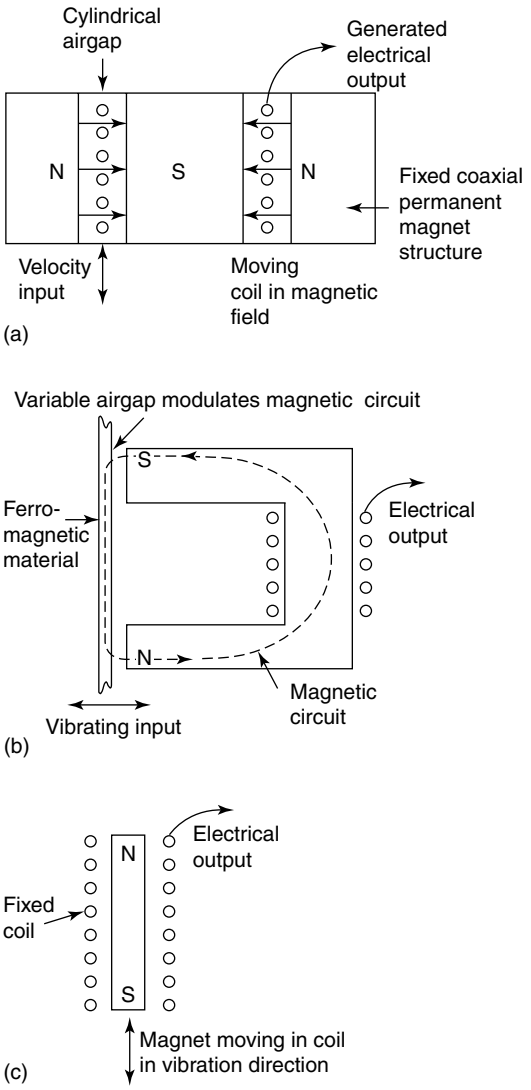

Figure 2. Forms of velocity sensor. (a) Moving coil, (b) variable reluctance, (c) moving permanent magnet.

where B is the flux density in Tesla, l the effective length of conductor contributing in total flux-cutting, and v the instantaneous velocity, expressed in ms^{-1}, of the coil relative to the magnet. Given that the design ensures that the magnetic field is uniform in the path of the fixed conductor length, the sensor can provide very linear output.

6 PRACTICE OF VELOCITY MEASUREMENT

These were the sensors adopted in early seismology studies because of their inherently high output at relatively low velocities. The coil impedance will generally be low, enabling signals with good signal-to-noise ratios to be generated along with reduction of error caused by variations in lead length and type. They are, however, large with resultant mass and rigidity problems. Many of the forms tend to have relatively low resonant frequencies (tens of hertz), which restricts use to the lower frequencies. It will be apparent that these sensors cannot produce signals at zero velocity because no relative movement occurs to generate flux-cutting.

A second variation of the self-generating velocity sensor, the variable-reluctance method, uses a series magnetic circuit containing a permanent magnet to provide permanent magnetic bias. A part of this circuit, the armature, is made so that the effective air gap is varied by the motion to be monitored. Around the magnetic circuit is placed a pickup coil. As the armature moves, the resulting flux variation cuts the coil, generating a signal that can be tailored by appropriate design to be linear with vibration amplitude. This form of design has the advantage that the armature can readily be made a part of the structure to be monitored, as shown in Figure 2(b). This version is not particularly sensitive, for the air gap must be at least as large as the vibration amplitude. As an example, a unit of around 12-mm diameter, when used with a high magnetic permeability moving disc set at a 2-mm distance, will produce an output of around $150\,mV\,ms^{-1}$.

A third method uses a permanent magnet as the mass supported on springs. One example is shown in Figure 2(c). Vibration causes the magnet to move relatively to the fixed coil, thereby generating a velocity signal. This form can produce high outputs, one make having a sensitivity of around $5\,V\,ms^{-1}$.

Where a fixed reference cannot be used, this form of sensor, instead of a displacement sensor, can be built into the seismic sensor arrangement. In such cases, the vibrating seismic sensor will then directly produce velocity signals. These will follow the general responses given in Figure 1. From those curves, it can be seen that there is a reasonably flat response above the natural frequency, which is inherently quite low.

1 THE NATURE OF CHEMICAL MEASUREMENTS

Chemical analytical instrumentation, used to determine the chemical properties of materials, relies heavily upon optical, chemical, and physical techniques combined with electronic signal control and processing, and also fine mechanics to structure the optical components in relation to the source, detectors, and materials under test.

This class of measuring system, although based upon the same physical and mathematical processes as other classes, incorporates a wide range of arrangements used in its own characteristic way. It, therefore, provides another facet of measurement system design that often involves concepts and methods unlike those found in physical measurements. Of particular relevance to chemical measurement is the fact that the initially sensed signal energy levels are usually very low and therefore require sophisticated signal processing to extract the meaningful information – see the articles under the section on **Signal Recovery in the Presence of Noise**.

This class of measurement system concerns considerable information about numerous variants. The field, overall, had adopted numerous types of transducers. This along with its varied application, makes a general comprehensive account virtually impossible in even one reasonably large text. This article, and **Article 210, Optical Transducers for Chemical Measurements, Volume 3**; **Article 211, Mass Spectrometry, Volume 3**; **Article 212, Chromatography, Volume 3**; and **Article 213, Electrochemical Measurements, Volume 3** introduce the main methods.

Texts on analytical measurements tend to concentrate on specific areas within the class: for example, on spectroscopy; on chromatography; on air or water purity; on process control instruments; and on principles of instrumental analysis. Given at the end of this article is a bibliography of representative works.

Chemical measurement presents significant problems of clear classification and definition. The discipline as a whole is large enough to support separation into areas that are themselves regarded as disciplines, examples being organic and inorganic chemistry. Locating information on how measurements are done can be difficult because all or part of many measuring methods overlap these divisions.

Also covered are those sensing systems that can distinguish and/or quantify different chemical species, that is, establish what chemicals are present in a sample and to what extent, usually as a percentage of the sample size. This is an empirical definition, and excludes, for instance, the chemical applications of density measurement.

Chemists classify their techniques partly by field of application, and partly by principle. The classification given here is restricted to the principle of the transducer; this will sometimes lead to problems. For example, one could

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

entertain a lengthy debate on the principle of mass spectrometry itself.

Space permits only a condensed summary to be provided on commonly available chemical transducers. Where possible, references are given to industrial measurement applications of chemical transducers, although these are not extensive compared with laboratory applications. A systems approach to chemical measurement will greatly assist in taking laboratory methods to the industry. Global markets for analytical instruments are the subject of regular surveys; they are a major sales line. The latest links to these services – they can be expensive – can be found on the Internet using search words 'analytical instrument market survey'.

2 CHEMICAL PROPERTIES OF MATTER

To provide a basis for considering chemical measurements, what is first needed is a quick overview of the basic nature of matter and its properties in the perspective of measuring their presence in a sample.

As is common knowledge, matter is composed of atoms formed into elements. The comparatively small size of these basic entities gives the first clue to the difficulties in sensing them. They are all very small in terms of the things into which they are built, and to which measurement is mostly needed. Typical atom sizes are in the subnanometer region. They are all but impossible to view via an image of them. They are investigated as a collection that is present in a sample and the measurement is expressed as a percentage of the whole. The electron microscope can just about detect some of them, but only in strictly controlled conditions of ultrahigh vacuum and after illuminating them in their steady state with an electron beam. Rarely do chemical detectors actually 'see' the individual mass parts at this level. The electron has a rest mass of 9.10×10^{-30} kg – it is particularly small as an entity to observe.

The mole is the unit of substance; it is commonly used in chemistry. It is defined as the amount of substance that contains as many elementary entities as there are atoms in 0.012 kg of carbon.

Atoms divide into a central mass called the *nucleus* that is formed by protons and neutrons, around which rotate a varying number of electrons. These elemental entities occur only as certain sets of combinations that are ordered according to the well-known periodic table of the elements. For example, the hydrogen atom has just 1 electron, 1 proton, and zero neutrons. The table is available from several sources using the search words 'chemical periodic table'; including http://www.chemicalcelements.com.

There are some 112 known elements; this number is still rising slowly because of the discovery of others in the nuclear isotope group. Since the discovery of radio isotopes in the early twentieth century, it has also been found that there are many subatomic particles other than those classically described above for the atom.

The number of electrons for an element follows a strict relationship as shown in the periodic table. The number is related to the assembly of nucleus parts, the neutron and the proton. The proton is 1836 times larger in mass than the electron, but that is still small for direct imaging or sensing as a lone item.

The manifestation of the electron is alternatively described as a charged particle spinning around the nucleus of the atom – the corpuscular theory. Alternatively, it is also considered as a statistically existing energy source that is present at a point only for some of the time – the wave theory. These alternative models of the electron are used as they best fit a particular situation; no single model has yet been developed that explains all of the known properties.

A key issue regarding the measurement of chemical properties is that all components of matter involve energy as well as mass. Again, the basic quantities involved are very small. Electrons possess the same fixed value of negative electrostatic charge of nominally 1.6×10^{-19}. As an ampere is a flow of one coulomb per second, it needs a vast number of them to cause measurable currents even when detection has only current levels less than a microampere available. The nucleus is positively charged to hold the element together by the forces of attraction.

The quantity of charge associated with electrically charged particles of known magnitudes therefore follow the discrete values for elements according to the number of electrons present in the element. The magnitude of forces that bind matter together follow known laws, making measurement feasible if the physical construction of material can be detected.

It is possible to temporarily add or remove electrons in the dynamic state of matter. These *ions*, as they are called, alter the charge levels again affording the opportunity to determine specific elements.

Moving up to large chemical entities, the elements combine in numerous ways to form molecules. With over 100 elements available in numerous combinations for forming molecules, and these in turn, forming sets of molecules and mixtures (those materials wherein the chemical components are not converted but retain their state), it is easy to see why there are innumerable chemical molecules and mixtures in existence.

To end this primer on the nature of matter, it is also important to remember that a material can exist in one or more of four states:

- solid
- liquid

- gaseous
- plasma.

The electrical properties of electrical conduction vary in these different states. With increase in temperature, most pass from solid to plasma state passing through each as the temperature rises. Some do not follow the ascendancy rule. Carbon, an element, for example, passes from solid to gas and cannot be liquified. These variations are often used to enable an analysis.

3 MEASURABLE CHARACTERISTICS OF CHEMICAL VARIABLES

Thus, measurement of chemical species in a sample can be carried out using one or more of many different principles that are based on energy, mass separation, and force sensing. The individual regions of the electromagnetic energy spectrum, ranging from longwave microwaves up through the infrared, visible, ultraviolet X-ray to the shorter radiation frequencies are also useful for their varying properties and effects on materials. It will be found that chemical instrumentation will fit one of the following classes:

- Makes use of direct measurement of an existing physical variable (passive measurement);
- Requires some kind of conversion to render the chemical parameter observable before a direct physical measurement can be employed (active measurement).

In general, a chemical measurement is usually made by detecting the differences between two or more entities; far less so is the absolute value determined. Given a baseline value as a standard, it becomes feasible to measure the makeup of a sample of matter. This leads to many possibilities. Table 1 lists some common methods.

Measurements can be made by observing the steady state levels of parameters of the sample, as with sensing the color of diluted blood to estimate the red cell level, this being done as a comparison against a reference material as the standard. Alternatively, they can be made by observing the properties of a chemical reaction that is taking place between the sample and a reacting medium, such as in the use of an ion sensitive probe. This kind of measurement consumes energy or mass in its operation, so it will have a given interval of usefulness unless the additional materials are replenished.

The time given to make an observation can often be very short; some being as short as a microsecond. To overcome this, if the reaction can be repeated continuously, the source is continuously reexcited and lockin amplifiers are used that retrieve the signal – *see* **Article 184, Photon Counting, Volume 3**.

Table 1. Examples of types of chemical measuring instruments.

Type of detection	Example of instrument class
Mass of atoms present in sample	Mass spectrometry
Energy of reradiation, after energy added at another spectrum location	Fluoroscopy
Energy emitted by sample as energy added	Emission spectroscopy
Energy absorbed as energy added	Absorption spectrophotometry
Conversion of energy spectrum by adding energy	Raman spectrometry
Migration rates of chemical species through a separation medium	Chromatography (liquid and gas)
Electrical charge variations in voltage and current terms	Voltametry, ion selective probes. Polarography.
Color value without addition of reagent	Colorimetry
Color change with addition of reagent	Colorimetry

The amplitude of the signals produced can be extremely small, some methods literally counting the photons (packets of energy) being emitted. Photons are energy packets given off when an electron jumps between orbits of an element. The threshold for this to happen is nominally 1.2 eV, meaning that with 1000 V as the electric potential the energy level is just 1000 electron charges per photon.

In general, a sound knowledge of the appropriate chemistry is needed to create chemical instruments and this has to be coupled with well-understood signal processing in the physical electrical regime. Interpretation of data then needs sound chemical appreciation. Crossing all of these discipline boundaries needs care and special experience.

Finally, in this overview is covered the need to appreciate that chemical species rarely exist in isolation from others. Even the purest materials will possess some level of impurity. The various methods available are rarely able to detect the required variable while ignoring all others present in the test. Many methods can give biased results depending on the type and magnitude of the contaminant present.

It is essential to first appreciate what spread of species are expected to be available in a sample, and then to set up a measurement system that will work properly with those of no interest being present. This also raises the converse problem, that of missing a key parameter because a suitable test was not done for it.

In the measurement of mineral assays, for instance, the analytical instruments chosen need to have their settings set to look for the species of interest. Not doing the right

tests can be a major failing; there was once the case of an assay for gold that did not recognize that there might be (and there was in high proportion!) antimony present in the sample whose economic value far exceeded that of the percentage of gold.

The usual activities of a chemical instrument are as follows:

- prepare the instrument to make it ready to measure;
- calibrate the instrument;
- prepare the sample ready for presentation/coupling to a sensing detector.

Up to this stage, the main techniques used are mechanical, hydraulic, chemical, and heat. Electrical methods and signal processing is not used other than to control any automation of these stages.

For example, a pollution gas monitor for a given gas will first purge its intake tubes and test chambers. A reference gas is then admitted to calibrate the sensor. The sample is then passed in and the values are recorded.

Then comes the following stages:

- presentation to the sensor;
- processing of signals in real time or off line.

These stages are more akin to physical instrument design.

In some cases, purging and calibration will be applied at the end of the test to set down drift reference points at each end of the time-varying process in order to allow removal of drift in the final determination.

A useful reference to have on hand when making these low-level chemical measurements is Armutat (2004).

4 TERMINOLOGY

Chemical entity description uses a notational method developed to describe the many forms of matter and is thus based in the physical description of energy. Some say it is all physics and nothing else! However, it has needed to constantly develop its own shorthand notation to cater for the great variety of structures and interactions involved. These groups are as follows:

- Names of chemical elements
  Example: The notation 'Ag' is the shorthand symbol for the element silver. This, and the other elements notations are found defined in the period table.
- Molecule description
  Example: The shorthand notation AgCl represents the molecule combining silver and chlorine in a given way and proportion – called '*silver chloride*'. Some molecules are so complex, possessing such a long name, that a shorthand form is used to reduce the writing needed, for example, 'polyvinyl chloride' has the acronym name of PVC.
- Relationships taking place in chemical reactions
  Example: When two or more chemical species are placed together in given circumstances they can react to form other species and by-products. An example reaction used as a standard reference half cell in electrochemical measurements is

$$\mathrm{AgCl} + \mathrm{e} \longrightarrow \mathrm{Cl} + \mathrm{Ag}$$

This means that each molecule of a large number of silver chloride molecules in the reference electrode has an electron added for which the result, after dynamic energy effects have died out, is that the silver and the chlorine are no longer combined as a molecule and are now free in their elemental forms. The electron provides the energy to break the bonding forces keeping the two together.

Interpretation of notations and equations, and what they represent, needs the skills of people truly experienced in chemistry. This discipline is not always taught in detail to engineers who design instruments. Conversely, chemists are not taught much about engineering design. A partnership between these two is essential for the creation and modification of chemical instrumentation.

Today, the computer is used extensively to model the structure of atoms, elements, molecules, and to compute complex reactions. Databases as handbooks and computer databases are maintained that contain the names and properties of chemical substances. A good start is http://chemfinder.cambridgesoft.com and the search words are 'chemicals databases'.

5 UNITS

Numerous different techniques are involved; many measurement units will be encountered in chemical measurements. These need care in interpretation for instrument designers are not always familiar with chemical quantities.

Commonly encountered basic units are as follows:

Mass: The kilogram is the preferred unit, but subdivisions are commonly used because of it being too large for most sample sizes. Often used are the microgram, milligram, and gram.

Amount of substance: The mole, symbol mol, is defined as the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kg of carbon. This is met in reaction equations and in dilution proportions.

Electrical: Electrical field variables are also encountered – volts, amps, watts with generally very small magnitudes at the sensing stage. Capacitance is common but not so with inductance. Electric field variable are also commonly seen.

Radiation: The EM spectrum variables, such as wavelength, bandwidth, center frequency, and spectral graphs are used in many methods, as are optical energy levels as power, reflectance, absorption, and photon count.

Temperature: This is usually expressed in terms of the Absolute Temperature scale, with units of the kelvin, K.

Pressure: The SI metric unit is the bar, but in practice the more engineering forms such as the pascal are used. In many cases, the measurement is assumed to be in conditions of stable P, V, and T. This can be a trap. Placing an instrument inside a sealed insulated chamber to avoid pressure effects can lead to changes as the temperature varies.

Laws of gases relate their pressure, P, temperature, T and volume, V, as

$$PV/T = \text{constant}$$

where T is measured in kelvin.

Changing any one of these will alter others. The need to control this set of interactions in measurements of gaseous forms is obvious.

Units of measurement are discussed in more detail in **Article 9, Nature and Properties of Measurement, Volume 1**.

6 STANDARDS

As has been explained, the chemical measurement field employs numerous means to make measurements, and they are easily corrupted by poor practice and incorrect methodology of setting up and conducting the measurement.

Because of the importance of unwanted species being present, it is necessary to ensure that the test equipment does not introduce other species from foreign sources, such as sample tube contamination, or from residues left over from a previous test where the instrument parts have not been cleaned sufficiently. Purging all feed lines and vessels is usually an essential part of chemical instrument design.

Instrument calibration using samples of known purity is essential to avoid poisoning difficulties by the prior sample. They are also needed to set up the detection sensitivity to the required precision and accuracy. Few instruments are inherently calibrated by features of their design.

In chemical analysis, standards are required for both qualitative and quantitative analysis.

In qualitative analysis, only the purity and identity of the substance are important. Modern fine chemical suppliers of simple molecules usually assure these, although some doubts as to the optical purity (that is, presence of unwanted optical isomers) of samples can occur. These are best resolved by measuring the optical rotation or circular dichroism spectrum of the sample. Indeed, it will often only be in such measurements that optical purity will have significance. Most other chemical transducers are insensitive to optical isomerism.

Real problems and expense arise in quantitative analysis where it is necessary to obtain analyzed samples whose precision and accuracy of analysis is well known. For many common acids and bases, ampoules of carefully standardized solutions are commercially available. Mixtures of known composition are much harder to obtain and the analysis needs to be established by careful collaborative work, involving different laboratories and methods. Such samples, called *standard reference materials* (SRM), can sometimes be obtained commercially or from the appropriate national standards body (such as the National Institute of Science and Technology (NIST), US, and the Physikalisch-Technische Bundesanstalt (PTB), Germany). This applies particularly to standard ores, cements, or alloys, which are essential for the proper standardization of methods such as X-ray fluorescence spectrometry. It will often be necessary to hold a range of such standard materials. As an aside, it must be mentioned that it is possible to buy cylinders of standardized polluted air!

In organic analysis, the problems are much more diverse and it is true to say that rigorous standardization of organic analysis is less developed than it is in inorganic analysis. There is a tendency for industries requiring organic analyses to rely on empirical, often indirect, measures, rather than making use of the concentration of a specific substance. For this and other reasons, the commercial demands for precision and accuracy in quantitative organic analysis are usually not as rigorous as those needed for inorganic analysis.

International bodies, such as the Organization Internationale de Métrologie Légale (OIML), have laid down specific analytical methods and reagent purities for both organic and inorganic analysis. National standards bodies have also defined many standard analytical procedures for local contractual and legal purposes. These procedures are commonly classified according to the product of interest rather than the method, and often rely on the traditional empirical measures referred to above.

More detail on the standards of measurement are found in **Article 43, Units, Volume 1**.

1 PRINCIPLES OF OPTICAL CHEMICAL MEASUREMENTS

As explained in **Article 209, Characteristics of Chemical Measurements, Volume 3**, chemical measurements make use of some form of optical interaction with the chemical species of interest. In use, the term *optical* usually includes the Electro Magnetic (EM) spectrum of radiation between the wavelengths 20 μm to 200 nm, which extends from the long Infrared (IR) wavelengths (20 μm and shorter) through the comparatively narrow visible band (red 700 to violet 400 nm) to the outer edge of the ultraviolet wavelengths (below 400 nm and extending out to the X-ray region).

Typically, interaction of an incident optical beam with a chemical species results in changes in its original characteristics. These changes observed in the emerging beam are exploited to identify, characterize, and quantitate a chemical species of interest. Parameters of interest are absorption, emission, wavelength shifts, or associated polarization changes, these being measured using a suitable optical radiation detector. Unlike a radio wave detector, which is capable of coherently measuring both amplitude and phase across the whole radio frequency spectrum, an optical detector is limited to comparatively narrow bands. Excellent photodetectors are now commercially available that detect

- energy within specific bandwidths; examples are photodiodes, photomultipliers, diode arrays, and charged coupled devices;
- total energy integrated as a whole; these are often called *bolometers*.

The performance characteristics of a light source and optical detector deteriorate with their use. It is therefore necessary to calibrate an optical chemical measurement instrument periodically using reference calibration curves, a standard reference material (SRM), (chemical actinometry), secondary reference (such as a standardized optical source or a frequency generator) and an electrochemical half-cell.

Optical systems can be quite sophisticated. A well-drawn optoelectronic element layout is essential to achieve desired optical beam profiles, including shape, energies, power and phase, and so on. Both active and passive elements are used in beam designing, shaping, and processing of

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

optical signals. A photosensitive device (detector) is used to convert an optical output signal into an electronic signal, which is then processed by using electronic circuits to obtain a meaningful output.

Old instruments widely employed photographic plates and later analog circuits. Modern instruments use digital signal processing and microprocessor technologies to achieve the desired output type. In all cases, several energy conversion stages are involved between the original optical signal and the output data – *see* **Article 108, Transducer Fundamentals, Volume 2**.

Instruments methods of optical chemical measurement may be classified into two types of measurement on the basis of

- incident radiation
- emitted radiation.

This article discusses incident radiation–based methods of optical chemical measurement.

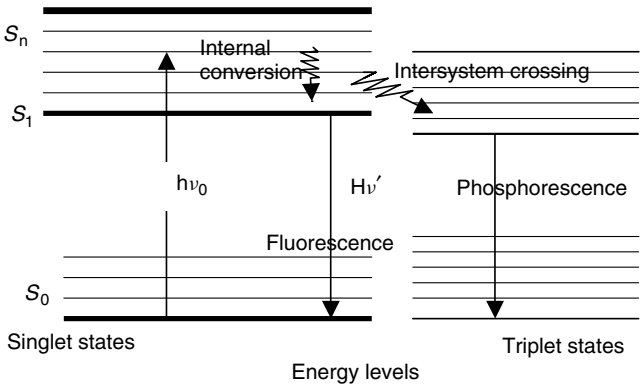

Figure 1. The interaction of a molecule with a photon of frequency ν_0. The molecule initially in a ground equilibrium energy state S_0, is promoted to a higher excited equilibrium state S_n. The molecule deactivates its energy via the *intersystem crossing* and after a time t, it returns to the ground equilibrium state S_0 emitting fluorescence. In favourable conditions the excited molecule may undergo intersystem crossing resulting in phosphorescence emission.

2 INCIDENT RADIATION METHODS FOR CHEMICAL MEASUREMENT

The scientific basis of an optical radiation–based chemical measurement is the interaction of radiation with a molecule.

Typically, a molecule upon interacting with a photon of frequency ν_0 in a ground equilibrium energy state S_0, is promoted to a higher excited equilibrium state S_n. After momentarily residing in this state (known as its *lifetime*), the molecule deactivates its energy via processes termed as the *intersystem crossing*. After a time τ, the molecule returns to the ground equilibrium state S_0.

During this deactivation process, the molecule looses energy resulting in a photon of new frequency ν' (Figure 1). Usually, $\nu' < \nu_0$ and the measurement process involves examination of the population of reemitted photons as compared to absorbed photons. Information such as an emitted photon's frequency, intensity and state of polarization, phase, and delay can then be used to infer the identity or concentration of the molecule.

Given here are some specific examples of optical transducers, classified according to the measurement made on the reemitted photon.

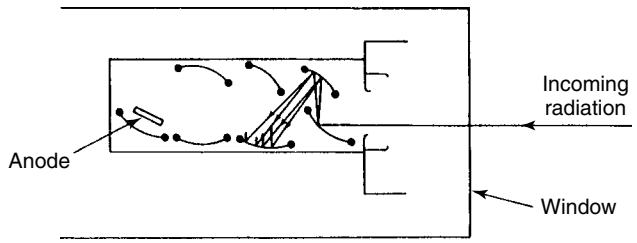

Figure 2. The photomultiplier: Incident radiation strikes an electron emissive surface; secondary electrons collide with successive electrodes in a many-from-one cascade process.

3 INTENSITY MEASUREMENT

The most common type of optical transducer is for the intensity measurement that is made by using a photodetector. The most widely used photodetector is a photomultiplier (Figure 2), which provides measurement capabilities for a varied photon flux. When larger numbers of photons are to be detected, a solid-state detector (for example, photodiode, photovoltaic cell) is sufficient. In the infrared region, the low energy of the photon necessitates careful

Table 1. Infrared detectors.

Name	Type	Detection sensitivity (cm $Hz^{1/2}$ W^{-1})	Response time (ms)
Bolometer	Ambient thermal	10^8	1.0
Golay	Ambient thermal	1.5×10^9	15
Thermocouple	Ambient thermal	1.5×10^9	15
Pyroelectric	Ambient thermal	10^8	2×10^{-3}
Photoconductor	Cooled semiconductor	10^9	10^{-1}–10^{-6}

choice of detector. Several photodetector types, together with their characteristics, are listed in Table 1.

In qualitative analysis, energy dispersion monochromation of the incident photon beam is usually carried out prior to intensity measurement. An exception to this is the X-ray fluorescence spectrometry. Some examples of optical systems are now given.

4 UV–VISIBLE ABSORPTION

The intensity of incident photons I_0 can be related to the transmitted intensity I by the Beer–Lambert law:

$$\log\left(\frac{I_0}{I}\right) = abc \tag{1}$$

where

a = molar absorptivity (a constant for a given species under given conditions) (g^{-1} cm^{-2})
b = cell path length (cm)
c = concentration (g cm^{-3})

This relation is commonly used by chemists in quantitative analysis: solutions of known concentration are used to plot a calibration curve, from which unknown solution concentrations may be read (see Hargis and Howell, 1980).

Most absorption measurement instruments are designed with a 1 × 1-cm cell to allow 1-cm path length of sample, thus simplifying calculations ($b = 1$ in the above relation). There are many variations in instrument design (Lue, 1979), depending on the applications that are available:

1. quantitative analysis, with infrequent wavelength changes and low spectral band-pass requirements (Figure 3);
2. quantitative analysis, with frequent wavelength changes and stringent spectral band-pass requirements (Figure 4);

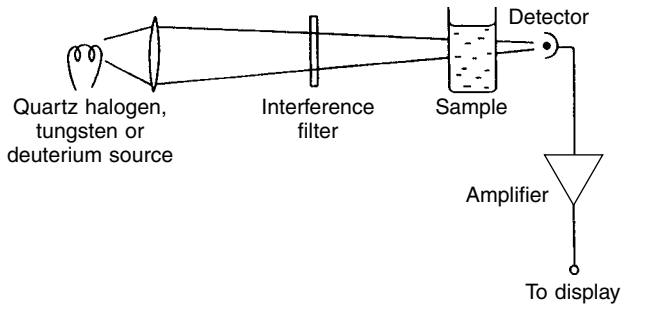

Figure 3. A simple colorimeter, or filter photometer, commonly used in repetitive quantitative analysis in the laboratory or process stream.

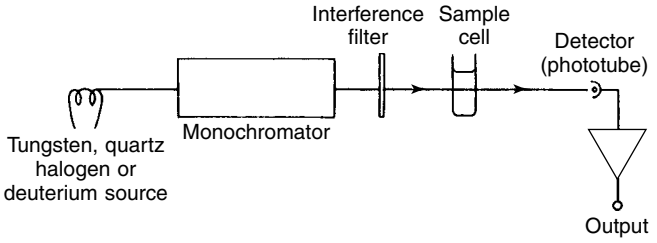

Figure 4. A single-beam spectrophotometer of a design used commonly in routine quantitative analysis.

3. qualitative analysis and structural studies, with wavelength scanning and stringent band-pass requirements (Figure 5).

Many other configurations are possible. Table 2 lists the major instrument components and their characteristics.

5 ATOMIC ABSORPTION

This special case of UV–visible absorption spectrometry is of particular importance because of its wide use in trace metal analysis (Koirtyohann, 1980), and because of the transducer design (Figure 6).

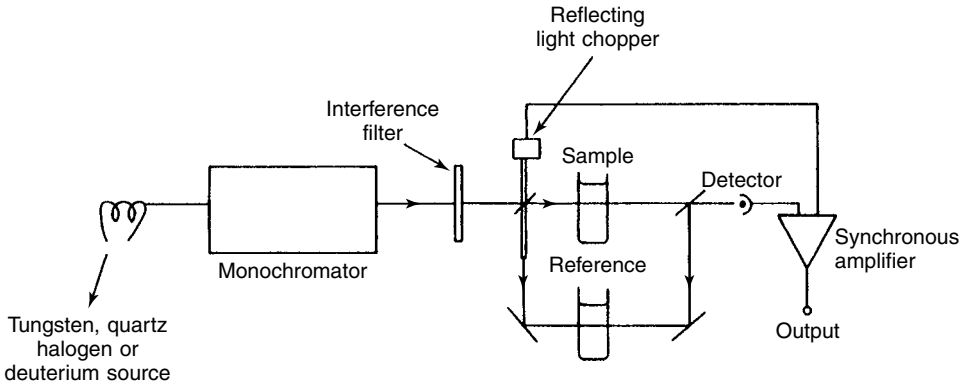

Figure 5. A double-beam UV–visible spectrophotometer of a design used for obtaining absorption spectra for qualitative analysis, structural work, and multicomponent quantitative analysis.

Table 2. Major instrument components in UV–visible spectrometers.

Item	Description
Light source	Visible: tungsten or quartz halogen lamp UV: hydrogen, deuterium, or (more expensively) xenon lamp Usually requires stabilized power supply
Monochromator	Almost always uses a reflection grating – quality of grating determines resolution. Optical design can reduce stray light
Filter(s)	Can be absorption (color) or interference; used to remove unwanted orders of diffraction due to grating
Modulator	May be rotating sector disc (chopper) or modulation achieved by switching the light source power supply
Detector	Solid state in simple instruments, phototube in intermediate, and photomultiplier in most sensitive instruments

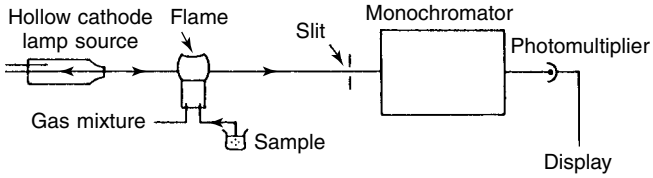

Figure 6. A simple design of atomic absorption spectrometer. Solutions are aspirated, nebulized, and swept into the flame, where neutral analyte atoms are formed. These absorb the characteristic radiation of the source by an amount proportional to the original solution concentration.

The light source is an atomic emission lamp (usually a hollow cathode lamp), in which the cathode is of the same metal as the analyte. Its emission spectrum is, therefore, coincident on the absorption spectrum of the vaporized element in the sample. Since atomic spectra are sharp line spectra, this provides an inherently high degree of freedom from interelement spectral interference. Thus, the monochromator needs only possess resolution sufficient to remove neighboring lines (Figure 7).

Detection is achieved via use of a modulated source being synchronized with this, a lock-in detector amplifier, *see* **Article 184, Photon Counting, Volume 3**. This approach removes much of the ambient light entering the sample or detector and interfering with the amplified signal; photomultiplier saturation must be avoided. The sample is vaporized either by flame, inductively coupled plasma, or in an inductively heated graphite furnace. This heating of the sample serves to remove the solvent and organic sample matrix (if any), but it also renders the analyte into the unionized atomic state, which then absorbs the source radiation.

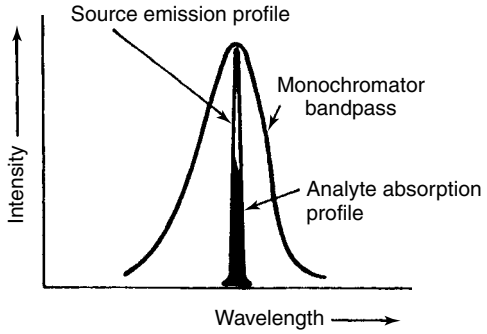

Figure 7. Spectral profiles of atomic spectra and the low-resolution monochromator typically used in atomic absorption spectrometry.

Atomic absorption of photons is primarily a quantitative tool, although the freedom from interelement interference can allow it to be used as a qualitative tool as well. The Beer–Lambert law applies strictly to atomic absorption in a flame; however, self-absorption and the vagaries of the sample vaporization process result in a nonlinear plot. A calibration curve is usually plotted from measurements on solutions of known concentrations.

Some common analytes, limits of detection, and relative precision are listed in Table 3. The major difficulty with the atomic absorption analysis method is interference due to the sample matrix, which can take many forms, including molecular band spectra, failure of the analyte to dissociate, matrix suppressions, and so on.

6 USE OF DERIVATIVE SPECTRA

One disadvantage of instruments designed to relate transmittance ($T = I/I_0$) to concentration using the Beer–Lambert law is the logarithmic dependence between the two. This restricts the sensitivity of simple absorption methods compared with say, fluorescence, where the relationship is approximately linear.

This problem can alternatively be expressed as the limited usable range of the change in concentration with transmittance (or specific response)

$$\frac{\mathrm{d}c/c}{\mathrm{d}T} = \frac{0.4343}{T \log T} \tag{2}$$

In practice, measurements above about 1.2 or below about 0.1 absorbance units will be difficult.

An alternative is to record $\partial^2 T/\partial\lambda^2$, the second derivative of transmittance with respect to wavelength. The relationship between the normalized second derivative of transmittance and concentration is now approximately linear:

$$-\frac{1}{T}\frac{\partial^2 T}{\partial\lambda^2} \simeq bc\frac{\partial^2 a}{\partial\lambda^2}$$

Table 3. Common analytes and limits of detection in atomic absorption spectrometry (AAS). Precision is typically 1 to 4% relative, depending on sample matrix and instrumentation.

Element	Wavelength (nm)	Flame type	Typical limit of detection ($\mu g\,cm^{-3}$)
Aluminum	309.3	N_2O/C_2H_2	0.2
Arsenic	193.7	Air/C_2H_2	0.4
Barium	553.5	N_2O/C_2H_2	0.3
Cadmium	228.8	Air/C_2H_2	0.002
Calcium	422.7	Air/C_2H_2	0.005
Chromium	357.9	Air/C_2H_2	0.008
Cobalt	240.7	Air/C_2H_2	0.02
Copper	324.8	Air/C_2H_2	0.002
Gold	242.8	Air/C_2H_2	0.02
Iron	248.3	Air/C_2H_2	0.02
Lead	217.0	Air/C_2H_2	0.02
Magnesium	285.2	Air/C_2H_2	0.0005
Manganese	279.5	Air/C_2H_2	0.002
Molybdenum	313.3	N_2O/C_2H_2	0.1
Nickel	232.0	Air/C_2H_2	0.02
Potassium	766.5	Ar/H_2	0.004
Rhodium	343.5	Air/C_2H_2	0.01
Selenium	196.0	Air/C_2H_2	0.2
Silicon	251.6	N_2O/C_2H_2	0.5
Silver	328.1	Air/C_2H_2	0.006
Sodium	589.0	Air/C_2H_2	0.001
Strontium	460.7	N_2O/C_2H_2	0.006
Tin	224.0	N_2O/C_2H_2	0.2
Titanium	264.3	N_2O/C_2H_2	0.4
Zinc	213.9	Air/C_2H_2	0.001

Note: N_2O = nitrous oxide, Ar = argon, C_2H_2 = acetylene, H_2 = hydrogen.

The problem of recording second derivatives is one of avoiding noise amplification. For gaseous pollutant studies, this has been done optically (Figure 8) (Kroon, 1978). Many modern recording spectrometers, however, now perform numerical differentiation on the digitized absorption spectrum. This is useful not only for extending the limit of detection in certain cases but also for removing baseline drift due to broad interfering absorption.

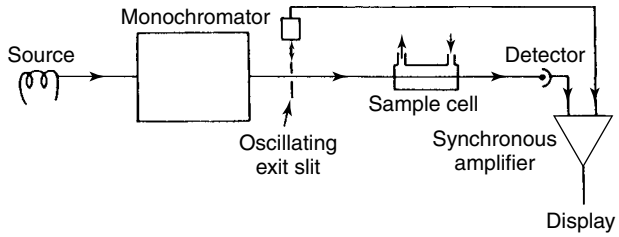

Figure 8. A second derivative spectrometer with optical differentiation. The wavelength of the source is modulated at frequency 2ω and is synchronously amplified. This is proportional to the second derivative of transmittance with respect to wavelength.

The effect of taking the second derivative with respect to wavelength is to emphasize those regions of the spectrum that have a rapid change in transmittance with wavelength that is sharp peaks. This increases the ease with which species that have interfering absorption spectra may be resolved.

7 PARALLEL SPECTROMETERS

The conventional UV–visible recording spectrometer, using a continuum light source, monochromator, and scanning mechanism is still widely used. However, the availability of photodiode array detectors with the requisite sensitivity has now made possible parallel spectrometers, in which a large region of the spectrum is recorded simultaneously by allowing the dispersed radiation to fall on a high resolution detector array after it has passed through the sample (Figure 9).

This design has many advantages which are

1. accumulation is possible of the entire spectra in short time intervals, thus facilitating, for example, the measurement of spectra on the chromatograph eluent;

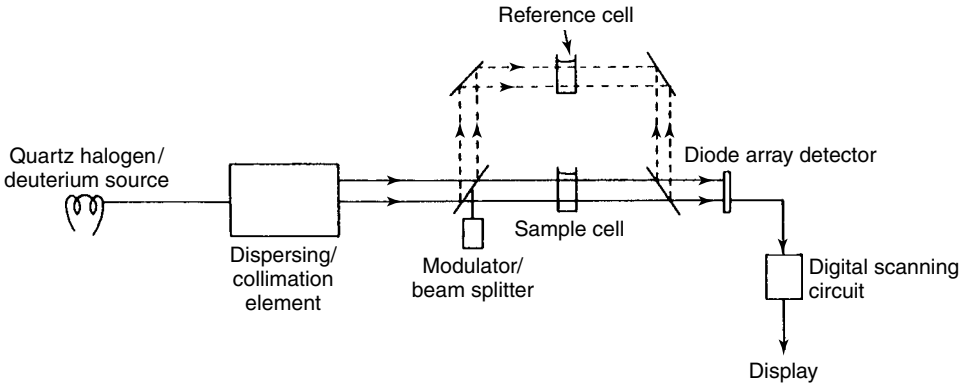

Figure 9. A parallel UV–visible spectrometer. The dispersed radiation is not resolved by slits into small wavelength regions, but is allowed to fall on a photodiode array. This allows simultaneous measurement of intensity at all wavelengths.

2. reduction of instrument noise and complexity through greater use of solid-state components;
3. absence of a monochromator and slits, with a resultant increase in light throughput and relative simplicity of optical design.

Advances in the technology of photodiode arrays have also meant better signal-to-noise ratios in light measurement, and a reduction in blooming (the effect where one light-sensitive element scatters light into a neighboring element, thus decreasing the effective resolution of the spectral information).

Conventional scanning instruments can measure with an absorbance precision of typically no better than 10^{-3} units. Careful design in a parallel spectrometer can reduce this to 10^{-4} units. This has important implications for multicomponent analysis of compounds with overlapping spectra. The least squares analysis of such spectra can be extended to species with almost-coincident spectral profiles, and to mixtures of 6 to 8 components.

Such advances have restored UV–visible spectrometry to its former preeminence as a general method of trace inorganic analysis.

8 INFRARED ABSORPTION

Initially, infrared spectrometry was used mainly in qualitative and structural chemistry. Several instrumental developments changed this situation radically. They were

1. introduction of low cost, large bandpass, single-beam instruments (Figure 10);
2. development of differential reflectance instruments for solids analysis (Figure 11);
3. introduction of better to use, and more affordable, infrared detectors, and sources (notably, for the latter, the use of diode lasers).

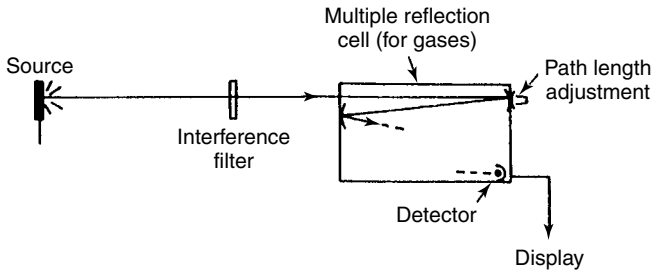

Figure 10. A simple single-beam infrared spectrometer suitable for quantitative analysis. The filter may be fixed or variable; in the latter case, a crude spectrum can be obtained, but the chief use is in quantitative work, where the high energy throughput gives a low limit of detection.

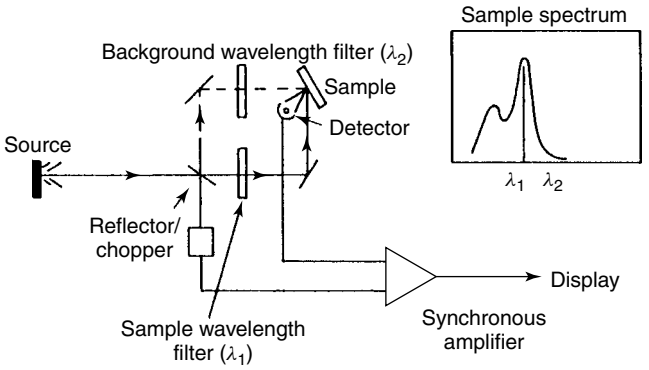

Figure 11. A differential reflectance infrared spectrometer suitable for rapid quantitative analysis in solid samples. The diffuse scattering caused by the uneven solid sample requires that the absorbance at the analyte wavelength be corrected by a simultaneous baseline absorbance (see inset).

Instrumental design for the infrared has always been plagued by the low energy of the infrared photon. This limits the sensitivity of semiconductor detectors, which rely on the incident photon promoting an electron into the conduction band.

Efforts to use thermal detectors meet with another problem: their slow response limits source modulation frequencies to regions where ambient infrared contributes significantly to instrument noise. The lower the frequency of a noise signal, the more difficult it is to filter out a reasonable averaging time. Nevertheless, the conventional double-beam scanning design has found wide application in chemistry. Table 4 lists some of the common components of this design and their characteristics.

Relatively recent developments of the instrument, concomitant with digital recording and control, include an online spectral library search database, and multicomponent mixture analysis with derivative spectra facilities.

Table 4. Major components of scanning infrared spectrometers.

Item	Description
Source	Electrically heated element, for example, Globar, Nernst glower
Monochromator	Reflective grating
Modulator	Rotating sector mechanical disc (low rotation speeds used because of large time constant of some detectors). Switching of source possible only with lasers
Sample cell	Usually sodium chloride (fragile, water soluble); can use silica for some spectra, also calcium fluoride. Sample may be pressed into potassium bromide disc
Detector	See Table 1

Table 5. Common diode lasers[a].

Type	Available range (cm^{-1})	Typical tuning range (cm^{-1})	Continuous power (mW)
$Pb_{1-x}CD_xS$	5000–2600	50	0.25
$PbS_{1-x}Se_x$	2600–1200	200	0.50
$Pb_{1-x}Sn_xTe$	1500–300	50	0.10
$Pb_{1-x}Sn_xSe$	1200–300	50	0.10

[a]Changing the doping of a given semiconductor type alters the range that the diode will cover. For a specific diode, tuning is achieved by varying the temperature within a cryogenic range.

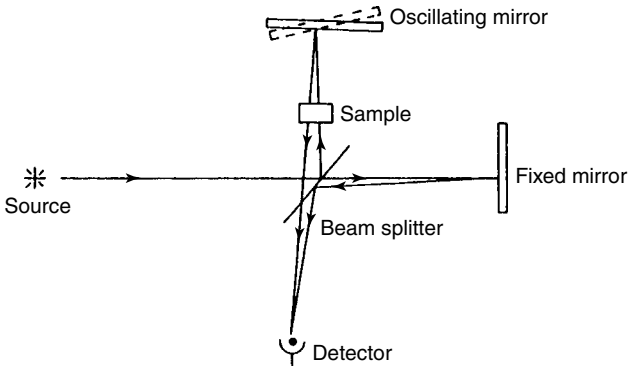

Figure 12. A Fourier transform infrared spectrometer. The sample spectrum, as the Fourier transform, is obtained in a time of the order of a mirror oscillation. Resolution of wavelength is very high (of the order of 0.01 cm^{-1}).

The use of tunable diode lasers, while bringing higher routine resolution to infrared spectrometry, also brings instrumental complexities, such as the need for cryogenic tuning and multiple sources. Table 5 lists some of the more common diode lasers, their wavelength range, and typical power output.

Fourier transform infrared spectrometers (Figure 12) offer resolution higher than conventional spectrometers. The interferometric principle also gives high optical throughput Fellgett's advantage, and a very short scan time, which makes them suitable for chromatograph eluent monitoring (*see* **Article 212, Chromatography, Volume 3**).

9 PROCESSING OPTICAL TRANSDUCER SIGNALS

Setting up both optical and electronic aspects of electro-optical systems is definitely more of an art than science, unless considerable design support is available to allow use of sophisticated computer modeling.

Computer tools have now used to perform otherwise laborious ray tracing work that is needed to establish how much energy exists in positions of interest, and to decide the level of optical aberration due to less than perfect optical elements and types of elements used. Today, a 10-element zoom lens system design is done in hours using computer tools, when by long hand methods it used to take tens of man-years of effort.

Electrical regime modeling is also easier now at least once the model is operating entirely in that regime.

The difficult area is the interface wherein the optical energy is converted. This is because the material properties, optical signal levels and stray radiation all can rarely be modeled to better than 10 to 30% uncertainties.

The development of these systems requires good modeling tools, a costly experimental optical laboratory and a large number of optical high-grade 'optical quality' optical elements. Educational grade parts (those with greater than 1 wavelength defects) are rarely usable for they can introduce significant errors. For example, an uncoated lens can act as weak Fabry-Perot interferometer introducing fringes in the final image, by virtue of their own two surfaces being an interferometer. Lack of flatness of windows can cause distortion in images that give incorrect levels in array detectors.

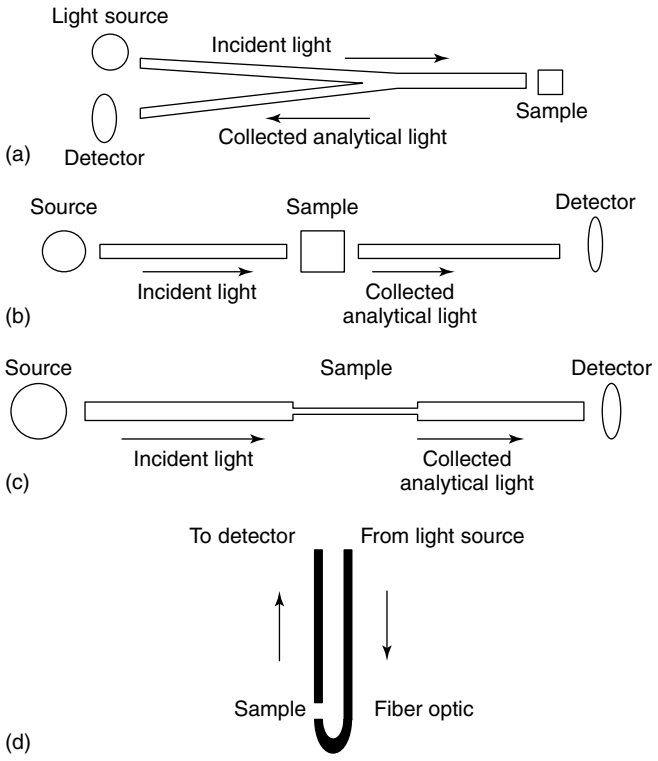

Figure 13. Various fiber-optic light guide configuration for incident light interaction measurement (a) bifurcated fiber optic, (b) two fiber split configuration, (c) evanescence field interrogated fiber-optic configuration and (d) U-shape fiber-optic cell configuration.

The difficulties of designing such systems have been covered in Hobbs (2000); see also Smith (2000), and Weber (2002).

10 FIBER-OPTIC TRANSDUCTION

With the advances of fiber-optic technology, a number of molecular measurement applications have chosen to use this outstanding and flexible means to transport photons to and from a sample. Increasingly, UV–absorption spectrometers are now available that offer fiber-optic attachments or have a fully integrated fiber-optic channel for delivery and collection of light energy, both types allowing analyses of remote chemical samples. Usually, one fiber carries the incident light beam from the light source to the sample, and the other carries the analytical beam from the sample to the detector optics. Some times these fiber designs are referred to as *sensors*. Various fiber-optic sensor configurations for analytical applications are explained in Sharma and Schulman (1999), (Figure 13).

1 PRINCIPLES OF THE MASS SPECTROMETER

Mass spectrometry is the process whereby a molecule in the vapor state is broken into charged fragments that are then separated according to their mass/charge ratio, being detected according to their number. For the basics, see www.chem.vt.edu/chem-ed/ms/ms-intro.html.

Mass particles flowing through a magnetic or electric field are acted upon by the electric forces being continuously deflected as long as they are in the presence of the field.

A sample, in solid, liquid, or gaseous state, is processed into the gas-phase ion state. This is then beamed as emitted protons towards a target. As the mass particles pass through a uniform electric or magnetic field separator region, the various mass particles present will be deflected apart according to their atomic mass/electron charge (m/e) ratio.

The physics of this process is well understood in terms of engineering dimensions, field type, and projection method. Many variations on the basic theme exist. Over time they have become very sophisticated (Nier, 1998).

2 THEORY OF THE MASS SPECTROMETER

The resolution R of the ion separation power of a mass spectrometer is defined as

$$R = \frac{m}{\Delta m} \tag{1}$$

where m is the ion mass and Δm is the difference in mass between two resolvable peaks in a mass spectrum. For example, a mass spectrometer with a resolution of 1000 can resolve an ion with an m/e ratio of 100.0 from an ion with an m/e ratio of 100.1.

A mass spectrometer is therefore a complex set of processing modules for fragmenting, resolving, and detecting. It can, nevertheless, be viewed, as are optical spectrometers, as a transducer for converting a unique chemical structure into a highly individual fingerprint of response versus mass/charge ratio of its daughter fragments.

Figure 1 illustrates the structure of a mass spectrometer in simplified block form. Table 1 lists some common types of fragmentation systems. It may be added that the task of bringing the molecule into the vapor state prior to fragmentation is usually accomplished by using a gas chromatograph – *see* **Article 212, Chromatography, Volume 3** – as a sampling and/or separating device. Samples may also be introduced by direct injection.

The fragments are accelerated by a series of electrostatic slits to pass into the mass–charge separator. The various beam products emerging at different angles are detected by setting the beam or detector in the various locations, by scanning the detector across the region using multiple detectors, or by beam manipulation to scan it across the

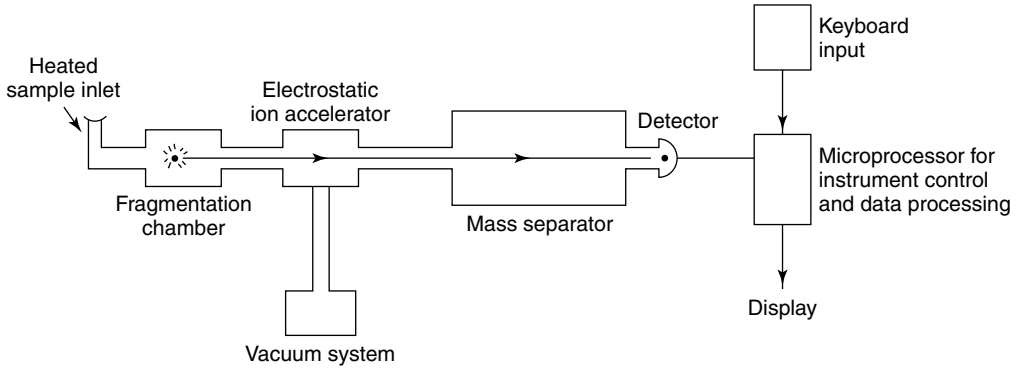

Figure 1. The principal components of a mass spectrometer.

Table 1. Fragmentation systems used in mass spectrometry.

Type	Description
Electron impact	Molecules bombarded with 70 eV (usually) electrons; fragmentation is violent, and molecular ion may not be observed
Chemical ionization	An ionized reactant gas (e.g. methane) forms reactive intermediates with itself; these react with sample to produce a simple spectrum. Quasi-molecular ion (at molecular weight plus one) often formed
Spark source ionization	RF spark (e.g. 800 kHz, 100 kV) applied to high melting point solids; equal sensitivity for all elements; high resolution spectrometer required because of wide energy spread of ions; useful for minor elements in semiconductors
Laser microprobe	Focused pulsed laser (e.g. 10^8 W cm^{-2} on 50 μm^2) used to vaporize sample; electron impact used to fragment; time of flight spectrometer used; can use small samples and plot element distributions

detector. A detector array can read several beam products at once.

3 MASS SPECTROMETER DESIGNS

The most common types of separators are listed in Table 2. Resolution here is defined as

$$R = \frac{m}{\Delta m} \tag{2}$$

where Δm is the mass difference between peaks at m and $(m + \Delta m)$ when the peaks overlap at 10% of their mean height (this is referred to as 10% valley definition).

Detection is accomplished using one of the devices listed in Table 3.

A mass spectrum can be used for the following:

Table 2. Mass separators used in mass spectrometry.

Type	Resolution (see text)	Comment
Magnetic deflection:		
(a) Single focusing	200–600	Available with permanent magnet
(b) Double focusing	to 35 000	
Quadrupole	400–1200	Rapid, linear scan; simple relative to magnetic types
Time of flight	400–600	50-μs scan time; suitable fast kinetic studies

Table 3. Detectors used in mass spectrometers.

Type	Description
Faraday cup	Ions impinge on insulated cup and absorbs an electron – results in ion current, for example, 10^{-12}–10^{-15} A
Electron multiplier	Beryllium–copper dynode chain used to amplify primary emitted electron caused by impact of fragment ions; for example, 10^{-18} A limiting current
Channeltron	Secondary electron multiplier in the form of fine tubes coated with internal layers of secondary emissive material–typical limiting current 10^{-19} A

- Qualitative analysis
- Quantitative analysis
- Structural work.

There are two common ways in which qualitative analysis can be performed:

1. Using the known abundances of isotopes, together with rules derived from the valence (binding power) of atoms, to fix the numbers of atoms of a given type in a molecule whose spectrum is given. This method depends on having available accurate mass/charge ratio measurement and high resolution.

2. Using the observed mass spectrum as an empirical fingerprint of the molecule, which may then be compared with a library of spectra using a statistical matching criterion. Such is the individuality of the information about a molecule contained in a mass spectrum that this method is most demanding of instrument reproducibility rather than resolution. Libraries of the spectra are held in the computer associated with these instruments.

As with many other spectral methods, quantitative analysis is achieved by comparison of peak heights or areas per unit of standards against those of unknowns.

The inherent high resolution of mass spectra allows multicomponent analysis, particularly in gas mixtures, this being done rather more easily than in common forms of optical spectroscopy.

Structural work is of limited interest in analysis and will not be discussed further here.

A useful process monitor based on mass spectrometric design is the quadrupole gas analyzer. This is a simple quadruple mass spectrometer designed for quantifying low mass molecules (up to say, molecular mass 100). Samples are pumped directly from the process stream through a restrictor into the fragmentation chamber; the mass separator is merely required to separate whole number masses. A resolution of 150 is often adequate. Quantification can be obtained by monitoring the parent ion current (that is, the detector current as the molecular mass of the compound).

Separation chamber designs have been made in numerous forms. The challenge of making the separation large for small-length separator units has resulted in multiple-folded separator systems.

Ardrey (2003), Hoffmann and Stroobrant (2002), Siuzdak (1996), and Watson (1997) give detailed information on mass spectrometers.

1 PRINCIPLES OF CHROMATOGRAPHY

The chromatographic separation process occurs because of repeated sorption/desorption of sample components onto and off a stationary phase surface as they are carried over or through that stationary phase by a mobile phase. The relative affinities of these sample components for both the stationary phase and the mobile phase govern how much time is spent in each phase and, therefore, how long it takes for each component to travel over or through the chromatographic system. The higher the affinity of a particular component for the stationary phase, the more time it will spend being stationary. Equally, those components with a low affinity for the stationary phase will travel through the chromatographic system at a rate close to that of the mobile phase.

The stationary phase itself can be either a solid (adsorption chromatography) or a liquid (partition chromatography) coated or chemically bonded to a solid. Planar Chromatography is the name given to the mode of chromatography where the stationary phase is immobilized on a flat planar surface. An example of planar chromatography is (TLC) Thin Layer Chromatography, where the stationary phase, usually alumina or silica gel, is immobilized on a glass plate. Alternatively, the stationary phase can be immobilized or packed within a column. Techniques involving such columns are grouped within the umbrella term *Column Chromatography*. The common column chromatographic techniques form the focus of the following sections.

The mobile phase in column chromatographic methods is usually either a gas or a liquid. Hence, we have either (GC) Gas Chromatography or (LC) Liquid Chromatography. The former is often further characterized as either (GSC) Gas–Solid Chromatography or (GLC) Gas–Liquid Chromatography depending on whether a solid or liquid stationary phase is used.

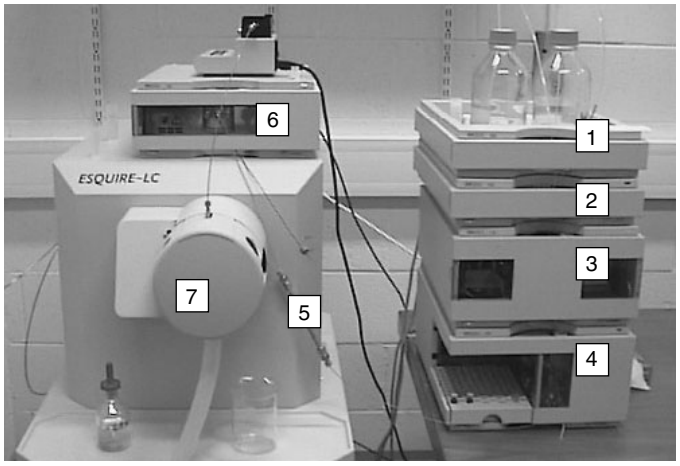
An alternative to the above two types of mobile phases exists in the form of supercritical fluids. These represent an intermediate phase between a liquid and a gas and exist at certain elevated temperatures and pressures. The technique of (SFC) Supercritical Fluid Chromatography has some advantages over both GC and LC but has not found such widespread application due to cost and complexity of the required instrumentation. In LC, the liquid mobile phase is also called the *eluent*, prior to passage through the column, and the *eluate*, after it has emerged from the end of the column. The emergence of the liquid mobile phase from the column, with the sample components contained therein, is called *elution*.

2 LIQUID CHROMATOGRAPHS

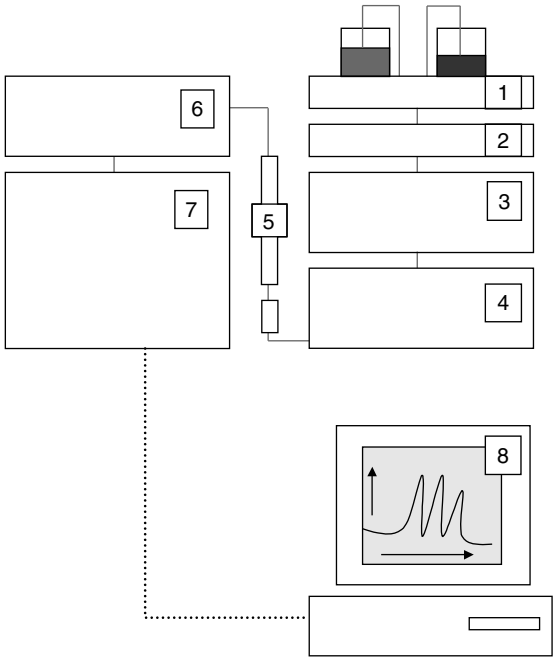
High-performance Liquid Chromatography (HPLC) is the name given to the form of LC carried out using

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

high-performance grade stationary phases (generally, 5–10-μm stationary phase particles) packed into stainless steel or polymer columns, with mobile phases delivered through the stationary phase under high pressures (generally between 500 and 3000 psi). As the solutes emerge from the column, they are carried by the mobile phase through a suitable detector equipped with a flow cell (predominantly, either an (UV–Vis) ultraviolet–visible absorbance spectrophotometer or an electrochemical detector being monitored to produce a chromatogram).



The instrumentation used to perform HPLC is generally modular in type and collectively termed a *high-performance liquid chromatograph*. The complete system generally consists of a mobile phase reservoir and delivery module, a sample/standard injector module, a guard column and the analytical column, a detector module, and, finally, some form of data recorder to produce the resultant chromatograms. A schematic diagram of a typical HPLC system is shown alongside a photograph of a commercial modular HPLC system in Figure 1 below.



In almost all modern HPLC systems, the mobile phase is delivered to the analytical column via the injector module by one or more high-pressure HPLC pumps. Modern pumps can operate at variable flow rates, generally between 0.1 and 10 ml min^{-1}, with most mobile phase flow rates being between 0.5 and 2.5 ml min^{-1} when using standard HPLC columns.

The majority of modern HPLC pumps are based upon either single or dual alternating pistons. With dual piston pumps, the pistons are operated 180° out of phase to ensure a pulse free flow. With single piston pumps, a pulse dampener device is often included to reduce any such mobile phase pulsations. HPLC pumps can be further classified as either being isocratic or gradient pumps, meaning they are capable of delivering either a single mobile phase of constant composition or a mobile phase whose composition can be changed automatically over time.

Injection of samples and standards onto the column in HPLC is problematic as the mobile phase into which the sample is to be injected is flowing under the high pressure and cannot be stopped during sample injection. In addition, the injection procedure used must be capable of reproducibly injecting microliter quantities of sample. Most modern instruments circumvent this problem with the use of six-port switching valves, which contain a sample loop of fixed volume (generally 5–100 μL) that is filled with sample using a simple syringe. These valves can be switched manually or automatically to quickly insert the filled sample loop into and out of the path of the mobile phase without affecting the flow or pressure of the mobile phase.

The actual HPLC columns and various types of flow-through detectors used in HPLC, which together with the

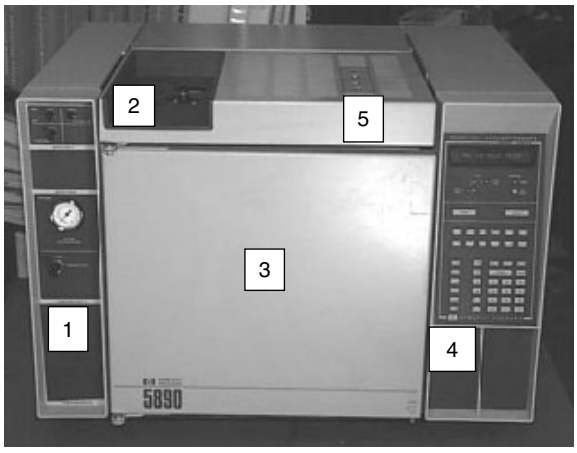
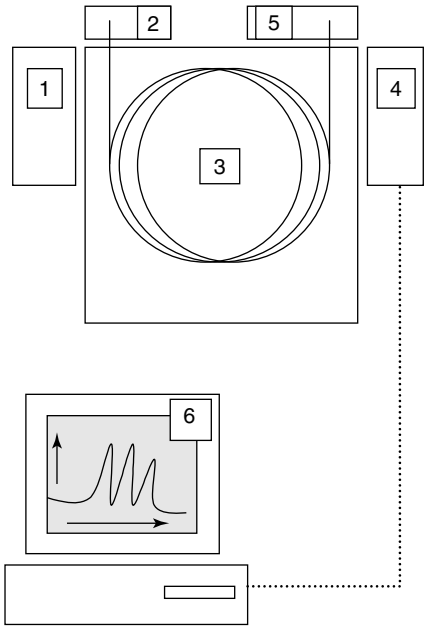
above make up the complete HPLC instrument, will be discussed in Sections 4 and 5 below.

3 GAS CHROMATOGRAPHS

As mentioned in Section 1, the mobile phase in GC is an inert gas, generally nitrogen, helium, or hydrogen. Just like the liquid mobile phase in HPLC, within a gas chromatograph, the mobile phase (more commonly termed the *carrier gas*) passes through a sample injection port; then through the GC column, which is held within a thermostated oven; and finally, out through a flow-through detector. The instrumentation required to carryout GC could be viewed as being simpler than that required for HPLC as there is no requirement for high-pressure pumping systems. Instead, the gas is delivered from a pressurized source, commonly a pressurized cylinder supply, via a moisture trap to remove any traces of water, directly into the gas chromatograph. This is possible because of the much lower viscosity and increased difussivity of a gas compared to a liquid, which means the pressure drop across the GC column is much less than that found in HPLC.



This also means the length of the GC column is less restricted by this pressure drop than a standard HPLC column, allowing open tubular columns typically of 50-m length to be used (for more details on gas and liquid chromatography columns, see Section 4).



Unlike HPLC, most gas chromatographs are nonmodular single unit designs, although modern instruments will have optional modules, such as autosamplers.

Figure 2 shows a schematic diagram of a typical gas chromatograph alongside a photograph of a commercial system.

Sample injection in GC is perhaps the most complex aspect of the instrumentation. In most common applications of GC, the sample has to be in a gaseous or vapor state prior to entering the chromatographic column. This limits GC itself to the separation of volatile solutes. Therefore, the injector in GC must act not only as an inlet for the sample itself but also to vaporize and mix the sample with the carrier gas before the sample enters the head of the analytical column. To achieve this, the injector is subject to temperature control and is generally operated at 50 °C above the boiling point of the least volatile solute.

Most modern applications of GC utilize capillary columns (discussed in more detail in Section 4), which are only capable of accepting minute quantities ($<1\,\mu L$) of sample before becoming saturated. Therefore, injectors capable of reproducibly and accurately injecting such small volumes have been developed. Split/splitless injection is a technique that allows the analyst to inject larger volumes of sample while controlling by means of a vent valve the proportion of the injected sample that actually reaches the head of the column. Split ratios are used to describe this diverted proportion of sample, with split ratios varying from 1 : 20 to 1 : 500, with the latter indicating that

Figure 2. Schematic diagram of a typical gas chromatograph alongside a photograph of a commercial system.

only 0.2% of the volume of sample injected actually enters the column. The remaining 99.8% is carried to waste by vent gas.

As shown in Figure 2, the column is housed in a temperature-controlled oven, which can be rapidly heated or cooled, from 40 to 450 °C, with most modern chromatographs stabilized to within 0.5 °C. The temperature of the column can be ramped up or down over time, allowing temperature gradients to be used to speed up or slow down elution of solutes.

Upon exit from the column, the carrier gas transports the solutes to the detector where their relative concentrations in the carrier gas are determined. The various types of detectors commonly used in GC are discussed in Section 5.

4 COLUMN CHARACTERISTICS

4.1 HPLC columns

All HPLC columns are straight tubes made of either stainless steel or, less commonly, inert polymers such as (PEEK) poly ether ether ketone. Typical dimensions range from 3.0 to 25.0 cm in length and from 0.2 to 0.5 cm in (ID) internal diameter. The stationary phase substrate is pressure packed within the column and held in place using porous frits (0.2–0.4-μm pores) and pressure-tight end fittings.

The majority of separations using HPLC are achieved using silica gel–based stationary phases. These may be bare silica, which is generally applied to the separation of polar solutes using a nonpolar mobile phase, a mode of HPLC termed *normal phase HPLC*, or bonded silica, where organic functional groups are covalently bonded to reduce the polarity of the stationary phase. Commonly, these organic groups have linear alkyl chains from 2 to 18 carbon atoms, with most HPLC applications using C_{18} bonded silica gels, otherwise known as (ODS) *octadecyl-silica*. These ODS columns are applied to the separation of nonpolar solutes, using polar mobile phases, in what is termed *reversed phase HPLC*. Table 1 shows the range and description of some of the large number of HPLC bonded phases available.

Table 1. HPLC bonded phases.

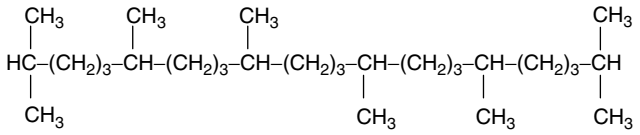
Type (bonded group)	Description	Typical solutes
Silica gel	Classic normal phase material	Polar nonionic organic compounds
Nitro (NO_2)	Normal phase material	Aromatic compounds, compounds with double bonds
Phenyl (C_6H_5)	Reversed phase material	Large proteins, macromolecules
Butyl (C_4)	Reversed phase material	Aromatic compounds
Hexyl (C_6)	Reversed phase material	Nonpolar/moderately polar solutes
Dodecyl (C_{12})	Reversed phase material	Nonpolar/moderately polar solutes
Octadecyl (C_{18})	Classic reversed phase material	Wide application – nonpolar organic compounds

4.2 GC columns

There are two main types of column used in GC, these being

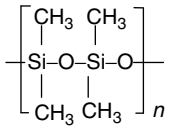
1. columns that are pressure packed with a stationary phase or stationary phase support material in a similar fashion to HPLC columns; and
2. columns that are not packed and thus open tubular in nature, with the inner walls acting as the support for the stationary phase material.

The former are the older type of GC column and rarely used in most modern GC applications today. The latter open tubular columns are more widespread today and in most instances are prepared from fused silica capillaries, the I.D. of which varies from 0.1 to 0.35 mm and length from anywhere between 5 and 50 m.



As mentioned above, these open tubular capillary columns have the actual stationary phase material coated or, in some cases, chemically bonded onto their internal surface. These are termed *wall-coated open tubular* columns, with the thickness of the stationary phase layer varying between 0.05 and 5 μm.

A reasonably large number of stationary phase materials have been developed for use in capillary GC columns; however, the majority are viscous organic liquids of varying polarity and generally fall within the classification of polysiloxanes, also known as *silicone oils*, or polyethylene glycols. Figure 3 shows some of the common liquid stationary phases used in capillary column GC.



5 DETECTORS USED WITH CHROMATOGRAPHS

Detectors for HPLC and GC can be classified as either universal, meaning they register some degree of response to the presence of the majority of solutes, or as selective, meaning they only detect the presence of a particular class or group of solutes or, in some highly selective detectors, only individual solutes. For most detectors used in HPLC

Squalane: Solutes strongly retained: Sat. hydrocarbons, aromatic hydrocarbons, low polarity solutes.

SE-30 (Silicone gum): Strongly retained solutes: Low polarity as above.

Carbowax 20 M (Polyethylene glycol): Strongly retained solutes: (very polar) Hydroxyacids, polyhydroxyalcohols , polyprotic acids, aminoalcohols.

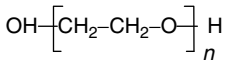


Figure 3. Some common liquid stationary phases used in capillary column GC.

and GC, the main requirement is that the detector does not register a large response for the mobile phase itself, which elutes the solute from the column.

5.1 Detectors for HPLC

The types of detectors used in HPLC can in most cases be classified as either photometric or electrochemical detectors. The former includes UV/Vis absorbance detectors, fluorescence and chemiluminescence detectors, the latter includes amperometric, potentiometric, and conductometric detectors. Alternative detectors that do not fit into the above classifications include refractive index and light scattering detectors, although these have only limited application. The commonality between all the above types of HPLC detectors is they all possess a flow-through cell connected to the end of the analytical column by HPLC grade tubing (<0.3 mm I.D.). These flow-though cells must have small internal volumes to ensure that sharp chromatographic bands eluting from the analytical column are maintained, although this is balanced with the need for sensitive detection, which in the case of spectrophotometric detectors is dependent upon cell length. Figure 4 shows a schematic diagram of a simple single wavelength UV absorbance detector as would be used in basic HPLC systems.

5.2 Detectors for GC

Two detectors common to most modern gas chromatographs are the (TCD) thermal conductivity detector and the (FID) flame ionization detector. Both are considered universal detectors, although the latter only responds to organic compounds.

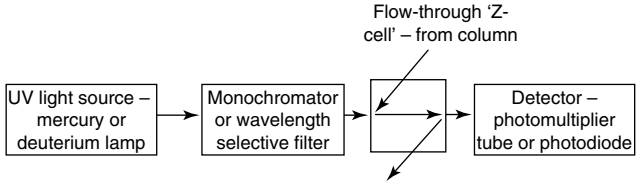

Figure 4. Schematic diagram of a simple single wavelength UV absorbance detector found in basic HPLC systems.

The TCD measures the thermal conductivity of the carrier gas and detects a change in this baseline conductivity when solute bands pass through the detector. Most organic solutes have a vapor phase thermal conductivity significantly lower than the carrier gas, particularly if this is H_2. Therefore, the detector records a decrease in conductivity as these solute bands pass through the detector.

Unlike the TCD, FID is a destructive detector, meaning the sample is actually destroyed as it passes through the detector. This is achieved by burning the solutes as they elute from the GC column in an air–H_2 flame. The burning of organic solutes in this way produces positive ions (CHO^+) and electrons within the flame, which itself is situated between an anode and cathode. The application of a voltage (+400 V) across these electrodes allows a current to be measured, the magnitude of which is dependent upon the concentration of organic solutes entering the flame. Figure 5 below shows a schematic diagram of an FID.

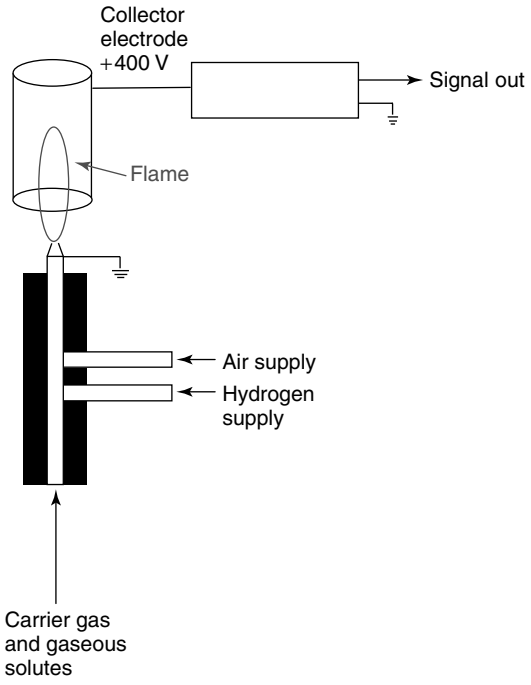

Figure 5. Schematic diagram of a flame ionization detection (FID) as used in standard gas chromatographs.

6 PROCESSING CHROMATOGRAPHIC SIGNALS

The chromatogram is the graphic result of a chromatographic separation. It represents the signal produced from the chromatographic detector plotted against time, beginning at the time of sample injection and ending upon elution of the last solute from the column.

Each solute has a characteristic t_R, retention time, when chromatographed under set stationary and mobile phase conditions. This is measured from injection to the point of maximum signal for each solute peak.

However, the mobile phase itself also takes a set amount of time to pass through the chromatographic column and this is termed t_M, *void time*. The positive difference between these two values represents the time the solute spends in or on the stationary phase and is represented as t'_R, adjusted retention time.

A more useful parameter used to describe solute retention behavior is the k', capacity factor. This is determined by t'_R/t_M. Capacity factors should conveniently be in the range 1 to 5. If k' is less than 1, solutes elute too quickly and so are not separated; if k' is much greater than 5, solutes are retained for long periods, making the chromatography impractical.

The potential of a chromatographic column to separate two solutes is described by α, the separation or selectivity factor. This is obtained by the division of respective capacity factors for the two solutes, $\alpha = k'_2/k'_1$. In general, α must be at least 1.02 to 1.05 for acceptable separations in GC and 1.05 to 1.20 for good separations in HPLC. However, the above parameter is based upon retention times for solutes only and does not include the width of the eluting chromatographic peaks. This, of course, will affect the ability of the system to produce an acceptable separation as broad peaks will tend to overlap if differences in retention are too small. Resolution, R_s, is a quantitative measure determined from a chromatogram, which, as it includes information on relative peak widths, more precisely describes the separation of two solutes. Resolution is obtained by (1), where W_n represents individual peak widths at their base:

$$R_s = \frac{t_{R2} - t_{R1}}{0.5(W_1 + W_2)} \tag{1}$$

The efficiency of a chromatographic separation is basically a measure of the degree of solute band broadening that occurs as the solute band passes through the column.

Ideally, the solute band should remain as narrow and concentrated as possible, as is the case with the most efficient systems. The term used to describe column efficiency is the theoretical plate number, N. The higher the number of theoretical plates, the higher the efficiency. Theoretical plate number can be determined using (2). The height equivalent to a theoretical plate, $HETP$, relates N to column length, L, and is determined using (3).

$$N = \frac{16t_R^2}{W^2} \tag{2}$$

$$HETP = \frac{L}{N} \tag{3}$$

Figure 6 shows a typical chromatogram for a six component sample obtained using HPLC.

7 PERFORMANCE AND LIMITATIONS OF CHROMATOGRAPHS

7.1 Liquid chromatographs

HPLC is an extremely versatile and established analytical technique. Modern liquid chromatographs suffer few of the problems of early instruments and are reliable and robust, with high quality pulsation-free pumps and sensitive low noise detectors. Because of this, liquid chromatographs can be found in a wide variety of laboratories belonging to the chemical industry, the food production and testing

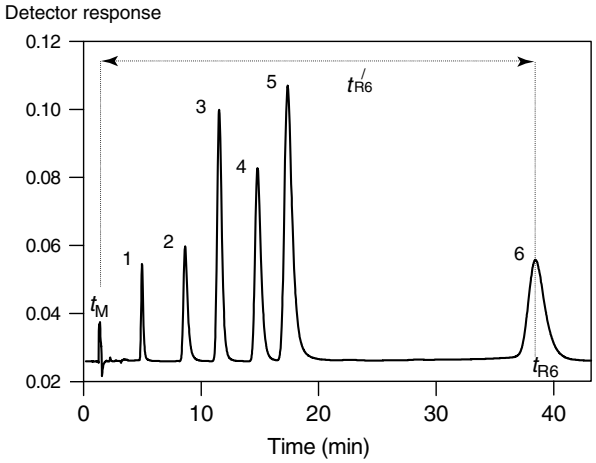

Figure 6. Typical HPLC chromatogram for a six component sample.

industries, environmental monitoring agencies, and pharmaceutical and biochemical plants.

The performance of the technique is to a large extent dependent upon the correct choice of mobile and stationary phases. Obviously, these have to be compatible with each other and with the actual solutes within the sample. Most problems encountered with HPLC are due to problems of this nature. A few simple rules should be followed to help avoid many such problems.

1. Always filter (<0.45-μm filter) and degas the mobile phase before use.
2. Always test the solubility of sample components in the mobile phase before injection.
3. Avoid the use of highly acidic pH < 2 or basic pH > 8 mobile phases with silica-based stationary phases.
4. Be careful with the use of organic solvents as mobile phases when using polymer-based stationary phases, which may dissolve.
5. Always use a short guard column before the analytical column to avoid fouling of the analytical column with strongly retained material.
6. When beginning or ending work with the chromatograph, slowly increase or decrease the mobile phase flow rate to that desired. This avoids sudden increases in back pressure, which can cause unwanted voids within the analytical column.

7.2 Gas chromatographs

In terms of efficiency and separation power, GC outperforms HPLC. Peaks are generally much sharper and resolution of complex mixtures often easier to obtain. However, as with HPLC, limitations of the technique are less to do with instrumentation and more to do with the chemistry involved.

Firstly, all solutes need to be volatile and readily vaporized, yet thermally stable, so that they do not degrade at the elevated temperatures within the injector, column, or detector.

Also, as it is generally not advisable to inject water into capillary GC columns, it is often the case that the solutes of interest first have to be extracted into a more volatile organic solvent prior to injection, which obviously adds unwanted complexity to the analytical method. The stability of the stationary phase itself is also often a cause of problems with GC. Coated capillary columns are often subject to the stationary phase bleeding off the column at elevated temperature, a problem that can show as high background detector noise levels or as reductions in retention times.

1 POTENTIOMETRY

Potentiometry is where the electrical potential (voltage) of an electrochemical cell is measured under conditions of zero current flow.

The potential of a galvanic cell measured in volts correlates with the activity (or approximately, concentration) of the species of interest. This measurement is based on the Nernst equation

$$E = E^s + \frac{0.059}{n} \log \left\{ \frac{[A]^a [B]^b}{[C]^c [D]^d} \right\} \quad (1)$$

for an electrochemical reaction

$$aA + bB + n\mathrm{e} \longrightarrow cC + dD \quad (2)$$

where e denotes an electron and the square brackets denote activity of the species (approximately concentrations). E is the measured potential, and E^s is a constant potential measured at defined conditions and activities. The term '0.059 V' is derived from thermodynamic considerations and includes the Gas constant, the Faraday, a conversion factor for log base 10, and absolute temperature 298 K. It represents the ideal or Nernstian electrode response for a one-electron transfer. Note the indirect relationship between potential and the base 10 logarithm of activity (approximately concentration) for a single chemical species, the analyte.

The potential can be related to the analyte concentration once a comparison or reference electrode is provided. From the cell potential, the electrode potential for the process of interest may in turn be derived. Three reference electrodes are given in Table 1. The first is the primary standard reference and the other two are secondary practical references used in everyday work.

Direct potentiometry is the most used technique in electroanalysis. Here, the potential of a selective electrode relative to a standard is measured at a very low, or zero, current.

2 ION TRANSPORT AND ION EXCHANGE

The performance of an electrode is determined by the control of the charge transfer process and any component voltages that result from that charge transfer. Let us simplify these processes to two major examples:

$$\text{Ion transport, } \mathrm{Ion}^{+(-)}/\mathrm{H}^+ \textit{ interface } \mathrm{Ion}^{+(-)}/\mathrm{H}^+/\mathrm{e}^- \quad (3)$$

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

Table 1. Electroanalytical reference electrodes.

Type	Description
Standard Hydrogen, SHE. The Primary reference electrode for electrochemistry.	A glass jacket surrounds platinum, so hydrogen gas can bubble at 1 atm pressure over the Pt surface immersed in 1 M HCl held at 25 °C.
The half-cell reaction is: $2H^+ + 2e \rightarrow H_2$ (gas)	E^0 value set as 0.00 V
Calomel Secondary Reference	Two concentric glass tubes, the inner one containing mercury, mercury (I) chloride, and potassium chloride paste. The outer tube contains potassium chloride solution and connects to the sample solution via a porous glass frit.
The half-cell reaction is: $Hg_2Cl_2 + 2e \rightarrow 2Cl^- + 2Hg$	E^0 (KCl saturated) +0.241 V against SHE
Silver/silver chloride Secondary Reference	A silver wire coated with silver chloride and immersed in a solution of potassium chloride saturated with silver chloride. Contact with the sample solution is via a porous glass frit.
The half-cell reaction is: $AgCl + e \rightarrow Cl + Ag$	E^0 (KCl saturated) +0.197 V against SHE

and Ion binding then transfer via an intermediate molecule called an *ionophore*

$$\text{Ion}^{+(-)}/\text{ionophore} \longrightarrow \text{complex } \textit{interface } \text{Ion}^{+(-)}/\text{H}^+/\text{e}^- \quad (4)$$

An important element of electrode control occurs at the internal membrane solution *interface*, where processes described in (3) and (4) by the all-embracing term, $\text{Ion}^{+(-)}/\text{H}^+/\text{e}^-$, occur, that is, ion transfer (+ or − analyte ion or via the hydrogen ion, H^+) or electron transfer, e^-, to a conducting surface.

An understanding of these electrodic processes has led to improved measurement performance for potentiometric sensors. Consider the most important ion-selective electrode (ISE), the glass electrode, and pH measurement.

The electrode has a thin-walled membrane of carefully doped glass and an internal reference (generally, silver/silver chloride with an electrolyte of KCl and HCl). The electrode is immersed in the test solution and the potential is measured against an external reference. The electrode falls under the general descriptive $\text{Ion}^{+(-)}/\text{H}^+$ *interface* $\text{Ion}^{+(-)}/\text{H}^+/\text{e}^-$, which may be simplified to hydrogen ion transport across the glass membrane, H^+ *interface* H^+, since other factors are constant.

With both the internal and external reference potentials constant, changes in the cell potential are decided at the membrane. For the glass electrode,

$$E_{\text{membrane}} = E_{\text{external surface}} - E_{\text{internal surface}} \quad (5)$$

or

$$E_{\text{membrane}} = E^s + \frac{0.059}{1}\log a_{\text{H}^+\ \text{external}} - \left(E^s + \frac{0.059}{1}\log a_{\text{H}^+\ \text{internal}}\right) \quad (6)$$

Since E^s, 0.059, and $\log a_{\text{H}^+\ \text{internal}}$ are constant, they can be replaced by an overall system constant, L, and so finally results in

$$E_{\text{membrane}} = L - 0.059\text{pH}_{\text{external}} \quad (7)$$

The transport process through the membrane confers selectivity on the electrode and has led to the modern definition of pH being

$$\text{pH} = -\log a_{\text{H}^+} \quad (8)$$

where a_{H^+} is the activity (approximately concentration) of the hydrated hydrogen ion in solution.

The impedance (~100 MΩ) of the circuit provided measurement difficulties in the past, but today, very high input impedance microelectronic amplifiers have simplified matters considerably.

The principle behind other ISEs (Table 2) is similar to that shown for the glass system, although the membranes used depend upon diverse transport processes for their selectivity. The principle transport mechanisms involve either ion flux through a crystalline lattice (as shown for the glass electrode), where the lattice's stability limits the size and charge of an acceptable ion, or diffusion facilitated through complexation by an ionophore, a specific binding agent for the selected species, held in a plastic membrane.

Essentially, ion transfer creates a concentration cell across the membrane and similar equations to that given for the pH electrode apply. The term 0.059 V or 59 mV represents the ideal or Nernstian electrode response for a one-electron transfer, with a factor of 10 for change in activity (approximately concentration) for the analyte. As the charge, n, on the ion rises, the sensitivity of the measurement declines as $0.059/n$ decreases.

Table 2. Examples of crystalline, pressed salt, and polymer-based ion-selective electrodes and their Limit of Detection (LOD). All listed electrodes are Nernstian.

Analyte	Membrane type	LOD ($mol\,dm^{-3}$)	Reference
H_3O^+ (pH)	doped alkali glass/silicate	10^{-11}	–
F^-	LaF_3 crystal	10^{-7}	Frant and Ross (1966)
Cl^-	Pressed $AgCl/Ag_2S$	10^{-6}	Midgley (1981)
Cl^-, Br^-, I^-	Ag/AgX lattice (X = Cl^-, Br^-, I^-)	10^{-6}	Papeschi, Bordi and Carla (1978)
SO_4^{2-}	$Pb/PbSO_4$	5×10^{-4}	Gorina and Ryvkina (1978)
Ag^+	Ag/Ag_2S	10^{-7}	–
Cu^{2+}	Cu_xSe	10^{-6}	
Ca^{2+}	CaF_2	10^{-6}	Ghosh *et al*. (1978)
K^+	Polymer/valinomycin	10^{-5}	Umezawa (1990)
NO_3^-	Polymer/4,4′-diphenyl 2,2′-bipyridine nickel	10^{-6}	Umezawa (1990)
S^{2-}	Ag_2S	10^{-7}; 10^{-14a}	Midgley (1981)
Cu^{2+}	copolymer/CuS	10^{-6}	Achmatowicz *et al*. (2000)
Ca^{2+}	PVC/organophosphate	10^{-7}	Moody, Saad and Thomas (1988)
Pb^{2+}	DOS/PVC/ETH 5428	10^{-6}	Ceresa and Pretsch (1999)
Al^{3+}	PVC/Furil	10^{-6}	Mousavi, Arvand-Barmchi and Zanjanchi (2001)
Cl^-	Polymer/Mercuracarborand	10^{-7}	Badr *et al*. (1999)
I^-	Polyflourinated phosphazene/AgI, Ag_2S	10^{-7}	Janata and Huber (1979)
Acetate	PVC/Urea-functionalized porphyrin	10^{-5}	Amemiya *et al*. (1999)
Nitrate	PVC/Tetraalkylammonium nitrate	10^{-5}	Midgley (1981)

Note: [a]LOD values are highly dependent on control of the medium. This is done using acid–base and metal ion buffers, and total salt (ionic strength) control (Midgley, 1981).

There are hundreds of different ISEs in use, with a small number having sufficient selectivity for routine field, laboratory, or factory measurements (Umezawa, 1990).

Perhaps the best known after the glass electrode is the fluoride electrode (Figure 1), which has a europium-doped lanthanum fluoride crystal membrane with strong selectivity for fluoride, via the ion transfer F^- *interface* F^-, which leads to

$$E_{\text{membrane}} = L' - 0.059 \log[F^-]_{\text{external}} \qquad (9)$$

Measurements require use of a buffered media, (the OH^- ion is able to compete with fluoride in the LaF_3 lattice, and is thus a major problem). Further solution controls include salt to control the solution resistance and activity factors and a metal complexing agent to 'release' the free fluoride ion, which otherwise binds to the same metal ions. Analyte matrix control, via an ionic strength and buffer solution, such as that for fluoride, is essential for successful application of ISEs. Control of temperature and measurement time is also important; for the fluoride ion the response is often Nernstian to $10^{-7}\,mol\,dm^{-3}$ (Frant and Ross, 1966).

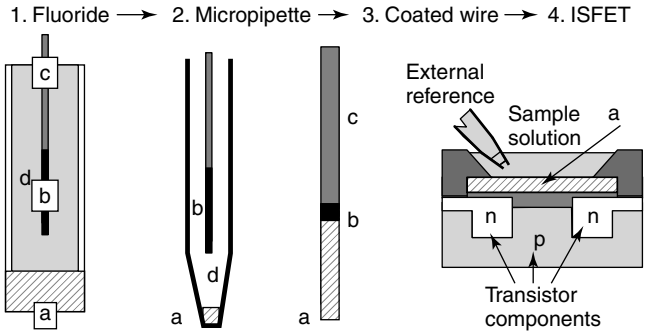

Figure 1. ISE construction and design trends, 1. the fluoride electrode; 2. micropipette; 3. a coated wire electrode; 4. the ISFET.

The antibiotic valinomycin gave important insights into the role of an ionophore in electrode selectivity; valinomycin provides an ion channel for potassium through the bacterial cell wall into the bacterium, the channel consisting of a ring of oxygen atoms of appropriate size for potassium ions. A selective electrode has been marketed using this design. Nonactin has also been found to be selective for ammonium ion for similar reasons. In a recent work by Amemiya *et al*. (1999), acetate ion has been selectively determined through a neutral hydrogen-bonding ionophore, (Table 2).

3 REFERENCE ELECTRODES AND MEASUREMENT STABILITY

Readings are found to drift with time for many potentiometric sensors, and a need to frequently check calibration is

commonly seen as essential practice. Finding the seat of the drift problem is often difficult, but examining the external reference electrode may be productive (Table 1). The reference electrode makes solution contact through a porous plug and the electrolyte flow must remain constant to avoid a so-called *junction potential shift*. Silver/silver chloride reference electrodes are subject to precipitation of silver chloride in the plug, this blocking process changing the overall potential. The problem can be reduced by trapping silver ions in a cation-exchange resin within the internal reference, with AgCl no longer precipitating. Ito *et al*. (1995) found that pH readings were consistent against freshly prepared pH sensors over many days with this modification.

4 FURTHER ISE DESIGN IMPROVEMENTS

Insight into ion fluxes in both the sensor and accompanying reference has led to important design improvements. Sokalski *et al*. (1997) dramatically improved the detection limit of a polymer membrane electrode for lead, using an internal complexing agent to ensure ion flux was directed inwards, avoiding contamination of the external analyte medium by the internal reference solution.

5 ION-SELECTIVE ELECTRODES AND MINIATURIZATION

Ion-selective electrodes have a strong advantage in the simplicity of their design, which has led to their miniaturization and application in many different clinical and industrial areas. As illustrated in Figure 1, micropipette (Gasser, 1988), coated wire (Cattrall and Hamilton, 1984), and transistor (ISFET) designs (Nam *et al*., 2003) are successful, with dimensions in the submillimeter range.

Figure 1 emphasizes the key features of these electrodes.

The Fluoride electrode (1) uses a lanthanum fluoride crystal (a), which promotes F^- ion transfer, the ion flux generating a potential in accord with (9). The internal reference (b) is $Ag/AgCl/Cl^-$ (Table 1) with some KF in solution(c).

The micropipette design (2) has led to clinical applications because of its small size (less than 1 mm). The design is otherwise similar to the fluoride example and excellent performance has been noted with detection limits at 10^{-9} M for calcium (Gasser, 1988)).

A coated wire electrode (3) dispenses with the internal reference and relies on electrical contact at (b) – see (4) and comments below.

The Ion-selective Field Effect Transistor ISFET (4) places the sensing membrane (a) over the gate of an n-p-n transistor. Potential again follows the Nernst expectation for pH or fluoride, as illustrated by (8) and (9).

Micropipette multibarrel potentiometric sensors, developed by clinical chemists and biologists, led to many novel applications, as discussed by Toth and coworkers (Toth *et al*., 1995). A zinc microelectrode provides potentiometric microscopy to nanometer resolution. More importantly, micropipette sensors inspired others to think of unique ways to miniaturize sensors.

The coated wire sensors are intriguing in that the internal reference is replaced by direct contact of the sensor coating with the metal contact (Figure 1, 3(b) and (3)). It is generally thought that a layer of metal salt forms and provides a pseudoreference potential for the sensor membrane (Cattrall and Hamilton, 1984). Despite the lack of understanding, the good performance of many coated wire systems gave the impetus for a similar arrangement in the ISFET where the membrane covers a silicon nitride layer.

6 ION-SELECTIVE FIELD EFFECT TRANSISTOR (ISFET)

The transistor and control of semiconducting properties of silicon has led to the ISFET. In the most common design, the ion-selective membrane is encapsulated in the device as the gate, the section that changes potential and allows a current to flow between regions of n-type silicon separated by a p-silicon section, Figure 1 (Nam *et al*., 2003). An active species, transported through the ISE membrane, can be measured via the potential needed to maintain an unchanged gate current. In the last situation, potential is found to follow the predictions of the Nernst equation (see (1), (7) or (9)).

6.1 Microfabrication of thick-film electrodes and electrode arrays

Electrodes can be made using screen-printing techniques on ceramic substrates with conducting pastes, which are then hardened by firing at high temperatures or by UV curing. Both heat and UV-cured approaches are described by Achmatowicz *et al*. (2000). Screen-printed methyl and butyl methacrylate copolymer-based copper sulfide sensors were found to give excellent Nernstian performance. An application of a multielectrode device to clinical analysis is illustrated by the use of coated silicon sensors by Scheipers *et al*. (2001). The authors discuss the on-line monitoring of blood electrolytes using potassium, sodium, and pH sensors deposited on silicon.

7 VOLTAMMETRY

Voltammetry is a process using applied voltages, which leads to electrolysis, loss of sample, and a current flow in the cell. By the use of a microelectrode, only a small part of the whole sample is used up in this electrochemical reaction. In electrical terms, however, this means the matching of the cell and the measuring instrument is not optimal as it is in potentiometry. Any problem is overcome by appropriate measurement operations designed mainly to protect the reference electrode.

It is a controlled potential method. The applied potential transfers electrons between the electrode surface and solution ions or molecules able to undergo reduction or oxidation at that potential. In this way, voltammetry provides information on what is present in the solution (the applied potential closely correlates with the standard potential of a reacting species). The current magnitude relates to how much is present, and the current direction tells whether oxidation or reduction is occurring.

8 POLAROGRAPHY

Voltammetric techniques are dominated by polarography and its variants. This is the measurement of the diffusion-limited current between a dropping mercury electrode (DME) (or working electrode) and a second or counter electrode. The applied potential is controlled against a reference (see Table 1), with no current drawn through the reference. The dropping mercury electrode (Figure 2) has major advantages over alternatives despite efforts to replace it as the working electrode because of environmental concerns. The mercury microdrop is renewed at a set time (a value within the range 0.5–2 s being commonly selected) at the end of a 100-μm glass capillary.

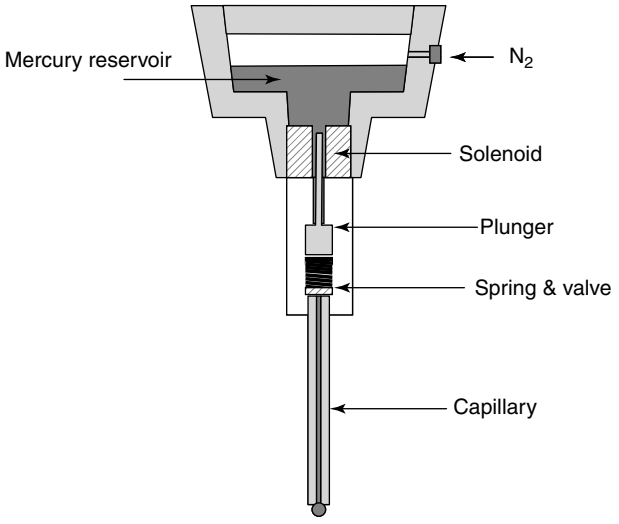

Figure 2. A controlled mercury capillary electrode. Mercury is held under nitrogen in the reservoir and drops are released at strictly controlled times as required. Skoog, Holler and Nieman (1998). (Reproduced by permission of Harcourt Brace College Publishers.)

Both depleted solution and the 'contaminated' electrode surface are renewed by the microdrop process. Secondly, mercury has a large hydrogen overpotential, which means that a wide range of cathode potentials is available without the danger of solution electrolysis.

The three electrode approach has come to dominate all voltammetric applications including polarography and its variants. The potential is scanned relative to a known reference electrode potential, while the diffusion-limited current between a DME and a counter platinum electrode is measured. Information on both the identity and the concentration of many electroactive compounds in a selected potential scan window are obtained. The potential observed is close, in most cases, to the standard potential seen in potentiometry and is typified by the Nernst equation. A small shift due to the influence of diffusion is observed, so the characteristic potential is called the *half wave potential*, $E_{1/2}$.

$$E_{1/2} = E^0 + K \log \left\{ \frac{D_{ox}}{D_{red}} \right\}^{1/2} \tag{10}$$

where E^0 is the standard reduction potential earlier defined for the Nernst equation, measured against a standard hydrogen electrode at $1\,\text{mol}\,\text{dm}^{-3}$ and 25 °C.

K is the Nernst factor, that is, $0.059/n$ V for log base 10, with n being the number of electrons transferred in the redox process. D_{ox} and D_{red} are the diffusion coefficients for the reduced and oxidized ions or molecules characterized by the process at that E^0.

The $E_{1/2}$ value is found half way up the polarographic wave – see later in Figure 4(a). It should perhaps be no surprise that $E_{1/2}$ will shift in value as does E in potentiometry if the conditions for E^0 to stay constant, for example, pH control, are not adhered to. Conversely, this means that pH influences on reactions are neatly studied by polarographic means.

An alternative form of the Nernst equation can be derived, which describes the polarographic waveform given in Figure 4.

$$E = E_{1/2} + K \log \left\{ \frac{i_d - i}{i} \right\} \tag{11}$$

where$\{(i_d - i)/i\}$replaces the concentration ratio in (1).

Measurement of the limiting diffusion current i_d and current, potential, i, $E_{1/2}$, data pairs over the polarographic

wave gives an excellent means of finding n values from calculated K values for reactions under study.

The additional theoretical basis of polarography is the Ilkovic equation:

$$i_d = knD^{1/2}Cm^{2/3}t^{1/6} \tag{12}$$

where

i_d = (measured) diffusion-limiting current
k = a constant dependent on both fundamental and system constants
C = concentration of electroactive species
m = mass flow rate of mercury
t = drop time

D and n are defined as given above.

The current flow in a practical measurement is limited by the rate of diffusion of the analyte molecule and its concentration. For given solution and electrode conditions, a plot of i_d versus C will provide a calibration graph from which unknown concentrations may be read. A useful account of the electrical side of the low-level signal need is Armutat (2004).

9 IMPROVED DME DESIGNS

Polarographic instruments use either a solenoid- or pressure-operated valve to release mercury from a 5-mL reservoir held under nitrogen, and generally a tapping device, to dislodge the mercury microdrop from its capillary tip to give exact time control of the microelectrode renewal. In the DC approach, the 'linear' potential scan is a series of small potential steps in unison with the drop release, a so-called *staircase sweep*, the current being read for say 20 ms late in the drop time (Figure 3a). The latter approach avoids problems in charging the drop and provides a cleaner and more easily processed signal.

The excellent reproducibility of the DME has been exploited in pulse techniques, which generally dominate voltammetry. Additional potential pulses are applied to the DC sweep to provide differential pulse polarography DPP and other variants (Garcia-Armada, Losada and de Vicente-Perez, 1996).

In Figure 3, a linear sweep (a) has been replaced by a staircase sweep in the DC method (b), while an additional potential pulse leads to a change in electrolysis current in the DP method (c). The current is read twice in each drop's life, before and after a potential pulse (e.g. 20–100 mV) is added to each 10-mV step in the staircase.

Comparison of the DC and DP polarographic approaches is further emphasized in Figure 4. The DC method reads a current, i, late in each drop time and displays i versus the applied potential E in a sigmoidal format where a redox process occurs. The DP approach, on the other hand, reads two current values, i_1 and i_2, and plots Δi against the applied potential E for each potential step.

The current change per potential pulse gives a peak data form or differential and has superior detection limits to the DC method. The potential at the DP peak differs slightly from the DC half wave potential because of the pulse size, that is,

$$E_{peak} = E_{1/2} - \Delta E_{pulse} \tag{13}$$

A differential pulse polarogram for two elements is shown Figure 5.

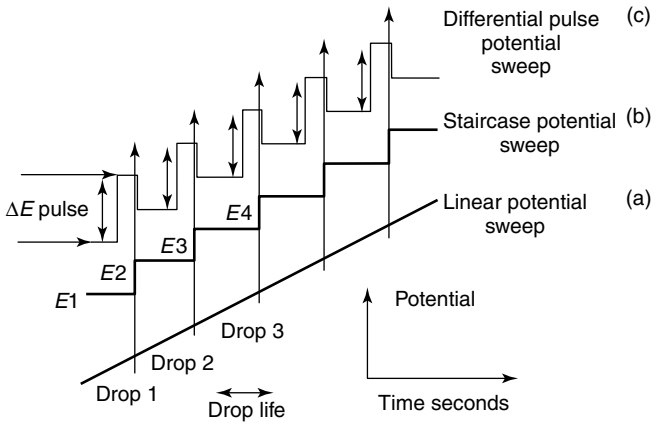

Figure 3. Potential–time sweep profiles used in voltammetric measurement methods. Pulse techniques replace a linear potential sweep with staircase potential time profiles.

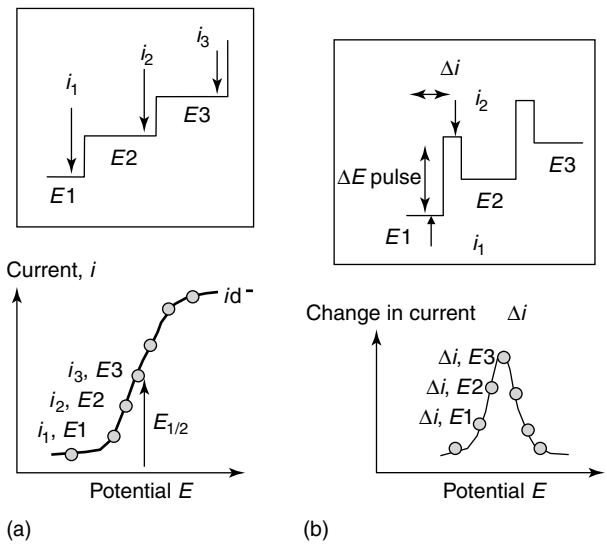

Figure 4. Potential and current relationships in DC and DP Polarography. The diffusion current i_d is proportional to concentration. $E_{1/2}$ is approximately equal to E^0.

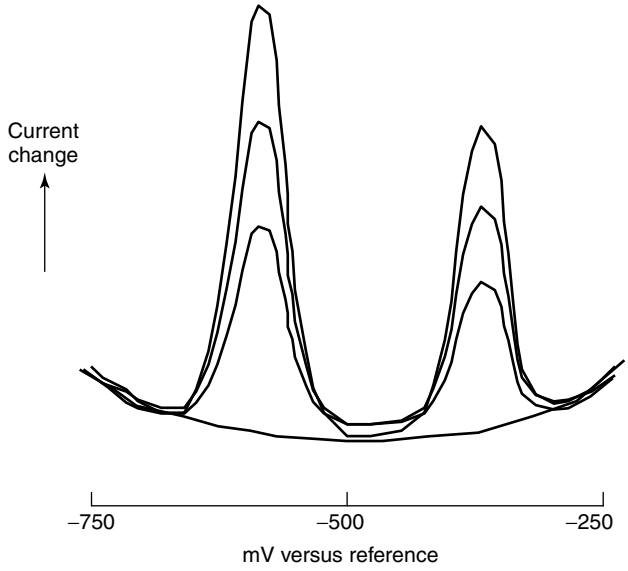

Figure 5. Standard addition traces for lead and cadmium in water, with applied potential read against the silver/silver chloride reference. Current is in nA for ppb concentrations.

9.1 Stripping voltammetry

A further refinement is found in stripping voltammetry (SV). The analyte is first plated on the working electrode at a fixed potential and then oxidized or reduced by a reversed potential sweep. Selected working electrodes include a hanging mercury drop and mercury films on a gold or graphite surface.

In anodic stripping voltammetry (ASV), analytes (importantly, heavy metal ions) are first reduced at a fixed electrode (often a mercury film on a platinum or graphite surface) and then oxidized by a rapidly sweeping reversed potential.

The advantage is that the limit of detection is improved by effectively integrating the measured current over a larger proportion (perhaps all) of the analyte in the sample, the analyte being preconcentrated on the electrode.

A disadvantage of ASV is that only species that undergo reversible electrode processes may be quantitated (Kipton, Powell and Florence, 1990). A summary of the limits of detection for the selected polarographic methods and stripping voltammetry is given in Table 3.

Table 3. Concentration ranges in polarography and voltammetry[a].

Mode	Typical limit of detection (mol dm^{-3})
DC sweep	10^{-4}–10^{-6}
DP sweep	10^{-4}–10^{-7}
Anodic stripping	10^{-6}–10^{-10}

[a]The limit of detection LOD is highly dependent on analyte and experimental conditions.

An interesting alternative to ASV is potentiometric stripping analysis. Plating follows the ASV approach, but stripping uses either a chemical oxidant or small oxidative current and follows the potential/time trend for each analyte's oxidation at its characteristic potential. The method is more tolerant of interferences in real solutions than ASV, and oxygen can be exploited as the oxidant (Jagner, 1983)).

Cathodic stripping voltammetry extends the range of species accessible by stripping procedures by adsorbing analytes held in complex form, the latter undergoing accessible reduction or oxidation. The technique has led to an improved understanding of environmental situations where metal bioavailability is controlled by naturally formed complexes and their equilibria with labile species (Herbert, 1999).

Voltammetric methods are widely used in environmental and industrial applications and are relatively inexpensive. Barek *et al*. (2001) discuss the polarography of carcinogens, pesticides, herbicides, dyes, and pharmaceuticals. A number of clinical and industrial measurements have been automated (Arnold and Meyerhoff, 1988; Hart and Wring, 1997).

9.2 Microvoltammetric electrodes

The application of microelectrodes to monitoring generally has immense promise, with electrode arrays being manufactured with hundreds of individual sensing elements and low cost per array (Montenegro, Queiros and Daschbach, 1991).

Arrays can be tuned to particular elements in a mixture, giving improved selectivity over conventional single electrodes. Saban and Darling (1999) measured heavy metals in aqueous solution with arrays having working electrodes such as Hg, C, Au, Ag, and Pt. Stripping voltammetry of Cu, As, Cd, Pb, Cu, Zn, Sn, and Hg was successfully illustrated to trace levels. Sullivan *et al*. (1999) provide an excellent description of both manufacture and application of simple arrays, in this case using 64 electrodes.

10 BIOSENSORS

An outstanding sensor based on voltammetric principles is the glucose sensor. The concept combines the discovery of a specific enzyme that oxidizes glucose to gluconic acid when oxygen forms hydrogen peroxide. Monitoring of the enzymatic process can follow oxygen depletion, peroxide formation, or changes in mediators.

An applied potential, tuned to the selected product, produces a current, and a glucose reading can be displayed.

This device has dramatically changed the lives of thousands of people suffering from diabetes.

The fundamental principles of the enzymatic electrode were laid down by Clark in the 1960s, and commercial success followed research at Oxford on immobilized mediator chemistry (Turner, Karube and Wilson, 1987).

A multichannel analysis of enzyme reactions is nicely illustrated by the work of Kasai, Matsue and Uchida (1996). A flow-through cell containing sixteen 100-μm Au electrodes probed the kinetics of horseradish oxidase and xanthine oxidase reactions with various electron donors. Each electrode could be scanned independently of the other. The continuing search for implantable electrodes and automated monitoring of health measures is discussed by Henry (1998).

1 DEFINITION

Accelerated testing is the application of stresses in excess of those that would be expected to be experienced by a product in service, in order to

1. create failures during development, to provide information on how the design might be improved;
2. cause faulty production items to fail without damaging good ones, so that delivered items will be reliable.

2 ROLE OF ACCELERATED TESTING

Stresses, in the widest sense, can lead to failures. Variations of strength, stress, and other conditions can influence the likelihood of failure or the duration (time, distance, cycles, etc.) to failure. (Stress–strength variation and interactions are discussed in **Article 98, Reliability and Maintainability, Volume 2**.) In this module, we will describe how tests should be designed and conducted to provide assurance that designs and products are reliable and durable in service.

Testing for reliability and durability is fundamentally different from testing to measure other performance parameters. The reasons are that we never know what is the 'uncertainty gap' between the theoretical and real reliability and durability of the design and the products made from it, for the whole population, over their operating lives and environments. The effects of these uncertainties can seldom be evaluated with confidence by design analysis methods. Therefore, we must perform tests that will reduce the uncertainty gap to an extent that we can be assured of reliability and durability, whilst taking due account of practical constraints such as cost and time. *To do this we must not test to demonstrate successful achievement, but test to cause failures.*

Then the following questions must be asked, for each failure:

1. Could this failure occur in use (on other items, after longer times, at other stresses, etc.)?
2. Could we prevent it from happening in use?

The stresses that were applied are relevant only in so far as they were the tools to provide the evidence that an opportunity exists to improve the design. We have obtained information on how to reduce the uncertainty gap. Whether the opportunity is taken is a management issue, in which other aspects such as cost, weight, time, and so on must be considered.

The uncertainty described above is shown in Figure 1. If we consider only one stress and the failures it might cause, the stress-to-failure distribution of production items might be as shown. As discussed in **Article 98, Reliability and Maintainability, Volume 2**, the exact nature of this distribution is almost always uncertain, particularly in the

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.

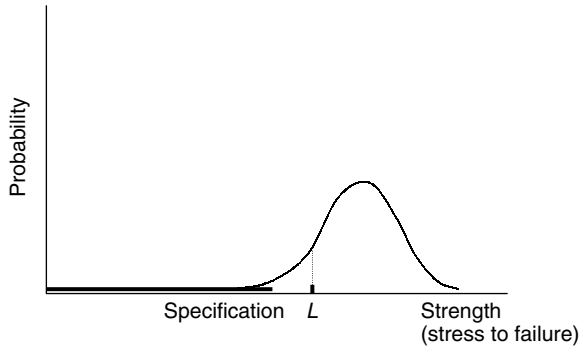

Figure 1. Stress, strength, and test failures (1).

tails, which are the most important areas as far as reliability and durability are concerned.

Suppose the first test failure occurs at stress level L. At this stage, we might have only a few items to test – maybe only one. We can state that the strength of this item represents a point on the distribution, but we cannot say whether it was an average strength item, a strong one, or a weak one. The only way to find out the nature of the strength distribution is to test more items to failure, and to plot and analyze the results. Inevitably, most of the items tested will be near the average, because that is where most of the population will lie. Therefore, it is unlikely that any item tested will represent the weakest in the future population. Also, testing large numbers is usually too expensive to be practicable.

However, if we analyze the actual cause of the failure, by whatever means is appropriate, and take action to prevent its recurrence, then in effect we will move the strength distribution to the right. *We can use high stresses in place of large samples*. The design will therefore be made more reliable.

For many items subject to stress, particularly electronic systems, two types of failures can occur: transient or permanent failures. With transient failures correct operation is recovered when the stress is reduced, but there is no recovery from permanent failures. The general case is illustrated in Figure 2.

If the failure is due to a wear-out mechanism, such as wear or fatigue, the horizontal axis of the distribution will represent time (or cycles), for any particular stress value. In addition to the uncertainty regarding the stress and strength, we now have the further uncertainty of time. Failure on test after time t at stress level L will represent one point on an unknown 3-dimensional distribution (Figure 3). As Figure 3 illustrates, an important feature of wear-out mechanisms is that the resulting distributions of times to failure become wider as damage accumulates, thus further increasing the uncertainty.

In many engineering situations, failures are caused by combinations of stresses and strength values, not just by one stress and one strength variable. Some might be time-dependent, others not. Between any two or more variables there might also be interactions, as described in **Article 98, Reliability and Maintainability, Volume 2**. Therefore, even for relatively simple and common failure situations, there is not just one distribution that is important, but a number of possible distributions and interactions.

Accelerated stress testing can provide quantitative cause-and-effect information when the mechanisms of failure are

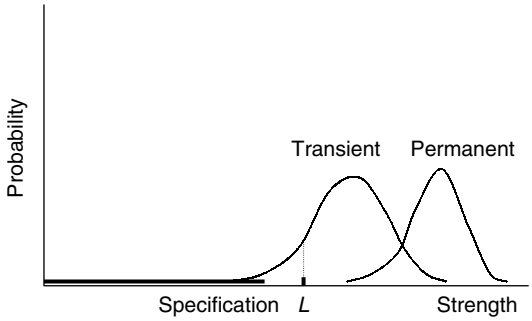

Figure 2. Stress, strength, and test failures (2).

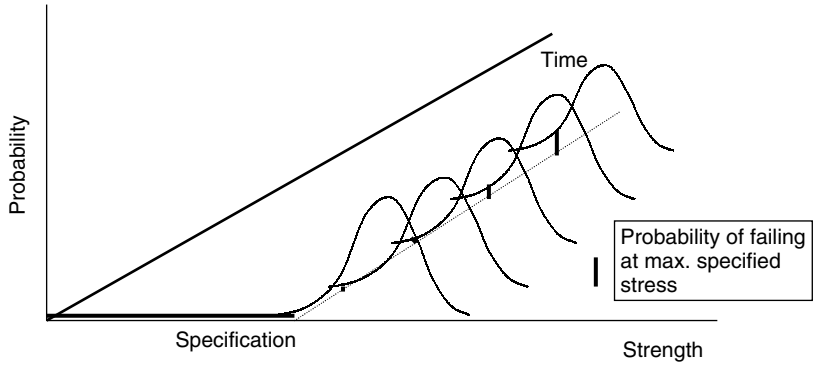

Figure 3. Stress, strength, and test failures (3): wear-out failures.

already understood (e.g. material fatigue), and when the tests are planned specifically to provide such information. We must decide whether we need the extra information that more 'scientific' or statistical tests can provide.

Accelerated tests can also be applied to production and to repair.

3 HIGHLY ACCELERATED LIFE TESTING (HALT)

Nearly all standardized approaches to stress testing (O'Connor, 2001) demand the use of typical or maximum specified stresses. However, the highly accelerated life testing (HALT) approach to accelerated testing is a logical extension of the preceding discussion. With HALT, we increase stresses (individual or combined) so that we cause failures to occur, then use the information to improve reliability and durability. The logic that justifies the use of very high stresses, not necessarily representative of expected application conditions, is based upon four aspects of engineering reality:

1. The causes of failures that will occur in the future are often very uncertain.
2. The probabilities and durations of failures are also highly uncertain.
3. Time spent on testing is expensive, so the more quickly we can reduce the uncertainty gap the better.
4. Finding causes of failure during development and preventing recurrence is far less expensive than finding new failure causes in use.

It cannot be emphasized too strongly: testing at 'representative' stresses, in the hope that failures will not occur, is very expensive in time and money and is mostly a waste of resources.

The HALT approach, and variations of it, are also referred to as (highly) accelerated stress testing ((H)AST), stress-induced failure environmental (STRIFE) testing, failure mode verification test (FMVT), and other terms.

Clearly, there might be practical limits to the stresses applied. These could be set by

- the fundamental limits of the technology, for example, there is no point in testing an electronic system at temperatures above the melting point of the solder used;
- the limits of the test capability, such as the maximum temperature of the test chamber.

4 TEST APPROACH FOR ACCELERATED TEST

4.1 Development

The approach that should be applied to any accelerated test programme during the development phase to assure reliability/durability should be as follows:

1. Try to determine, as far as practicable, what failures might occur in service. This should have been performed during design analysis and review, particularly during the failure modes, effects, (and criticality) analysis (FME(C)A) as described in **Article 98, Reliability and Maintainability, Volume 2**.
2. List the application and environmental stresses that might cause failures.
3. Plan how the stresses that might stimulate foreseeable and unforeseen failures can most effectively be applied in test. Set up the item (or items) to be tested in the test chamber or other facility so that it can be operated and monitored.
4. Apply a single stress, at or near the design maximum, and increase the level stepwise until the first failure is detected.
5. Determine the cause and take action to strengthen the design so that it will survive higher stresses. This action might be a permanent improvement, or a temporary measure to enable testing to be continued.
6. Continue increasing the stress/stresses to discover further failure causes (or the same cause at a higher stress), and take action as above. This approach is called *step-stress testing*.
7. Continue until all of the transient and permanent failure modes for the applied stress are discovered and, as far as technologically and economically practicable, designed out. Repeat for other single stresses.
8. Decide when to stop (fundamental technology limit, limit of stress that can be applied, cost or weight limit).
9. Repeat the process using combined stresses, as appropriate and within the equipment capabilities (temperature, vibration, power supply voltage, etc.).

4.2 Production

The basic difference between the objectives of accelerated test in development and in manufacturing is that, whilst we try to cause all development test items to fail in order to learn how to improve the design (of the product and of the production processes), we must try to avoid damaging good manufactured items, whilst causing weak or defective

ones to fail so that they can be corrected or segregated. Therefore, the stress regime applied is less severe. This is called *environmental stress screening* (ESS). When applied to electronic components and assemblies, it is also referred to as *burn-in*.

Applying accelerated testing during development provides evidence not only on how to make designs more robust but it also provides the information necessary to optimize ESS for manufacturing. The knowledge that we gain by applying the full HALT philosophy, including the design ruggedization, can be used to design a stress test regime that is optimized for the product, and that is far more effective than conventional ESS. This is called *highly accelerated stress screening* (HASS). HASS provides the same benefits in manufacturing as HALT does in development, in greatly increasing the effectiveness of manufacturing screens whilst reducing test cost and time.

4.3 In service

ESS can be applied to items that have been repaired. The HASS approach can be particularly beneficial in confirming that repairs have been successful, and in identifying the causes of intermittent or transient failures that often lead to 'no fault found' (NFF) (or 're-test OK' (RTOK)) diagnoses and repeat failures in service.

4.4 Accelerated test facilities and services

Special test chambers have been developed for HALT/HASS. These enable higher stresses to be applied (primarily temperature rates of change and vibration) than is possible with conventional environmental test chambers. Figure 4 shows a chamber. Training and consulting on HALT/HASS is provided by Hobbs Engineering (URL: http://www.hobbsengr.com) and by some equipment and service providers. The method and the equipment are fully described in Hobbs (2000).

Other facilities are available for the provision of accelerated tests, with the emphasis on specific stresses, for example, vibration in the FMVT approach. Equipment and service suppliers are listed in the homepage of O'Connor (2001) (URL: http://www.pat-oconnor.co.uk/testengineering.htm). More information is provided in **Article 216, Test Facilities, Volume 3**.

5 EXAMPLES OF ACCELERATED TESTING

Accelerated tests, and in particular the HALT/HASS approach, can be applied in principle to any kind of product or technology. For example:

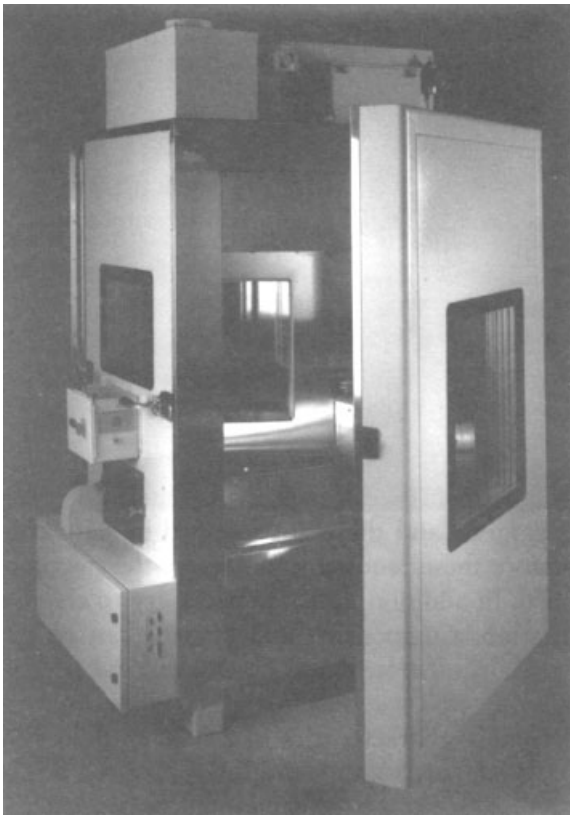

Figure 4. HALT/HASS chamber. (Copyright QualMark Corporation.)

Engines, pumps, power transmission units such as gearboxes, and so on.

- Start tests with old lubricants or other fluids (coolants, hydraulics, etc.), rather than new.
- Run at low fluid levels.
- Use fluids that are heated, cooled, or contaminated.
- Use old filters.
- Misalign shafts, bearings, and so on.
- Apply out-of-balance to rotating components.

Electro-mechanical assemblies such as printers, document, material or component handlers, and so on.

- Apply high/low temperatures, vibration, humidity/damp, and so on.
- Use components with out-of-tolerance dimensions.
- Misalign shafts, bearings, and so forth.
- Use papers/documents/materials/components that exceed specifications (thickness, weight, friction, etc.).

Small components or assemblies such as electronic packages, mechanical latches, switches, transducers, and so on.

- Apply high/low temperatures, vibration, humidity/damp, and so forth.

- Apply high frequency vibration by fixing to suitable transducers, such as loudspeaker coils, and driving with an audio amplifier.

215: Automatic Test Systems

Patrick D.T. O'Connor
Consultant, UK

1 Definition of an Automatic Test System (ATS) 1464
2 Role of an Automatic Test System 1464
3 Elements of an ATS 1464
4 Setting up an ATS 1465
5 Example of ATS 1466
References 1466

1 DEFINITION OF AN AUTOMATIC TEST SYSTEM (ATS)

An automatic test system, ATS (also called *automatic test equipment* (ATE)), is one in which the tasks of measurement and of categorizing items under test are controlled and performed automatically. An ATS can in some cases also perform other functions including diagnostics, data logging, and so on. Automatic test equipment is the term generally used in the context of testing electronic components, circuits, and system (*see* **Article 79, Testing Electronic Systems, Volume 2**). The term *unit under test* (UUT), or *system under test* (SUT), is often used in the context of ATS to refer to the item or system being tested. For more information, see Sheppard and Simpson (1994).

2 ROLE OF AN AUTOMATIC TEST SYSTEM

The primary role of an ATS is to improve the efficiency (primarily by reducing test time or cost) of the test process, by replacing human actions with equipment that can perform tests more rapidly and also usually more consistently. ATS can be applied during development, in production, and in service. For some modern systems, particularly complex electronic circuits (microcircuits and assembled systems), ATS is the only feasible approach since the test problem (number of test conditions, system operating speed) makes manual testing impracticable or impossible. In many modern production situations, the throughput is so high that ATS is the only practicable approach. In-service equipment is sometimes tested by ATS that is integrated into the system. This is called *built-in test* (BIT), *built-in test equipment* (BITE), or *built-in self-test* (BIST).

BIT can run tests fully automatically, either continuously or, for example, on system start-up or when selected. Automatic calibration is also a type of BIT. For further information, see Stroud (2002).

3 ELEMENTS OF AN ATS

An ATS can consist of individual test equipments controlled by a separate controller, or it can be a fully integrated system. Most electronic ATE is in the latter category. The primary elements of an ATS are as follows:

- *Interfaces*: The ATS must be connected to the UUT so that stimuli can be applied and responses measured. Interfaces can be electrical connectors, special adaptors, transducers, and so on, and can also include functions such as analog to digital (A/D) conversion, signal conditioning, and so on.
- *Data acquisition*: The ATS must provide automatic data acquisition DAQ – *see* **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**. This typically

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

includes capabilities for sampling the parameters or states being measured, capturing the data, and transmitting it to the appropriate instruments and so on. A wide range of systems is available. See the section below.
- *Measurement*: Appropriate instruments must be provided for measuring the relevant parameters.
- *Display and recording*: Input and output data must be displayed and recorded. Displays can include dials, screens, and so on. Data can be recorded on magnetic tape, or on computer storage media.
- *Analysis*: The ATS might include capabilities for data analysis, such as graphical analysis, Fourier analysis, statistical analysis and control, and so on.
- *Software*: The functions listed above are controlled and performed mainly by software. See the sections below.
- *Others*: Depending on the requirements of the system, the ATS might include other capabilities, such as warnings, communications with design or database systems, Internet connectivity, and so on.

3.1 PC-based ATS

Personal computers (PCs) can be used to implement and control ATS. The PC, with appropriate software, can perform the functions of test and instrument control, data acquisition, display, analysis, and so on. The LABVIEW® software (National Instruments Corp. (URL: http://www.ni.com)) enables PC-based ATS to be designed graphically, and all test functions to be controlled from PCs. See Johnson (1997). PCs can also be used in conjunction with special PC cards in lieu of dedicated test instruments, such as oscilloscopes (*see* **Article 79, Testing Electronic Systems, Volume 2**).

3.2 Test Data Acquisition

There is a wide range of available systems for test data acquisition. These convert analog electrical signals to digital and control the data transfer between the UUT and the tester. The important performance characteristics are high speed–multichannel data sampling, high noise rejection, high bandwidth, and data transfer to computer memory.

Modern electronic test systems use standard data bus software. IEEE488 was the first test data bus standard, and most modern instruments include it. It is also called the *general purpose interface bus* (GPIB). More information is available from instrument suppliers, such as Agilent Technologies (URL: http://www.agilent.com), *see also* **Article 167, Asynchronous and Synchronous Interface Protocols, Volume 3**; **Article 168, RS 232 and EIA/TIA 232 Serial Interface, Volume 3**; and **Article 170, IEEE-488 Instrumentation Bus, Volume 3**.

The PC interface (PCI) bus or PCI extensions for instruments (PXI) bus are the versions used for PC-based testing. More information is available from instrument suppliers, particularly from National Instruments Corp. (URL: http://www.ni.com).

Larger functional test ATE systems use the VXI bus standard, which allows higher test speeds and greater accuracy.

DAQ or DAS systems are described in more detail in **Article 132, Data Acquisition Systems (DAS) in General, Volume 3**; **Article 136, Quantizing Theory Relevant to DAS, Volume 3**; and **Article 140, Integrating Type A/D Converters, Volume 3**. Computer bus systems are described in the section on **Distributed and Networked Measuring Systems**.

3.3 Test Software

Test software must be developed for any system that is to be tested on ATS. For some systems, particularly for aerospace electronics (avionics) and military systems, the abbreviated test language for all systems (ATLAS) is used. The LABVIEW® software, mentioned above, includes the appropriate control software so that it is not necessary to write test programs.

3.4 Conclusions

More information on the topics and systems described above is available in O'Connor (2001). The book's homepage (URL: http://www.pat-oconnor.co.uk/testengineering.htm) provides lists of hardware and software suppliers.

4 SETTING UP AN ATS

To set up an effective ATS, it is necessary to consider

- the items to be tested in terms of quantities, technologies involved, test requirements, and so on;
- the test conditions to be applied (e.g. climatic, vibration, loads, electromagnetic, etc.; *see* **Article 214, Accelerated Testing, Volume 3**; **Article 216, Test Facilities, Volume 3**);
- the costs of the facilities and options (manual vs automatic) in terms of fixed and variable costs;
- the costs of alternative options for setting up the facility (use of other facilities, reliance on previous tests).

The management aspects of ATS are discussed in more detail in O'Connor (2001).

5 EXAMPLE OF ATS

Modern vehicle development testing relies heavily on ATS. PC-based systems control the testing and data acquisition of a number of parameters, while the vehicle is driven on test tracks or subjected to other environmental conditions. Vehicle subsystems such as power trains, suspension, and so on are also tested automatically on special facilities. The PC communicates with the various test instruments via a PXI bus. The design of the tests (parameters, limits, sampling rates, data acquisition and analysis, etc.) are programmed using appropriate software such as LABVIEW (mentioned above), *see* **Article 105, Modeling with LabVIEW™, Volume 2**.

1 NATURE AND SCOPE OF TEST FACILITIES

In this module, the term test facility is used to include any location or organization in which test capabilities (product test, instrumentation, etc.) are provided. For convenience, test facilities are classified as follows:

- materials, components, and structures;
- systems;
- specialist facilities, including those for electromagnetic testing and calibration.

These are described in turn, including the main types of equipment used.

Facilities that are used wholly or mainly for manufacturing test are not included.

There are many independent test facilities, offering capabilities for most of the tests described below. Some of them specialize in particular industry or technology areas. Many of the industry-based facilities also offer independent services.

Major national and international test facilities are listed in Section 5.

2 MATERIALS, COMPONENTS, AND STRUCTURES

This article covers the methods used to test materials, components, and structures to determine their strength and other characteristics. These tests can be applied to samples of the materials used in which case the data is applicable to any component made of the material. However, sometimes the tests are performed on finished components and structures as well, particularly if the manufacturing processes can alter the material properties.

The main tests, with links to **Part 8, Elements: B – Signal Conditioning, Volume 2**, are as follows:

Static strength: Static tests are performed to measure strength: tensile, compressive, shear, buckling, and so on. Figure 1 shows a typical test machine.

Fatigue strength: Fatigue tests are performed on material specimens by applying controlled cyclic stresses, for example, using a tensile test machine, and recording the cycles until fracture occurs. For large components and structures, such as vehicle bodies, aircraft wings, and train bogies, special test rigs must be constructed, and the stresses are applied by hydraulic actuators. Figure 2 shows a rail passenger vehicle being tested using a hydraulically excited undersupport system. Such systems exist for testing several hundred tonne equipments such as battle tanks.

Hardness: Hardness is determined by measuring the indentation in material specimens when a defined shape is forced on to the specimen with a defined load. Two commonly applied hardness tests are the Brinell test and the Rockwell test. The Vickers and the Knoop hardness

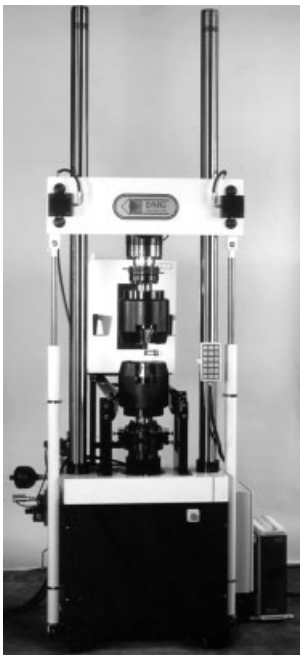

Figure 1. Tensile test machine. (Reproduced by permission of Denison-Mayes.)

Figure 2. Strength/fatigue test on rail passenger vehicle. (Reproduced by permission of TuV Product Service.)

tests are similar. This test is not developed from formal scientific description; in each case, the hardness number is an empirical value, with units of force/length^2. Its use is a comparative test.

Toughness: Toughness is measured by impact tests in which the energy level that causes a prepared specimen to fracture indicates the material toughness. The Charpy V-notch test uses a specimen with a defined V-shaped notch machined across the centre.

Wear resistance: Resistance to wear is measured by subjecting the materials to wear conditions (adhesive, fretting, abrasive, etc.) in suitable test rigs. The amount and nature of the wear is measured by examination of the surfaces and by weight comparisons.

Corrosion and chemical attack: Tests for the ability to withstand corrosion or chemical attack are performed by appropriate methods, such as salt spray, immersion, and so on.

3 SYSTEMS

3.1 Climatic, thermal

Climatic and temperature testing is performed using chambers in which the temperature can be varied. These can range in size from small bench-top units of less than 1 m^3, to very large facilities in which complete items such as cars, rail vehicles, aircraft, medium size houses, rocket motors under simulated space conditions, and major military systems can be tested. High temperatures are generated using electrical heaters. Radiant heating may also be applied. Low temperatures are generated by refrigeration units, or by using liquid nitrogen. Humidity, condensation, freezing, and precipitation conditions can be applied with appropriate chambers.

Typical chambers provide temperature ranges between $+60\,^{\circ}\mathrm{C}$ and $-40\,^{\circ}\mathrm{C}$. An important further performance characteristic is the rate of change of temperature that can be achieved, particularly for tests that require rapid or frequent temperature excursions. Powerful electrical heaters and liquid nitrogen cooling systems can generate rates of change of $20\,^{\circ}\mathrm{C\,min^{-1}}$, and up to $100\,^{\circ}\mathrm{C\,min^{-1}}$ in special chambers such as highly accelerated life test (HALT) chambers (**Article 214, Accelerated Testing, Volume 3**). Another way of generating high rates of change, or temperature shock, is to use a two-chamber system, with one hot chamber and one cold one, and a rapid transfer of the item under test between the two chambers.

3.2 Vibration

Items can be subjected to a vibration test by being secured to platforms that are vibrated. The vibration systems are variously called *shakers, vibrators, exciters*, or *thrusters*,

though vibrator is the ISO preferred term. The VIBKIT98™ (http://www.lds.com) software is an effective tool for determining vibration and shock test parameters. Harris and Crede (1976) cover the subject of vibration and shock testing in detail. *See also* **Article 205, Theory of Vibration Measurement, Volume 3**.

3.2.1 Vibration sources

The main vibration sources for test are as follows:

- Eccentric rotating weights. These are simple, low-cost systems, and being strictly harmonic systems, lack frequency spectrum modification.
- Electrodynamic (ED) (moving element with armature coil, suspended in a static magnetic field, and driven by alternating electric current). The frequency and intensity can be varied by the control system. Such systems can range in size and power from small vibrators with frequency ranges up to 10 kHz, to very large, water-cooled units with frequencies up to 2 kHz and thrust values up to 300 kN. Figure 3 shows an ED vibrator, being used for evaluating squeak and rattle in automotive assemblies.
- Pneumatic and hydraulic-actuator systems are used when larger displacements are needed, and for heavy items such as vehicles.
- Multiaxis systems, such as the following:
  - multiaxis shake tables (MAST). These are large systems that use multiple hydraulic or pneumatic actuators to drive the platform;
  - Multiaxis repetitive shock systems, such as HALT vibrator tables, which are powered by a number of pneumatic hammers mounted on the underside. These input completely random, 6 degree of freedom (3 axial, 3 rotational) vibration up to 0.1 g $(\text{rms})^2$/Hz over a wide frequency range (10 Hz–10 kHz). *See* **Article 214, Accelerated Testing, Volume 3**.
  - The Cube™ of TEAM Corp. (http://www.team.com) is a freely suspended hollow rigid cube, with pneumatic actuators mounted onto the inside faces (upper and four sides). Items to be tested are fitted to the outside faces.

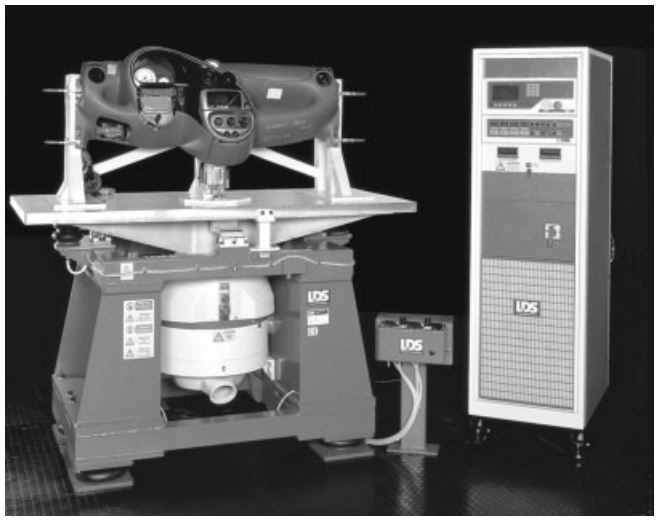

Figure 3. Electrodynamic vibrator (LDS). (Copyright © LDS.)

3.2.2 Vibration characteristics

Vibration may be applied at a simple fixed frequency, over a swept range of frequencies, or simultaneously over a selected range of frequencies. Random vibration is vibration that is applied over a range of frequencies and amplitudes that vary randomly over time. Pseudorandom vibration is what is actually applied, because generation of true random vibration is not practicable. By stimulating a range of vibrations simultaneously, the existence of simultaneous resonances can be determined.

Power spectral density (PSD) is the term used to quantify vibration power at a frequency within the range. The unit of PSD is g_n^2/Hz (or, more correctly, g_n rms^2/Hz or the SI units $\text{m/s}^2/\text{Hz}$). The total force rating of a vibration system, over its frequency range, is expressed as g_n rms, kgf rms, N rms or lbf rms. It is the area under the curve of PSD versus frequency, such as in Figure 4.

Vibration control systems permit the vibration pattern and intensity to be planned and controlled. The vibration parameters measured on the unit under test (usually from suitably positioned accelerometers) are compared with the defined inputs, and the controller provides the required outputs to the drive amplifier of the vibrator. A typical random vibration test specification is shown in Figure 4.

Other vibration and shock inputs can also be applied, such as sine superimposed on random, specific shock patterns, and so on.

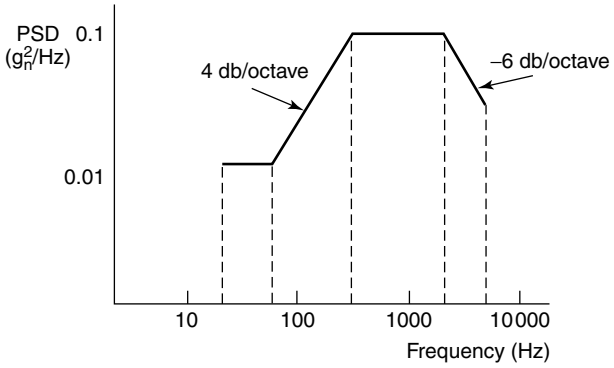

Figure 4. Typical random vibration test profile. (Reproduced from *Test Engineering*, O'Connor, 2001 © John Wiley & Sons Ltd.)

Figure 5. Combined environment test facility. (Repoduced by permission of Thermotron.)

3.3 Shock testing

Shocks are single events of high energy, or which might result in short-duration high frequency vibration. Mechanical shock or impact can cause fracture, or repeated shocks can cause fatigue leading to fracture. Shock tests are performed by dropping the item on to a rigid base, by using shock test machines, which allow defined accelerations to be applied, or by using more dramatic methods such as crash tests on vehicles. The term often used for shock impact is *jerk*, that being the derivative of acceleration.

3.4 Combined environments

To be realistic, environmental stresses are often applied in combination. This is sometimes referred to as *combined environmental reliability testing* (CERT). Typical combinations used are temperature and vibration, as well as other stresses such as electrical power, humidity, solar radiation, and so on. Figure 5 shows a CERT chamber along with its computer control and data acquisition and visual display recording system.

4 SPECIAL TEST FACILITIES

4.1 EMI and EMC

Electromagnetic interference (EMI) is the conducted or radiated emissions ('noise') from an electrical or electronic equipment that could interfere with the correct operation of other equipment.

Electromagnetic compatibility (EMC) is the capability of equipment to operate correctly in the presence of known levels of electromagnetic radiation or conducted electrical or magnetic disturbance. This is sometimes called electromagnetic immunity.

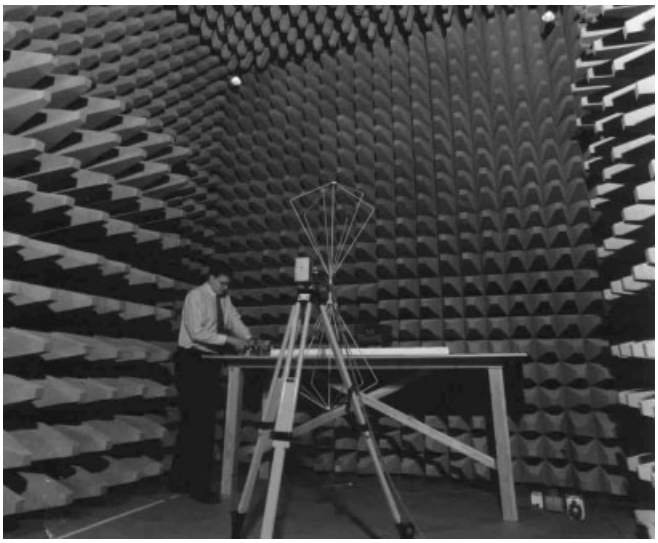

Figure 6. EMI/EMC test chamber. (Reproduced by permission of TuV Product Service.)

Testing for EMI/EMC consists of operating the equipment and measuring the noise outputs, and submitting the equipment to specified conditions. Special Radio Frequency (RF) anechoic chambers, equipped with appropriate measuring and transmitting equipment, are used (Figure 6). The cones on the walls are foam laden with RF absorbing materials to attenuate RF reflections inside the chamber. Doors are sealed, using silver finger contacts, to prevent RF emissions. Walls are provided with RF screening to make the enclosure an effective Faraday Cage.

Williams (1992) describes EMI/EMC requirements and test methods. *See also* **Article 17, EMC and EMI, Volume 1**.

4.2 Industry-specific facilities

Many large companies operate test facilities for their own product development. The major automotive companies operate facilities that include most of the special test equipment described in this module, as well as test tracks, dynamometers, and so on. Military and aerospace companies, as well as other industry sectors (telecommunications, railways, etc.), also operate appropriate facilities. Industry-specific facilities are also operated by consortia and by government and nongovernment organizations.

4.3 Calibration

Nationally accredited facilities are operated in most countries to provide calibration with reference to primary

metrology reference standards, to which all lower-level calibrations must be traceable. Calibration requirements and standards are described in **Article 46, Calibration Interval, Volume 1**; and **Article 47, Internet Calibration, Volume 1**, *see also* Morris (1997).

There is an increasing trend toward international and transnational operations for test and calibration as this avoids double testing and reduces duplication of test plant.

The international standard for the accreditation of measurement and test laboratories is ISO17025.

A test facility may be offered for third-party testing, in which case it is likely to be offered under a certified accreditation scheme. Many test equipments, however, are proprietary and kept for company use only.

4.4 Other specialist facilities

Other specialist test facilities exist to provide services as required for other conditions and susceptibilities, such as humidity, mold growth, atmospheric pressure, space vacuum, ultraviolet radiation, and so on. Information on these can be obtained from the lists in Section 5, and from appropriate specialist publications and standards.

5 LIST OF KEY TEST FACILITIES

This list presents information on other test facility lists that are available. It also provides a selection of the major national and international test facilities.

5.1 Test facility listings

1. Homepage to O'Connor (2001) (http://www.patoconnor.co.uk/testengineering.htm). This includes lists of facilities, information sources, and so on.
2. Institute of Environmental Sciences and Technology (USA) (IEST) (http://www.iest.org). The IEST publishes lists of test facilities and equipment suppliers, mainly in the USA.
3. Society of Environmental Engineers (SEE) (UK) (http://www.environmental.org.uk). The SEE publishes a directory of test facilities and equipment suppliers, mainly in the United Kingdom but also in the rest of Europe and the United States.
4. The relevant national accreditation agencies maintain lists of accredited test facilities. UK Accreditation Service or UKAS (http://www.ukas.org.uk); USA: Underwriters' Laboratory UL (http://www.ul.org).

5.2 Selected UK facilities

1. AEA Technology (http://www.aeat.co.uk). Test facilities, including nondestructive test NDT (UK National NDT Centre).
2. British Standards Institution (BSI) (http://www.bsi.org.uk). BSI operates test and measurement laboratories.
3. Electrical Research Association (ERA) (http://www.era.co.uk). Wide range of materials and component test and research, EMI/EMC test.
4. Motor Industry Research Association (MIRA) (http://www.mira.co.uk). Test facilities, primarily to support automotive applications.
5. National Engineering Laboratory (NEL) (http://www.nel.co.uk). Structural testing and flowmeter evaluation.
6. National Physical Laboratory (NPL) (http://www.npl.co.uk). NPL maintains the primary UK reference standards for calibration and measurement. It undertakes measurement research and development, calibration, and EMI/EMC testing.
7. QinetiQ (was Defence Evaluation and Research Agency (DERA)). (http://www.qinetiq.co.uk). Range of test facilities, primarily for military equipment and systems test.

5.3 Selected USA facilities

1. Underwriters' Laboratory (UL) (http://www.ul.com). In addition to maintaining the primary US national reference standards for calibration and measurement and accrediting lower-tier facilities. UL operates test and measurement laboratories.
2. Wyle Laboratories (http://www.wylelabs.com). Wide range of environmental test facilities.

5.4 International

1. TuV Product Service (TUV-PS) (http://www.tuvglobal.com). TuV operates a number of test laboratories in the United States, United Kingdom, and Europe, covering a wide range of environmental conditions, including HALT/HASS (*see also* **Article 214, Accelerated Testing, Volume 3**).

1 INTRODUCTION

A definition of instrument evaluation that is generally accepted among the major cooperative instrument evaluation groups is 'the investigation and testing of the performance of instruments and related equipment in accordance with an agreed program based on the manufacturer's specification, relevant national, and international standards and specific user requirements'. The agreed program will usually include performance evaluation under reference conditions and simulated environmental conditions (often referred to as *influence conditions*) together with an assessment of standards of construction and adequacy of documentation, such as operating instructions and maintenance handbooks.

The process can most succinctly be described as a comprehensive technical audit. The concept of instrument evaluation has been developed over a 40-year period in order to meet the needs of instrument users and manufacturers of industrial instrumentation and process control equipment. It is aimed at producing the maximum possible amount of information on the performance of instruments and related equipment bearing in mind the needs of the user and the rights of the manufacturer to a fair and consistent assessment of his product.

2 THE NEED FOR INSTRUMENT EVALUATION

Back in the 1950s, with the increasing use of sophisticated measurement and control equipment in process plants (which themselves were increasing in size, complexity, and cost) came the realization of the increasing financial consequences of instrument failure. Such consequences do not only apply in the event of a complete failure of an instrument, which, because of a fail-safe system philosophy, could result in a costly plant shutdown. They also, and more commonly, apply in cases in which the performance of the instrument gradually deteriorates in an undetected manner as a result of an influence condition or just over a period of time. Such deterioration can cause a shift in the performance of an automated plant away from a state of optimum performance as defined by a required cost and quality target. It is relatively straightforward, although sometimes costly, to provide instrument redundancy so that a fail-safe plant shutdown only occurs if, say, two out of three instruments fail simultaneously in a catastrophic sense. However, it is less simple to arrange that such redundancy will compensate for the gradual deterioration of the measurement or for the susceptibility of the instrument to the variations of a particular environmental parameter, such as temperature, vibration, or electromagnetic interference. The financial consequence of instrumentation failing to meet its expected performance criteria led to an increasing insistence by user industries of comprehensive evaluation as

Handbook of Measuring System Design, edited by Peter H. Sydenham and Richard Thorn.
© 2005 John Wiley & Sons, Ltd. ISBN: 0-470-02143-8.

a prerequisite to purchasing decisions. It is however recognized that in recent years partial control over the purchasing of equipment has been relinquished by some end users. This has come about by the contracting out of the supply of systems or parts of systems to third parties, with these contractors being more likely to rely on manufacturers' published specification rather than on independent comprehensive evaluation reports.

It is noted however that a concept that is becoming increasingly recognized in industry is the one of Life Cycle Costing, which considers the costs incurred from the conception of an application to the point of decommissioning and abandonment. Life Cycle Costing has two main components: CAPEX (CAPital EXpenditure), which includes all expenditure from conception to the end of commissioning, and OPEX (OPerating EXpenditure), which covers the cost from then on. It is clear for nominally identical products from different manufacturers that apart from the ex-factory cost of the item itself, the CAPEX costs (including those associated with design, specification, installation, commissioning, and documentation) are similar. However, OPEX costs can be quite different, primarily due to the ability of the equipment to operate within certain performance limits, over an extended period of time under the prevailing environmental conditions. For this reason, if for none other, the need for comprehensive instrument evaluation remains.

The cost of carrying out a comprehensive evaluation naturally depends on the type of instrument to be investigated and the details of the testing required, but would typically range from £10 000 to £30 000. While this may seem a reasonably large sum of money, it must be balanced against the savings that can be made from making informed decisions on the basis of evaluation findings.

While the needs of manufacturers for instrument evaluation are less obvious, they nevertheless exist. Particularly in relation to new designs, it is important to identify a serious design weakness before a significant number have been delivered. The direct cost penalty of retrieving and modifying such instruments is obvious enough, the penalty in terms of lost customer confidence and future sales is more serious. While the manufacturer may carry out significant testing of his product before its appearance on the market, there are still a surprising proportion of cases in which an independent evaluation reveals weaknesses that have not previously been identified. Data shows that a reasonably high proportion of evaluations lead to necessary design modifications, and it is not unusual for manufacturers to commission an independent evaluation prior to a major launch of a new instrument.

A more detailed account is given later in this article of the different phases of an evaluation.

3 COOPERATIVE INSTRUMENT EVALUATION

By cooperative instrument evaluation is meant the sponsorship of evaluation programs by groups of companies on the basis of cost sharing and results sharing. Instrument evaluation had been practiced individually for many years by the major instrument using companies in the chemical, oil, steel, and other industries as a means of guiding purchasing decisions, before cooperative instrument evaluation began in the late 1950s. In 1958 and 1959, Sira (then the British Scientific Instrument Research Association) commenced instrument evaluation work under contract separately to the Central Electricity Generating Board, as it was then known, and the United Kingdom Atomic Energy Authority. It was known that other major users of instruments had their own programs of instrument evaluation, and it was suggested that such users would obtain benefits from joining forces to sponsor evaluations cooperatively and share results. With a great deal of help from the UKAEA, a proposal for such a cooperative group project was put to a number of instrument user companies, and in 1961 a meeting was held at Sira, at which the cooperative instrument evaluation scheme was formalized. The founder members comprised CEGB, UKAEA, Imperial Chemical Industries (ICI), Distillers Co. (subsequently part of BP), Ministry of Defence, and Shell Research. The group, which eventually gave itself the acronym SIREP (Sira Instrument Evaluation Panel), had its inaugural meeting on 6 December 1961. SIREP, which recently changed its name to Evaluation International (EI) (http://www.evaluationint.com), contracts evaluation projects to Sira Test & Certification Ltd (http://www.siraservices.com) amongst other test houses.

In 1963, a similar group was formed in The Netherlands called WIB (working-party on instrument behavior). WIB (http://www.wib.nl) mainly uses the laboratories of TNO (Toegepast Natuurwetenscappelijk Onderzoek) (http://www.tno.nl) in Holland, although they have evaluations carried out in various laboratories across Europe. Finally in 1974, a French group, Association des Exploitants D'Equipments de Regulation Automatique (EXERA) (http://www.exera.com), was formed.

Although the administrations of EI, WIB, and EXERA differ in detail, the general objectives are the same, and over the years a close collaboration has grown between the three organizations, examples being the sharing of evaluation reports between the three groups and liaison to ensure that equipment by one group is not then evaluated by another. Although the membership of EI, WIB, and EXERA is still predominantly European there are member companies from North America, Japan, and the Middle East. The joint membership is currently over 70, which includes certain

group memberships such as the Swedish consortium SIP (Stiftelsen for Instrument Proving), which itself comprises some 30 members.

In the early years of instrument evaluation, it would be fair to say that the primary focus was on general process instrumentation, such as pressure, temperature, level, and flow equipment. As time moved on, the emphasis has moved onto more complex devices and certainly over the last five to ten years the main area of interest has been Analytical and Environmental Safety equipment. A list of the equipment having been evaluated by the three organizations can be found at their Web sites.

The commercial benefits of joining a cooperative evaluation group are clear for a major instrument user. Taking Evaluation International as an example, the annual subscription for the year 2004 is £9300, which is less than the cost of a single evaluation project. For this subscription, the members receive copies of all the reports issued by EI as well as those produced by WIB and EXERA. While a user may not be interested in all the reports produced, the contents of a single report each year can easily save a member his annual cost many times over.

4 INSTRUMENT EVALUATION METHODOLOGY

A number of steps can be identified in a typical instrument evaluation program, consisting of

- agreement on test program;
- tests under reference conditions;
- tests under simulated environmental (influence) conditions;
- assessment of construction standards, ease of use, and literature quality;
- review of manufacturer's quality assurance system and instrument status;
- draft report;
- final report.

Figure 1 shows how these steps are incorporated into a typical Evaluation International sponsored project.

4.1 The test program

The test program is a key document. It is prepared by the evaluator, who is guided by the manufacturer's specification, standard specifications, and standards relating to methods of evaluating and calibrating equipment. In particular, his experience guides him to seek performance information not revealed by the manufacturer's specification.

The basic reference document for the development of the test program is the manufacturer's specification; however, it is often a very incomplete statement of the performance, particularly in relation to influence conditions that depart significantly from laboratory reference conditions. In such circumstances, it is necessary to look for other guides to performance, which are acceptable both to manufacturer and user. Whether or not the specification is complete, the actual methods used for the evaluation need to be acceptable to manufacturer and user and not subject to significant modification when applied to different instruments of the same kind.

For these reasons, a great deal of attention has been given to specifications and testing procedures by national and international standards bodies. A standard specification is a technical specification or other document that has been evolved by cooperation between various bodies, and represents a consensus of the parties concerned. Such a standard may set out the quantities to be specified, the boundary values of accuracy classes, an explanation of the terminology used, and an outline of methods of measuring the quantities. Therefore, in the absence of a sufficiently detailed manufacturer's specification, a test program can be based on a national or international standard specification, with the manufacturer concerned having the reassurance that his instrument's performance will be compared with a specification evolved by consensus, that comparative instruments will be subject to the same comparison, and that the test methods used for the evaluation will be the same as that used for other instruments. There will of course be occasions where no such standard specification exists and the formulation of the test program relies even more on the experience of the evaluator, although a useful document in the generation of any such program would be IEC 60770-1:1999 'Transmitters for use in industrial-process control systems. Methods for performance evaluation', which largely cross references to the four-part standard IEC 61298 'Process measurement and control devices – General methods and procedures for evaluating performance'.

Once complete the test program is submitted to the sponsor and the manufacturer (if not the sponsor) and the evaluation only proceeds when the three parties, laboratory, manufacturer, and sponsor, have agreed to the program. In many instances, the agreement to a program is almost a formality. In other cases, the methods to be used to establish basic accuracy and environmental effects can be the subject of controversy, and lengthy discussions maybe required before an agreement is reached. For example, evaluation and calibration procedures for temperature or pressure transmitters are widely documented and accepted, but this is not the case for some

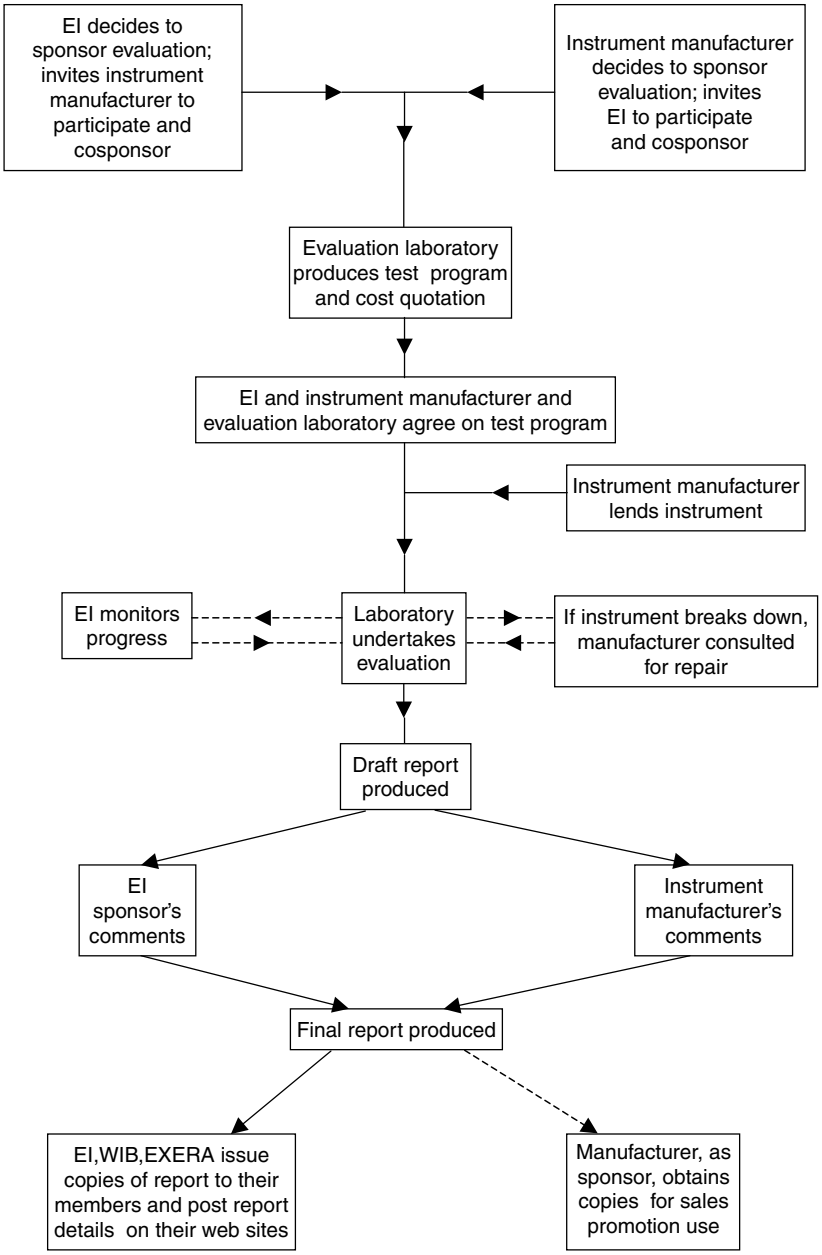

Figure 1. Evaluation International evaluation procedure.

chemical analysis devices. In such cases, evaluation work is often preceded by an amount of research and development in order to arrive at mutually acceptable methods of evaluation.

4.2 Tests under reference conditions

Presented below is a set of standard tests as indicated by IEC 60770-1.

Basic accuracy: Average error, repeatability, hysteresis, and linearity determined from three to five upscale and downscale full-range traverses, measuring at least six points.

Dead band: The smallest change results in a detectable output change at 10, 50, and 90% output.

Frequency response: The frequency response measured with a 20% span peak-to-peak input.

Step response: Record the step response time and the time for the output to reach and remain within 1% of its

final steady value, for varying input steps corresponding to 10 and 80% of the output span.

Start-up drift: Output monitored for 4 h after power is switched on.

Long-term drift: Output monitored for 30 days with an input of 90% span.

4.3 Tests under influence conditions

Presented below is a selection of standard tests from IEC 60770-1, which maybe applied to an electrically powered transmitter. It could be argued that some of the tests are covered by current legislation, such as immunity to radiated electromagnetic interference testing as part of CE marking in accordance with a European Directive. However, it is possible that the requirements of the legislation do not fully meet the needs of the demanding instrument user and indeed the work carried out in obtaining the approval of the legislation may not have been based on actual test results at all.

Ambient temperature: Specified tests to determine effects of exposing the instrument to

1. dry heat (+55 °C maximum or higher if applicable);
2. cold (−25 °C or as applicable)

in comparison to the operation under reference conditions.

Humidity: Specified tests to determine the effects of exposing the instrument to 40 °C, 93% relative humidity in comparison to the operation under reference conditions.

Vibration (sinusoidal): Effect of vibrating the instrument along three mutually perpendicular axes at specified peak displacements, or peak accelerations, over a specified frequency range. The effects being looked at for being both changes on the output and any mechanical resonances that may result in a premature failure.

Mounting position: Effect on output of 10° inclination about two planes at right angles to each other.

Over-range: Measurement of residual changes at 0 and 100% span, which result from over-ranging the input by 50% for a period of 1 min and after allowing a 5-min recovery period.

Accelerated life: Measurement of the change in performance of the instrument after the application of 100 000 cycles of amplitude equal to half the span.

Supply voltage and frequency variations: Effect at 0 and 100% span of changing the supplied voltage (and supply frequency where appropriate) between specified limits.

Short-term supply voltage interruptions: Measurement of the output changes, and recovery time, following a series of interruptions of specified duration.

Common mode interference: The effect of applying extraneous voltages between earth and each input and output terminal. Initially, by applying 250 V rms at mains frequency, followed by positive and negative 50 V DC potentials.

Magnetic field interference: Effect on output of a mains frequency magnetic field of 400 A m^{-1}.

Open and short-circuit of input/output: Effect of interrupting each input connection in turn for 5 min, followed by the effect of shorting the connection. Test repeated for each output connection.

Radiated electromagnetic interference: Effect on output of subjecting instrument to a specified field strength, typically 10 V m^{-1}, over a specified frequency range, typically 80 MHz to 1 GHz.

Output load variations: Effect on the instrument performance of varying the output load within specified limits.

Degree of protection provided by enclosure: Determination of the effectiveness of the enclosure's protection to water and dust ingress by performing appropriate tests as defined in IEC 60529 'Degrees of protection provided by enclosures (IP Code)'.

4.4 Assessment of construction standards, ease of use and literature quality

Standards of construction and finish: Overall design quality, robustness, and quality of components.

Packaging: Adequacy and method of delivery.

Use: Ease of operation in terms of installation and commissioning, general operation, maintenance requirements, and component accessibility.

Safety: Clarity of labeling, accessibility to live terminals, whether certified for use in potentially explosive atmospheres.

Documentation: Quality, comprehensiveness and language(s) of documentation, adequacy of installation, operating and servicing instructions, inclusion of circuit diagrams, troubleshooting routines.

4.5 Review of manufacturer's quality assurance system and instrument status

Quality assurance system: The manufacturer is asked to provide details of any structured quality assurance policy that they may have adopted, if so, on which national/international standard it is based and if it is registered under any particular scheme.

Instrument status: The manufacturer is requested to confirm the expected life expectancy of the instrument, the guarantee period for the equipment and for how long after manufacture the product would be supported.

4.6 The evaluation report

A standardized format is used for reporting and IEC 61298 – 4 gives guidance as to the content of the report. The principle followed is to present findings in a concise and easy-to-refer-to manner. Major findings are presented immediately after a short introduction and contain enough information to enable a reader who does not wish to immerse himself in details to assimilate quickly the salient facts. A very important aspect of the report is a section devoted to the manufacturer's comments. This contains verbatim comments, additional information, and criticism (occasionally) by the manufacturer on the findings.

This section is followed by tabular and graphical results, and the main part of the report is concluded with a description of the test methods and references.

The report may have appendices, when appropriate, for additional theoretical discussion, descriptive material, quality assurance and instrument status information (provided by the manufacturer), and a copy of the manufacturer's relevant specification sheet.

5 REQUIREMENTS OF AN INSTRUMENT EVALUATION LABORATORY

In order for a laboratory to be competent to carry out comprehensive instrument evaluation projects, they must have appropriate staff, facilities, and procedures, and the adequacy of these can be independently confirmed by means of accreditation to an appropriate international standard.

5.1 Staff

As discussed above, a key document in the process of an evaluation is the test program. It is therefore important that in addition to knowledge of the current status of relevant specification standards, staff involved in the formulation of the program should have a fundamental understanding of the operation of the device, as well as the likely applications in which it would be used. To cope with the range of instruments being evaluated, staff experience with a mix of basic disciplines – physics, chemistry, electronics, and mechanics – is essential.

Once underway, in order that an evaluation is carried out efficiently, it is important that staff involved in the technical aspects of the work have a good understanding of the operation of the device being tested. In addition, it is beneficial for them to have an appreciation of the likely performance of the equipment under certain conditions in order that any spurious readings can be recognized as such, allowing work to be repeated at the time of testing rather than having the costly exercise of setting up a repeat test at a later date.

5.2 Facilities

The facilities that are used during an evaluation fall into three categories. Those that are used to supply an input to the equipment under test, those that are used to measure the instrument's response, and finally, there are the facilities that are used to generate an influence on the equipment.

5.2.1 Input generating devices

For the vast majority of evaluations, these would be well-proven devices, such as a pressure balance for the evaluation of pressure transmitter or a temperature bath and reference thermometers combination for the evaluation of a temperature device. It would be normal to expect the input device to be traceable to a national standard and its uncertainty to be significantly better than the quoted performance of the instrument under test. However, in occasional circumstances, for example, where a reference standard does not exist, it maybe acceptable to have an input that has been shown to be repeatable but the absolute performance is unknown.

5.2.2 Output measurement devices

A growing number of instruments tested either have a digital display or a digital output, which can be read using some form of communicator or communications software

usually supplied with the instrument. In these cases, the laboratory may at most need to provide a personal computer for taking output measurements.

However, many instruments still provide what would be regarded as standard outputs, whether they be voltage, current, frequency, or even pneumatic. In all these cases, the laboratory would be expected to have suitable measurement equipment, which would be traceable to national standards.

5.2.3 Influence generating facilities

From the list of possible tests given previously, it is clear that a wide range of facilities are required to perform a comprehensive evaluation program. Again, traceability of the measurement of the influence is important in order to demonstrate that any test criteria have actually been met. In addition, by ensuring traceability it is possible at some point in the future to replicate the test conditions either on the same piece of equipment, possibly in the case of a dispute, or on a subsequent device for comparative reasons.

5.3 Procedures

Having competent staff and appropriate equipment may in itself not be sufficient to ensure that the work is performed correctly, an important third component is written procedures. These may already be part of the agreed test program but are commonly taken from national or international standards or in-house laboratory procedures. The purpose of the procedures is to ensure that the work is carried out in a reproducible fashion to allow comparisons to be made between results obtained from different instruments. The content of the procedure may be more or less detailed depending on the nature of the work.

5.4 Accreditation

For a customer of an evaluation project, it is important for them to know that the laboratory they have chosen for the work has the above three components – competent staff, suitable facilities, and the appropriate procedures. Clearly an option open to them is to carry out an audit of the three aspects; however, there is an alternative and that is to choose a laboratory that has been independently accredited. It may not be reasonable to expect a laboratory to be formally accredited for all the tests they are to perform, primarily due to financial constraints. However, it would be reasonable to expect them to be accredited for the primary measurement, whether it be pressure, temperature, flow or suchlike, as well as for many of the influences that the device will see. The most appropriate standard for laboratories carrying out comprehensive instrument evaluation to be accredited against is ISO 17025:1999 'General requirements for the competence of testing and calibration laboratories'.

In the United Kingdom, the sole national accreditation body recognized by government to assess, against internationally agreed standards, organizations that provide calibration and testing services is the United Kingdom Accreditation Service (http://www.ukas.com). UKAS has a number of mutual recognition agreements with other national accreditation bodies.

6 RESULTS OF INSTRUMENT EVALUATIONS

Periodically, EI, WIB, and EXERA commission an analysis of the results of evaluation reports that they have commissioned. The last such analysis carried out in 2002, covered 107 reports on equipment supplied from 12 different countries, with the sample comprising the following instrument types.

Analytical and environmental safety	42%
Pressure	15%
Flow	10%
Temperature	10%
Control valves and ancillaries	12%
Level	10%
Others	1%

One might think that the results of an evaluation lose some validity in that they are based on tests carried out on a model that has been hand picked by the manufacturer and could therefore be unrepresentative. However, the figures would suggest that such hand picking does not occur, and the author's knowledge of instrument manufacturing companies suggests that it is unlikely to occur.

The analysis carried out shows the proportion of equipment deemed unsatisfactory in various categories. The categories and the relevant proportions are as follows:

1.	Unsatisfactory as received	20%
2.	Outside specification under reference conditions	39%
3.	Outside specification under simulated environmental (influence) conditions	74%
4.	Breakdown during evaluation	20%
5.	Inadequate documentation	89%

In addition, the analysis showed that 21% of the devices met all the required specifications under both reference and influence conditions, and 29% of the equipment evaluated in the sample were subject to modification in design or manufacturing method as a result of the evaluation.

Category 1 records the proportion of instruments, which, in some way had a fault on receipt, sometimes trivial such as a missing fuse, sometimes serious such as completely uncalibrated or missing one or more components.

In categories 2 and 3, the manufacturer's specification was used wherever possible. However, as can be seen below from the comments on category 5, this was more often not the case. Where performance was not specified by the manufacturer, it was judged in relation to a specification based on current practice in instruments of a similar kind.

Category 4 records the proportion of instruments that broke down during the evaluation. It was found that the breakdowns were more likely to be due to a mechanical fault than an electrical one.

Category 5 records the results of an assessment of the documentation accompanying the equipment. The main documents are the operating handbook, covering installation, operating principle, and operating instructions, the maintenance handbook, and a performance specification sheet. The evaluator forms an opinion of the adequacy of these as a guide to the potential purchaser.

It was indicated above that about one-quarter of the devices in the sample were subjected to modification as a consequence of the evaluation. The criterion for inclusion in this figure was that the manufacturer had made a statement in his published comments to the effect that such a change would be made.

While a number of conclusions can be drawn from the results, category 1 results probably cause more concern to users than the other categories. Other than failure occurring during finished goods storage or transit, the conclusion is that some instruments do not receive sufficient final testing for an obvious malfunction to be detected. There was no significant evidence of physical damage, which could be correlated with the instruments found to be faulty.

While in categories 2 and 3 no attempt has been made to assess the proportions of instruments that could be regarded as serious or less serious departures from specified performance, the figures suggest a tendency to optimism in specifications. Some manufacturers have indicated that this is so with regard to certain instruments and state that it is often due to the commercial pressures caused by competitors making performance claims known to be exaggerated. The problem is made more difficult by variations in the way in which performance specifications of similar kinds of instruments are described. For example, it is often unclear whether a specified performance relates only to reference conditions or takes some account of influence conditions. A significant improvement could be effected in this situation if the methods of specifying performance of instruments of a similar kind could be standardized.

Category 4, dealing with failures leading to instrument breakdown, cannot be used to draw conclusions about component reliability. The number and types used in instruments vary widely, and deductions of component reliability are better made from controlled tests on particular categories of components.

Category 5 results indicate that insufficient attention is being given to the preparation of information, which ensures that users get maximum effectiveness from the instrument after delivery. Further analysis shows that 80% of the instruments tested had inadequate performance specifications, and only 60% of the instruments had a manufacturer's specification for any influence condition. The subject of documentation for instrumentation is covered by British Standard 4462:1969 'Guide for the preparation of technical sales literature for measuring instruments and process control equipment'. It is hoped that manufacturers would produce their documentation in line with this standard in order that end users could benefit from the information available and allow them to make better comparisons between like equipment. However, it is recognized that such a hope is probably a forlorn one.

A reasonably high proportion of instruments are modified as a direct result of evaluation. The figure of 29% emphasizes both the benefit of and the need for instrument evaluation. It is a direct action to improve performance resulting from evaluation, and it indicates the positive way in which instrument manufacturers respond to the results of impartial evaluation.

Some of the books that may be of value are Anonymous (1989), Coggan (1990), Driscoll, Gudzinowicz and Martin (1984) and Sydenham (1983). There appears to be no more recent statements on the subject.
